"*Prop.* 6. If the firſt of four magnitudes be to the ſecond as the third is to a magnitude greater than the fourth, then certain equimultiples can be taken of the firſt and third, and certain equimultiples of the ſecond and fourth, ſuch, that the multiple of the firſt ſhall be leſs than the multiple of the ſecond, but the multiple of the third not leſs than the multiple of the fourth."

"*Prop.* 7. If any equimultiples whatever be taken of the firſt and third of four magnitudes, and any equimultiples whatever of the ſecond and fourth; and if when the multiple of the firſt is leſs than that of the ſecond, the multiple of the third is alſo leſs than that of the fourth; or if when the multiple of the firſt is equal to that of the ſecond, the multiple of the third is alſo equal to that of the fourth; or if when the multiple of the firſt is greater than that of the ſecond, the multiple of the third is alſo greater than that of the fourth: then, the firſt of the four magnitudes ſhall be to the ſecond as the third to the fourth."

And all theſe propoſitions Mr. Robertſon demonſtrates by ſtrict mathematical reaſoning.

RATIONAL, in Arithmetic &c, the quality of numbers, fractions, quantities, &c, when they can be expreſſed by common numbers; in contradiſtinction to irrational or ſurd ones, which cannot be expreſſed in common numbers. Suppoſe any quantity to be 1; there are infinite other quantities, ſome of which are commenſurable to it, either ſimply, or in power: theſe Euclid calls *Rational quantities*. The reſt, that are incommenſurable to 1, he calls *irrational quantities*, or *ſurds*.

RATIONAL *Horizon*, or *True Horizon*, is that whoſe plane is conceived to paſs through the centre of the earth; and which therefore divides the globe into two equal portions or hemiſpheres. It is called the Rational horizon, becauſe only conceived by the underſtanding; in oppoſition to the ſenſible or apparent horizon, or that which is viſible to the eye.

RAVELIN, in Fortification, was anciently a flat baſtion, placed in the middle of a curtain. But

RAVELIN is now a detached work, compoſed only of two faces, which form a ſalient angle uſually without flanks. Being a triangular work reſembling the point of a Baſtion with the flanks cut off. It raiſed before the curtain, on the counterſcarf of the place; and ſerving to cover it and the adjacent flanks from the direct fire of an enemy. It is alſo uſed to cover a bridge or a gate, and is always placed without the moat.

There are alſo double Ravelins, which ſerve to defend each other; being ſo called when they are joined by a curtain.

What the engineers call a Ravelin, the men uſually call a demilune, or halfmoon.

RAY, in Geometry, the ſame as RADIUS.

RAY, in Optics, a beam or line of light, propagated from a radiant point, through any medium.

If the parts of a Ray of light lie all in a ſtraight line between the radiant point and the eye, the Ray is ſaid to be *direct*: the laws and properties of which make the ſubject of Optics.—If any of them be turned out of that direction, or bent in their paſſage, the Ray is ſaid to be *refracted*.—If it ſtrike on the ſurface of any body, and be thrown off again, it is ſaid to be *reflected*.—In each caſe, the Ray, as it falls either directly on the eye, or on the point of reflection, or of refraction, is ſaid to be *incident*.

Again, if ſeveral Rays be propagated from the radiant object equidiſtantly from one another, they are called *parallel* Rays. If they come inclining towards each other, they are called *converging* Rays. And if they go continually receding from each other, they are called *diverging* Rays.

It is from the different circumſtances of Rays, that the ſeveral kinds of bodies are diſtinguiſhed in Optics. A body, for example, that diffuſes its own light, or emits Rays of its own, is called a *radiating* or *lucid* or *luminous* body. If it only reflect Rays which it receives from another, it is called an *illuminated* body. If it only tranſmit Rays, it is called a *tranſparent* or *tranſlucent* body. If it intercept the Rays, or refuſe them paſſage, it is called an *opaque* body.

It is by means of Rays reflected from the ſeveral points of illuminated objects to the eye, that they become viſible, and that viſion is performed; whence ſuch Rays are called *viſual* Rays.

The Rays of light are not homogeneous, or ſimilar, but differ in all the properties we know of; viz, refrangibility, reflexibility, and colour. It is probably from the different refrangibility that the other differences have their riſe; at leaſt it appears that thoſe Rays which agree or differ in this, do ſo in all the reſt. It is not however to be underſtood that the property or effect called colour, exiſts in the Rays of light themſelves; but from the different ſenſations the differently diſpoſed Rays excite in us, we call them *red Rays*, *yellow Rays*, &c. Each beam of light however, as it comes from the ſun, ſeems to be compounded of all the ſorts of Rays mixed together; and it is only by ſplitting or ſeparating the parts of it, that theſe different ſorts become obſervable; and this is done by tranſmitting the

beam through a glaſs priſm, which refracting it in the paſſage, and the parts that excite the different colours having different degrees of refrangibility, they are thus ſeparated from one another, and exhibited each apart, and appearing of the different colours.

Beſide refrangibility, and the other properties of the Rays of light already aſcertained by obſervation and experiment, Sir I. Newton ſuſpects they may have many more; particularly a power of being inflected or bent by the action of diſtant bodies; and thoſe Rays which differ in refrangibility, he conceives likewiſe to differ in flexibility.

Theſe Rays he ſuſpects may be very ſmall bodies emitted from ſhining ſubſtances. Such bodies may have all the conditions of light: and there is that action and reaction between tranſparent bodies and light, which very much reſembles the attractive force between other bodies. Nothing more is required for the production of all the various colours, and all the degrees of refrangibility, but that the Rays of light be bodies of different ſizes; the leaſt of which may make violet the weakeſt and darkeſt of the colours, and be the moſt eaſily diverted by refracting ſurfaces from its rectilinear courſe; and the reſt, as they are larger and larger, may make the ſtronger and more lucid colours, blue, green, yellow, and red. See COLOUR, LIGHT, REFRACTION, REFLECTION, INFLECTION, CONVERGING, DIVERGING, &c, &c.

Reflected RAYS, thoſe Rays of light which are reflected, or thrown back again, from the ſurfaces of bodies upon which they ſtrike. It is found that, in all the Rays of light, the angle of reflection is equal to the angle of incidence.

Refracted RAYS, are thoſe Rays of light, which are bent or broken, in paſſing out of one medium into another.

Pencil of RAYS, a number of Rays iſſued from a point of an object, and diverging in the form of a cone.

Principal RAY, in Perſpective, is the perpendicular diſtance between the eye and the vertical plane or table, as ſome call it.

RAY *of Curvature*. See *Radius of* CURVATURE.

REAUMUR (RENE-ANTOINE-FERCHAULT, Sieur de), a reſpectable French philoſopher, was born at Rochelle in 1683. After the uſual courſe of ſchool education, he was ſent to Poitiers to ſtudy philoſophy, and, in 1699, to Bourges to ſtudy the law, the profeſſion for which he was intended. But philoſophy and mathematics having very early been his favourite purſuits, he quitted the law, and repaired to Paris in 1703, to purſue thoſe ſciences to the beſt advantage; and here his character procured him a ſeat in the Academy in the year 1708; which he held till the time of his death, which happened the 18th of November 1757, at 74 years of age.

Reaumur ſoon juſtified the choice that was made of him by the Academy. He made innumerable obſervations, and wrote a great multitude of pieces upon the various branches of natural philoſophy. His Hiſtory of Inſects, in 6 vols. quarto, at Paris, is his principal work. Another edition was printed in Holland, in 12 vols. 12mo. He made alſo great and uſeful diſcoveries concerning iron; ſhewing how to change common wrought iron into ſteel, how to ſoften caſt iron, and to make works in caſt iron as fine as in wrought iron. His labours and diſcoveries concerning iron were rewarded by the duke of Orleans, regent of the kingdom, by a penſion of 12 thouſand livres, equal to about 500l. Sterling; which however he would not accept but on condition of its being put under the name of the Academy, who might enjoy it after his death. It was owing to Reaumur's endeavours that there were eſtabliſhed in France manufactures of tin-plates, of porcelain in imitation of china-ware, &c. They owe to him alſo a new thermometer, which bears his name, and is pretty generally uſed on the continent, while that of Fahrenheit is uſed in England, and ſome few other places. Reaumur's thermometer is a ſpirit one, having the freezing point at 0, and the boiling point at 80.

Reaumur is eſteemed as an exact and clear writer; and there is an elegance in his ſtyle and manner, which is not commonly found among thoſe who have made only the ſciences their ſtudy. He is repreſented alſo as a man of a moſt amiable diſpoſition, and with qualities to make him beloved as well as admired. He left a great variety of papers and natural curioſities, which he bequeathed to the Academy of Sciences.

The works publiſhed by him, are the following.

1. The Art of changing Forged Iron into Steel; of Softening Caſt Iron; and of making works of Caſt Iron, as fine as of Wrought Iron. Paris, 1722, 1 vol. in 4to.

2. Natural Hiſtory of Inſects, 6 vols. in 4to.

His memoirs printed in the volumes of the Academy of Sciences, are very numerous, amounting to upwards of a hundred, and on various ſubjects, from the year 1708 to 1763, ſeveral papers in almoſt every volume.

RECEIVER, *of an Air Pump*, is part of its apparatus; being a glaſs veſſel placed on the top of the plate, out of which the air is to be exhauſted.

RECEPTION, in Aſtrology, is a dignity befalling two planets when they exchange houſes: for example, when the ſun arrives in Cancer, the houſe of the moon; and the moon, in her turn, arrives in the ſun's houſe.—The ſame term is alſo uſed when two planets exchange exaltation.

RECESSION *of the Equinoxes*. See PRECESSION *of the Equinoxes*.

RECIPROCAL, in Arithmetic, &c, is the quotient ariſing by dividing 1 by any number or quantity. So, the Reciprocal of 2 is $\frac{1}{2}$; of 3 is $\frac{1}{3}$, and of a is $\frac{1}{a}$, &c. Hence, the Reciprocal of a vulgar fraction is found, by barely making the numerator and the denominator mutually change places: ſo the Reciprocal of $\frac{1}{2}$ is $\frac{2}{1}$ or 2; of $\frac{2}{3}$, is $\frac{3}{2}$; of $\frac{a}{b}$, is $\frac{b}{a}$, &c. Hence alſo, any quantity being multiplied by its Reciprocal, the product is always equal to unity or 1: ſo $\frac{1}{2} \times \frac{2}{1} = \frac{2}{2} = 1$, and $\frac{2}{3} \times \frac{3}{2} = \frac{6}{6} = 1$, and $\frac{a}{b} \times \frac{b}{a} = \frac{ab}{ab} = 1$.

Table of RECIPROCALS.

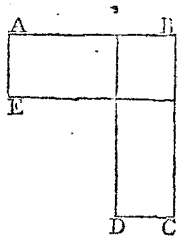
Of the preceding Table, the uſe is evidently to ſhorten arithmetical calculations, and will appear eminently great to thoſe mathematicians and others who are frequently concerned in ſuch kinds of computations. The ſtructure of the Table is evident; the firſt column contains the natural ſeries of numbers from 1 to 1000, the 2d the Reciprocals. Theſe Reciprocals (which are no other than the decimal values of the quotients reſulting from the diviſion of unity or 1 by each of the ſeveral numbers from 1 to 1000) are not only uſeful in ſhewing by inſpection the quotient when the dividend is unity, but are alſo applied with much advantage in turning many diviſions into multiplications, which are much eaſier performed, and are done by multiplying the Reciprocal of the diviſor (as found in the Table) by the dividend, for the quotient; they will alſo apply to good purpoſe in ſumming the terms of many converging ſeries.

The Reciprocals are carried on to 7 places of decimals (for the column of Reciprocals muſt be accounted all decimal figures, although they have not the decimal point placed before them, which is omitted to ſave room), each being ſet down to the neareſt figure in the laſt place, that is, when the next figure beyond the laſt ſet down in the Table came out a 5 or more, the laſt figure

figure was increaſed by 1, otherwiſe not; excepting in the repetends which occurred among the Reciprocals, where the real laſt figure is always ſet down; the Reciprocals, which in the Table conſiſt of leſs than ſeven figures, are thoſe which terminate, and are complete within that number; ſuch as ·5 the Reciprocal of 2, ·25 the Reciprocal of 4, &c.

RECIPROCAL *Figures*, in Geometry, are ſuch as have the antecedents and conſequents of the ſame ratio in both figures. So, in the two rectangles BE and BD, if AB : DC :: BC : AE, then thoſe rectangles are reciprocal figures; and are alſo equal.



RECIPROCAL *Proportion*, is when, in four quantities, the two latter terms have the Reciprocal ratio of the two former, or are proportional to the Reciprocals of them. Thus, 24, 15, 5, 8 form a Reciprocal proportion, becauſe

$$\frac{1}{24} : \frac{1}{15} :: 5 : 8, \text{ or } 15 : 24 :: 5 : 8.$$

RECIPROCAL *Ratio*, of any quantity, is the ratio of the Reciprocal of the quantity.

RECIPROCALLY. One quantity is Reciprocally as another, when the one is greater in proportion as the other is leſs; or when the one is proportional to the Reciprocal of the other. So a is Reciprocally as b, when a is always proportional to $\frac{1}{b}$. Like as in the mechanic powers, to perform any effect, the leſs the power is, the greater muſt be the time of performing it; or, as it is ſaid, what is gained in power, is loſt in time. So that, if p denote any power or agent, and t the time of its performing any given ſervice; then p is as $\frac{1}{t}$, and t is as $\frac{1}{p}$; that is, p and t are Reciprocally proportionals to each other.

RECKONING, in Navigation, is the eſtimating the quantity of a ſhip's way; or of the courſe and diſtance run. Or, more generally, a ſhip's Reckoning is that account, by which it may at any time be known where the ſhip is, and conſequently on what courſe or courſes ſhe muſt ſteer to gain her intended port. The Reckoning is uſually performed by keeping an account of the courſes ſteered, and the diſtance run, with any accidental circumſtances that occur. The courſes ſteered are obſerved by the compaſs; and the diſtances run are eſtimated from the rate of running, and the time run upon each courſe. The rate of running is meaſured by the log, from time to time; which however is liable to great irregularities. Anciently Vitruvius, for meaſuring the rate of ſailing, adviſed an axis to be paſſed through the ſides of the ſhip, with two large heads protending out of the ſhip, including wheels touching the water, by the revolution of which the ſpace paſſed over in a given time is meaſured. And the ſame has been ſince recommended by Snellius.

RECKONING, *Dead*. See DEAD *Reckoning*.

RECLINATION *of a Plane*, in Dialling, is the angular quantity which a dial-plane leans backwards, from an exactly upright or vertical plane, or from the zenith.

RECLINER, or RECLINING *Dial*, is a dial whoſe plane reclines from the perpendicular, that is, leans backwards, or from you, when you ſtand before it.

RECLINER, *Declining*, or *Declining* RECLINING *Dial*, is one which neither ſtands perpendicularly, nor oppoſite to one of the cardinal points.

RECOIL, or REBOUND, the reſilition, or flying backward, of a body, eſpecially a fire-arm. This is the motion by which, upon exploſion, it ſtarts or flies backwards; and the cauſe of it is the reſiſtance of the ball and the impelling force of the powder, which acts equally on the gun and on the ball. It has been commonly ſaid by authors, that the momentum of the ball is equal to that of the gun with its carriage together; but this is a miſtake; for the latter momentum is nearly equal to that of the ball and half the weight of the powder together, moving with the velocity of the ball. So that, if the gun, and the ball with half the powder, were of equal weight, the piece would recoil with the ſame velocity as the ball is diſcharged. But the heavier any body is, the leſs will its velocity be, to have the ſame momentum, or force; and therefore ſo many times as the cannon and carriage is heavier than the ball and half the powder, juſt as many times will the velocity of the ball be greater than that of the gun; and in the ſame ratio nearly is the length of the barrel before the charge, to the quantity the gun Recoils in the time the ball is paſſing along the bore of the gun. So, if a 24 pounder of 10 feet long be 6400lb weight, and charged with 6lb of powder; then, when the ball quits the piece, the gun will have Recoiled $\frac{28}{6400} \times 10 = \frac{7}{160}$ of a foot, or nearly half an inch.

RECORDE (ROBERT), a learned phyſician and mathematician, was born of a good family in Wales, and flouriſhed in the reigns of Henry the 8th, Edward the 6th, and Mary. There is no account of the exact time of his birth, though it muſt have been early in the 16th century, as he was entered of the univerſity of Oxford about the year 1525, where he was elected fellow of Allſouls college in 1531. Making phyſic his profeſſion, he went to Cambridge, where he was honoured with the degree of doctor in that faculty, in 1545, and highly eſteemed by all that knew him for his great knowledge in ſeveral arts and ſciences. He afterwards returned to Oxford, where, as he had done before he went to Cambridge, he publicly taught arithmetic, and other branches of the mathematics, with great applauſe. It ſeems he afterwards repaired to London, and it has been ſaid he was phyſician to Edward the 6th and Mary, to which princes he dedicates ſome of his books; and yet he ended his days in the King's-bench priſon, Southwark, where he was confined for debt, in the year 1558, at a very immature age.

Recorde publiſhed ſeveral mathematical books, which are moſtly in dialogue, between the maſter and ſcholar. They are as follow:

1. *The Pathway to Knowledge*, containing the firſt Principles of Geometrie, as they may moſte aptly be applied unto practiſe, bothe for uſe of Inſtrumentes Geometricall and Aſtronomicall, and alſo for Projection of Plattes much neceſſary for all ſortes of men. Lond. 4to, 1551.

2. *The Ground of Arts*, teaching the perfect worke and practice of Arithmeticke, both in whole numbers and

and fractions, after a more eaſie and exact forme then in former time hath beene ſet forth, 8vo, 1552.—This work went through many editions, and was corrected and augmented by ſeveral other perſons; as firſt by the famous Dr. John Dee; then by John Mellis, a ſchoolmaſter, 1590; next by Robert Norton; then by Robert Hartwell, practitioner in mathematics, in London; and laſtly by R. C. and printed in 8vo, 1623.

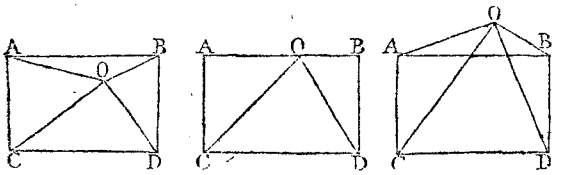
3. *The Caſtle of Knowledge*, containing the Explication of the Sphere bothe Celeſtiall and Materiall, and divers other things incident thereto. With ſundry pleaſaunt proofes and certaine newe demonſtrations not written before in any vulgare woorkes. Lond. folio, 1556.

4. *The Whetſtone of Witte*, which is the ſeconde part of Arithmetike: containing the Extraction of Rootes: the Coſſike Practiſe, with the rules of Equation: and the woorkes of Surde Nombers. Lond. 4to, 1557.—For an analyſis of this work on Algebra, with an account of what is new in it, ſee pa. 79 of vol. 1, under the article ALGEBRA.

Wood ſays he wrote alſo ſeveral pieces on phyſic, anatomy, politics, and divinity; but I know not whether they were ever publiſhed. And Sherburne ſays that he publiſhed *Coſmographiæ Iſagogen*; alſo that he wrote a book, *De Arte faciendi Horologium*; and another, *De Uſu Globorum, & de Statu Temporum*; which I have never ſeen.

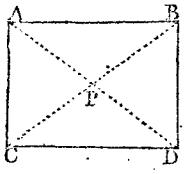
RECTANGLE, in Geometry, is a right-angled parallelogram, or a right-angled quadrilateral figure.

If from any point O, lines be drawn to all the four



angles of a Rectangle; then the ſum of the ſquares of the lines drawn to the oppoſite corners will be equal, in whatever part of the plane the point O is ſituated; viz, $OA^2 + OD^2 = OB^2 + OC^2$. For other properties of the Rectangle, ſee PARALLELOGRAM; for the Rectangle being a ſpecies of the parallelogram, whatever properties belong to the latter, muſt equally hold in the former.

For the Area of a RECTANGLE. Multiply the length by the breadth or height.—*Otherwiſe*; Multiply the product of the two diagonals by half the ſine of their angle at the interſection.



That is, AB × AC, or AD × BC × ½ ſin. ∠P = area. A Rectangle, as of two lines AB and AC, is thus denoted, AB × AC, or AB.AC; or elſe thus expreſſed, the Rectangle of, or under, AB and AC.

RECTANGLE, in Arithmetic, is the ſame with product or factum. So the Rectangle of 3 and 4, is 3 × 4 or 12; and of *a* and *b* is *a* × *b* or *ab*.

RECTANGLED, RIGHT-ANGLED, or RECTANGULAR, is applied to figures and ſolids that have at leaſt one right angle, if not more. So a Right-angled triangle, has one right angle: a Right-angled parallelogram is a rectangle, and has four right angles. Such alſo are ſquares, cubes, parallelopipedons.

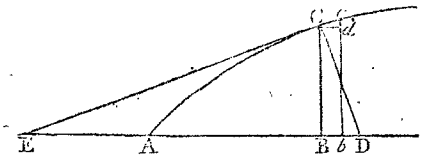
Solids are alſo ſaid to be Rectangular with reſpect to their ſituation, viz, when their axis is perpendicular to their baſe; as right cones, pyramids, cylinders, &c.

The Ancients uſed the phraſe *Rectangular ſection of a cone*, to denote a parabola; that conic ſection, before Apollonius, being only conſidered in a cone having its vertex a right-angle. And hence it was, that Archimedes entitled his book of the quadrature of the parabola, by the name of *Rectanguli Coni Sectio*.

RECTIFICATION, in Geometry, is the finding of a right line equal to a curve. The Rectification of curves is a branch of the higher geometry, a branch in which the uſe of the inverſe method of Fluxions is eſpecially uſeful. This is a problem to which all mathematicians, both ancient and modern, have paid the greateſt attention, and particularly as to the Rectification of the circle, or finding the length of the circumference, or a right line equal to it; but hitherto without the perfect effect: upon this alſo depends the quadrature of the circle, ſince it is demonſtrated that the area of a circle is equal to a right-angled triangle, of which one of the ſides about the right angle is the radius, and the other equal to the circumference: but it is much to be feared that neither the one nor the other will ever be accompliſhed. Innumerable approximations however have been made, from Archimedes, down to the mathematicians of the preſent day. See CIRCLE and CIRCUMFERENCE.

The firſt perſon who gave the Rectification of any curve, was Mr. Neal, ſon of Sir Paul Neal, as we find at the end of Dr. Wallis's treatiſe on the Ciſſoid; where he ſays, that Mr. Neal's Rectification of the curve of the ſemicubical parabola, was publiſhed in July or Auguſt, 1657. Two years after, viz in 1659, Van Hauraet, in Holland, alſo gave the Rectification of the ſame curve; as may be ſeen in Schooten's Commentary on Des Cartes's Geometry.

The moſt comprehenſive method of Rectification of curves, is by the inverſe method of fluxions, which is thus: Let AC*c* be any curve line, AB an abſciſs, and



BC a perpendicular ordinate; alſo *bc* another ordinate indefinitely near to BC; and C*d* drawn parallel to the abſciſs AB. Put the abſciſs AB = x, the ordinate BC = y, and the curve AC = z: then is C*d* = B*b* = $\dot{x}$ the fluxion of the abſciſs AB, and *cd* = $\dot{y}$ the fluxion of the ordinate BC, alſo C*c* = $\dot{z}$ the fluxion of the curve AB. Hence becauſe C*cd* may be conſidered as a plane right-angled triangle, $Cc^2 = Cd^2 + cd^2$, or $\dot{z}^2 = \dot{x}^2 + \dot{y}^2$; and therefore $\dot{z} = \sqrt{\dot{x}^2 + \dot{y}^2}$; which is the fluxion of the length of any curve; and conſequently, out of this equation expelling either $\dot{x}$ or $\dot{y}$, by means of the particular equation expreſſing the nature of the curve in queſtion, the fluents of the reſulting equation, being then taken, will give the length of the curve, in finite terms when it is

rectifiable,

rectifiable, otherwise in an infinite series, or in a logarithmic or exponential &c expression, or by means of some other curve, &c.

Ex. 1. *To rectify the common parabola.*—In this case, the equation of the curve is $2a.v = y^2$, where a is half the parameter. The fluxion of this equation is $2a\dot{x} = 2y\dot{y}$, and hence $\dot{x}^2 = \frac{y^2\dot{y}^2}{a^2}$; this being substituted in the general equation $\dot{z} = \sqrt{\dot{x}^2 + \dot{y}^2}$, it becomes $\dot{z} = \frac{\dot{y}\sqrt{aa + yy}}{a}$; the correct fluents of which give

$$z = \frac{y\sqrt{aa + yy}}{2a} + \tfrac{1}{2}a \times \text{hyp. log. of } \frac{y + \sqrt{aa + yy}}{a},$$

which is the length of the curve AC, when it is a parabola.

And the same might be expressed by an infinite series, by expanding the quantity $\sqrt{aa + yy}$. See my Mensuration, pa. 361, 2d edit.

Ex. 2. *To rectify the Circle.*—The equation of the circle may be expressed either in terms of the sine, or versed sine, or tangent, or secant, &c, and the radius. Let therefore the radius of the circle be DA or DC $= r$, the versed sine AB $= x$, the right sine BC $= y$, the tangent CE $= t$, and the secant DE $= s$; then, by the nature of the circle, we have these equations, $y^2 = 2rx - x^2 = \frac{r^2t^2}{r^2 + t^2} = \frac{s^2 - r^2}{s^2}r^2$; and by means of the fluxions of these equations, with the general equation $\dot{z}^2 = \dot{x}^2 + \dot{y}^2$, are obtained the following fluxional forms for the fluxion of the curve, the fluent of any one of which will be the curve itself, viz,

$$\dot{z} = \frac{r\dot{x}}{\sqrt{2rx - xx}} = \frac{r\dot{y}}{\sqrt{rr - yy}} = \frac{r^2\dot{t}}{r^2 + t^2} = \frac{r^2\dot{s}}{\sqrt{s^2 - r^2}}.$$

Hence the value of the curve, from the fluent of each of these, gives the four following forms, in series, viz, the curve, putting $d = 2r$ the diameter, is z

$$= (1 + \frac{x}{2.3d} + \frac{3x^2}{2.4.5d^2} + \frac{3.5x^3}{2.4.6.7d^3} \&c)\sqrt{dx},$$

$$= (1 + \frac{y^2}{2.3r^2} + \frac{3y^4}{2.4.5r^4} + \frac{3.5y^6}{2.4.6.7r^6} \&c)\,y,$$

$$= (1 - \frac{t^2}{3r^2} + \frac{t^4}{5r^4} - \frac{t^6}{7r^6} + \frac{t^8}{9r^8} \&c)\,t,$$

$$= (\frac{s - r}{s} + \frac{s^3 - r^3}{2.3s^3} + \frac{3(s^5 - r^5)}{2.4.5s^5} \&c)\,r.$$

See my Mensur. 2d edit. pa. 118 &c, also most treatises on Fluxions.

It is evident that the simplest of these series is the third, or that which is expressed in terms of the tangent. It will therefore be the properest form to calculate an example by in numbers. And for this purpose it will be convenient to assume some arc whose tangent, or at least its square, is known to be some small finite number. Now the arc of 45° it is known has its tangent equal to the radius; and therefore, taking the radius $r = 1$, and consequently the tangent of 45° or $t = 1$ also, in this case the arc of 45° to the radius 1, or the quadrant to the diameter 1, will be $= 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9}$ &c. But as this series converges very slowly, some smaller arch must be taken, that the series may converge faster; such as the arc of 30°, whose tangent is $= \sqrt{\frac{1}{3}} = .5773502$, or its square $t^2 = \frac{1}{3}$; and hence, after the first term, the succeeding terms will be found by dividing always by 3, and these quotients divided by the absolute numbers 3, 5, 7, 9, &c; and lastly adding every other term together into two sums, the one the sum of the positive terms, and the other the sum of the negative ones, then lastly the one sum taken from the other leaves the length of the arc of 30°, which is the 12th part of the whole circumference when the radius is 1, or the 6th part when the diameter is 1, and consequently 6 times that arc will be the length of the whole circumference to the diameter 1; therefore multiply the 1st term $\sqrt{\frac{1}{3}}$ by 6, and the product is $\sqrt{\frac{36}{3}}$ or $\sqrt{12} = 3.4641016$; hence the operation will be conveniently made as follows:

		+ Terms.	− Terms.
1)	3.4641016	(3.4641016	
3)	1.1547005	(	0.3849002
5)	3849002	(769800	
7)	1283001	(	183286
9)	427667	(47519	
11)	142556	(	12960
13)	47519	(3655	
15)	15840	(	1056
17)	5280	(311	
19)	1760	(	93
21)	587	(28	
23)	196	(	8
25)	65	(3	
27)	22	(	1
		+ 3.5462332	− 0.4046406
		− 0.4046406	
		3.1415926 the circumference.	

Various other series for the Rectification of the circle may be seen in different parts of my Mensuration, as at pa. 121, 122, 137, 138, 422, &c. See also my paper on this subject in the Philos. Trans. vol. 66, pa. 476.

RECTIFIER, in Navigation, is an instrument used for determining the variation of the compass, in order to rectify the ship's course. It consists of two circles, either laid upon, or let into one another, and so fastened together in their centres that they represent two compasses, the one fixed, and the other moveable. Each is divided into 32 points of the compass, and 360°, and numbered both ways, from the north and the south, ending at the east and west in 90°. The fixed compass represents the horizon, in which the north, and all the other points, are liable to variation. In the centre of

the moveable compaſs is faſtened a ſilk thread, long enough to reach the outſide of the fixed compaſs: but when the inſtrument is made of wood, an index is uſed inſtead of the thread.

RECTIFYING *of Curves.* See RECTIFICATION.

RECTIFYING *of the Globe or Sphere*, is a previous adjuſtment of it, to prepare it for the ſolution of problems. This uſually conſiſts in placing it in the ſame poſition as the true ſphere of the world has at ſome certain time propoſed; which is done firſt by elevating the pole above the horizon as much as the latitude of the place is, then bringing the ſun's place for the given day, found in the ecliptic, to the graduated ſide of the braſs or general meridian, next move the hour-index to the upper hour of 12, ſo ſhall the globe be Rectified for noon of that day; and if the globe be turned about till the hour-index point at any propoſed hour, then is the globe in the real poſition of the earth at that time, if the whole globe be ſet in the north and ſouth poſition by means of the compaſs.

RECTILINEAL, RECTILINEAR, or *Right-lined*, is the quality or nature of figures that are bounded by right lines, or formed by right lines.

RECURRING *Series*, is a ſeries conſtituted in ſuch a manner, that having taken at pleaſure any number of its terms, each following term ſhall be related to the ſame number of preceding terms according to a conſtant law of relation. See *Recurring* SERIES.

RED, in Phyſics, or Optics, one of the ſimple or primary colours of natural bodies, or rather of the rays of light.—The Red rays are the leaſt refrangible of all the rays of light. And hence, as Newton ſuppoſes the different degrees of refrangibility to ariſe from the different magnitudes of the luminous particles of which the rays conſiſt; therefore the Red rays, or Red light, is concluded to be that which conſiſts of the largeſt particles. See COLOUR and LIGHT.

Authors diſtinguiſh three general kinds of Red: one bordering on the blue, as colombine, or dove-colour, purple, and crimſon; another bordering on yellow, as flame-colour and orange; and between theſe extremes is a medium, which is that which is properly called Red.

REDANS, or REDANT, or REDENS, in Fortification, is a kind of work indented like the teeth of a ſaw, with ſalient and re-entering angles; to the end that one part may flank or defend another. It is called alſo *ſaw work*, and *indented work*.

Redans are often uſed in fortifying of walls, where it is not neceſſary to be at the expence of building baſtions; as when they ſtand on the ſide of a river, or a marſh, or the ſea, &c. But the fault of ſuch fortification is, that the beſiegers from one battery may ruin both the ſides of the tenaille or front of a place, and make an aſſault without fear of being enfiladed, ſince the defences are ruined.

The parapet of the corridor alſo is frequently Redented, or carried on by the way of Redans.

REDINTEGRATION, is the taking or finding the integral or fluent again, from the fluxion. See FLUXION and FLUENT.

REDOUBT, or REDOUTE, in Fortification, a ſmall fort, without any defence but in front, uſed in trenches, lines of circumvallation, contravallation, and approach; as alſo for the lodging of corps de garde, and to defend paſſages.

A Detached REDOUBT, is a kind of work reſembling a ravelin, with flanks, placed beyond the glacis.—It is made to occupy ſome ſpot of ground which might be advantageous to the beſiegers; and alſo to oblige the enemy to open his trenches farther off than he would otherwiſe do.

REDUCING *Scale*, or SURVEYING *Scale*, is a broad, thin ſlip of box, or ivory, having ſeveral lines and ſcales of equal parts upon it; uſed by ſurveyors for turning chains and links into roods and acres, by inſpection. They uſe it alſo to reduce maps and draughts from one dimenſion to another.

REDUCTION, in general, is the bringing or changing ſome thing to a different form, ſtate, or denomination.

REDUCTION, in *Arithmetic*, is commonly underſtood of the changing of money, weights, or meaſures, to other denominations, of the ſame value; and it is of two kinds, *Reduction Deſcending*, which is the changing a number to its equivalent value in a lower denomination; as pounds into ſhillings or pence: and *Reduction Aſcending*, which is the changing numbers to higher denominations; as pence to ſhillings or pounds.

RULE. *To perform Reduction;* conſider how many of the leſs denomination make one of the greater, as how many pence make a ſhilling, or how many ſhillings make a pound; and multiply by that number when the Reduction is deſcending; but divide by it when it is aſcending. So to reduce 23*l.* into pence; and converſely thoſe pence into pounds; multiply or divide by 12 and 20, as here below.

23 *l.*		12) 5520 *d.*	
20			
460 *sh.*		20) 460 *sh.*	
12			23 *l.*
5520 *d.*			

REDUCTION *of Fractions*. See FRACTION, and DECIMAL.

REDUCTION *of Equations*, in Algebra. See EQUATION.

REDUCTION *of Curves*. See CURVE.

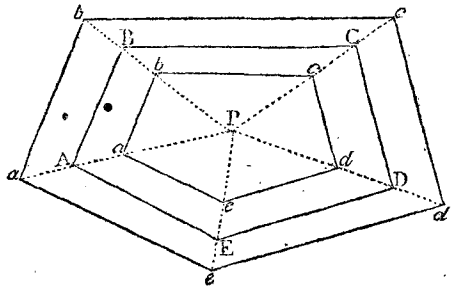
REDUCTION *of a Figure, Deſign, or Draught*, is the making a copy of it, either larger or ſmaller than the original, but ſtill preſerving the form and proportion.

Figures and plans are reduced, and copied, in various ways; as by the Pentagraph, and Proportional compaſſes. See PENTAGRAPH, and *Proportional* COMPASSES. The beſt of the other methods of reducing are as below.

To reduce a Simple Rectilinear Figure by Lines.

Pitch upon a point P any where about the given figure ABCDE, either within it, or without it, or in one ſide or angle; but near the middle is beſt. From that point P draw lines through all the angles; upon one of

of which take P*a* to PA in the propoſed proportion of the ſcales, or linear dimenſions; then draw *ab* parallel to AB, *bc* to BC, &c; ſo ſhall *abcde* be the reduced figure ſought, either greater or ſmaller than the original.

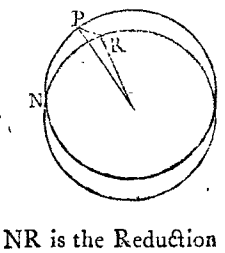


To Reduce a Figure by a Scale.—Meaſure all the ſides, and diagonals, of the figure, as ABCDE, by a ſcale; and lay down the ſame meaſures reſpectively, from another ſcale, in the proportion required.

To Reduce a Map, Deſign, or Figure, by Squares.—Divide the original into a number of little ſquares; and divide a freſh paper, of the dimenſions required, into the ſame number of other ſquares, either greater or ſmaller as required. This done, in every ſquare of the ſecond figure, draw what is found in the correſponding ſquare of the firſt or original figure.

The croſs lines forming theſe ſquares, may be drawn with a pencil, and theſe rubbed out again after the work is finiſhed. But a more ready and convenient way, eſpecially when ſuch Reductions are often wanted, would be to keep always at hand frames of ſquares ready made, of ſeveral ſizes; for by only juſt laying them down upon the papers, the correſponding parts may be readily copied. Theſe frames may be made of four ſtiff or inflexible bars, ſtrung acroſs with horſe hairs, or fine catgut.

REDUCTION *to the Ecliptic*, in Aſtronomy, is the difference between the argument of latitude, as NP, and an arc of the ecliptic NR, intercepted between the place of a planet, and the node.—To find this Reduction, or difference; in the right-angled ſpherical triangle NPR, are given the angle of inclination, and the argument of latitude NP; to find NR; then the difference between NP and NR is the Reduction ſought.



REDUNDANT *Hyperbola*, is a curve of the higher kind, ſo called becauſe it exceeds the conical hyperbola in the number of legs; being a triple hyperbola, with 6 hyperbolic legs. See Newton's Enum. Lin. tertii Ordinis, nomina formarum, &c.

RE-ENTERING *Angle*, in Fortification, is an angle whoſe point is turned inwards, or towards the place.

REFLECTED *Ray*, or *Viſion*, is that which is made by the reflection of light, or by light firſt received upon the ſurface of ſome body, and thence reflected again. See RAY, VISION, and REFLECTION.

REFLECTING, or REFLEXIVE, *Dial*, is a kind of dial which ſhews the hour by means of a thin piece of looking-glaſs plate, duly placed to throw the ſun's rays to the top of a cieling, on which the hour-lines are drawn.

REFLECTION, or REFLEXION, in Mechanics, is the return, or regreſſive motion of a moveable body, occaſioned by the reſiſtance of another body, which hinders it from purſuing its former courſe of direction.

Reflection is conceived, by the lateſt and beſt authors, as a motion peculiar to elaſtic bodies, by which, after ſtriking on others which they cannot remove, they recede, or turn back, or aſide, by their elaſtic power.

On this principle it is aſſerted, that there may be, and is, a period of reſt between the incidence and the reflection; ſince the reflected motion is not a continuation of the other, but a new motion, ariſing from a new cauſe or principle, viz, the power of elaſticity.

It is one of the great laws of Reflection, that the angle of incidence is equal to the angle of Reflection; i. e. that the angle which the direction of motion of a ſtriking body makes with the ſurface of the body ſtruck, is equal to the angle made between the ſame ſurface and the direction of motion after the ſtroke. See INCIDENCE and PERCUSSION.

REFLECTION *of the Rays of Light*, like that of other bodies, is their motion after being reflected from the ſurfaces of bodies.

The Reflection of the rays of light from the ſurfaces of bodies, is the means by which thoſe bodies become viſible. And the diſpoſition of bodies to reflect this or that kind of rays moſt copiouſly, is the cauſe of their being of this or that colour. Alſo, the Reflection of light, from the ſurfaces of mirrors, makes the ſubject of catoptrics.

The Reflection of light, Newton has ſhewn, is not effected by the rays ſtriking on the very parts of the bodies; but by ſome power of the body equally diffuſed throughout its whole ſurface, by which it acts upon the ray, attracting or repelling it without any real immediate contact. This power he alſo ſhews is the ſame by which, in other circumſtances, the rays are refracted; and by which they are at firſt emitted from the lucid body.

Dr. Prieſtley ſays, it is not more probable, that the rays of light are tranſmitted from the ſun, with an uniform diſpoſition to be reflected or refracted, according to the circumſtances of the bodies on which they impinge; and that the tranſmiſſion of ſome of the rays, apparently under the ſame circumſtances, with others that are reflected, is owing to the minute vibrations of the ſmall parts of the ſurfaces of the mediums through which the rays paſs; vibrations that are independent of action and reaction between the bodies and the particles of light at the time of their impinging, though probably excited by the action of preceding rays. Hiſt. of Light and Colours, pa. 309.

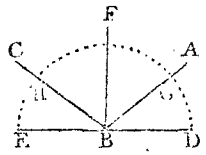
Newton concludes his account of the Reflection of light with obſerving, that if light be reflected not by impinging on the ſolid parts of bodies, but by ſome other principle, it is probable that as many of its

rays

rays as impinge on the ſolid parts of bodies are not reflected, but ſtifled and loſt in the bodies. Otherwiſe, he ſays, we muſt ſuppoſe two kinds of Reflection; for ſhould all the rays be reflected which impinge on the internal parts of clear water or cryſtal, thoſe ſubſtances would rather have a cloudy colour, than a clear tranſparency. To make bodies look black, it is neceſſary that many rays be ſtopped, retained and loſt in them; and it does not ſeem probable that any rays can be ſtopped and ſtifled in them, which do not impinge on their parts: and hence, he ſays, we may underſtand, that bodies are much more rare and porous than is commonly believed. However, M. Bouguer diſputes the fact of light being ſtifled or loſt by impinging on the ſolid parts of bodies.

REFLECTION, in Catoptrics, is the return of a ray of light from the poliſhed ſurface of a ſpeculum or mirror, as driven thence by ſome power reſiding in it.

The ray thus returned is called a *reflex* or *reflected ray*, or a *ray of Reflection*; and the point of the ſpeculum where the ray commences, is called the *point of Reflection*. Thus, the ray AB, proceeding from the radiant A, and ſtriking on the point of the ſpeculum B, being returned thence to C, BC repreſents the reflected ray, and B the point of Reflection; in reſpect of which, AB repreſents the incident ray, or ray of incidence, and B the point of incidence; alſo the angle CBE is the angle of Reflection, and ABD the angle of incidence; where DE is the reflecting ſurface, or at leaſt a tangent to it at the point B. Though ſome count the angle of incidence and of Reflection from the perpendicular BF.



General Laws of REFLECTION.—1. *When a ray of light is reflected from a ſpeculum of any form, the angle of incidence is always equal to the angle of Reflection.* This law obtains in the percuſſions of all kinds of bodies; and conſequently muſt do ſo in thoſe of light; and the proof of it may be ſeen at the article INCIDENCE.

This law is confirmed alſo by experiments on all bodies; and on the rays of light in this manner: A ray from the ſun falling on a mirror, in a dark room, through a ſmall hole, you will have the pleaſure to ſee it rebound, ſo as to make the angle of Reflection equal to the angle of incidence. And the ſame may be ſhewn in various other ways: thus ex. gr. placing a ſemicircle DFE on a mirror DE, its centre on B, and its limb or plane perpendicular to the ſpeculum; and aſſuming equal arcs DG and E H; place an object in A, and the eye in C: then will the object be ſeen by a ray reflected from the point B. But by covering B, the object will ceaſe to be ſeen.

II. *Every point of a ſpeculum reflects rays falling on it, from every part of an object.*

III. *If the eye C and the radiant point A change places, the point will continue to radiate upon the eye, in the ſame courſe or path as before.*

IV. *The plane of Reflection is perpendicular to the ſurface of the ſpeculum; and it paſſes through the centre in ſpherical ſpecula.*

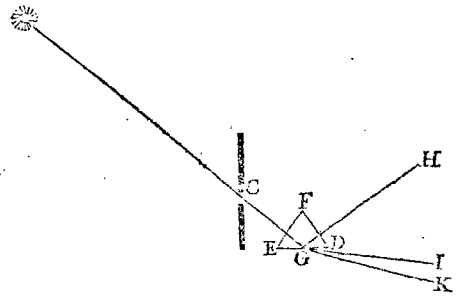
REFLECTION *of the Moon*, is a term uſed by ſome authors for what is otherwiſe called *her variation*; being the 3d inequality in her motion, by which her true place out of the quadratures differs from her place twice equated.

REFLECTION *is* alſo uſed in the Copernican ſyſtem, for the diſtance of the pole from the horizon of the diſc; which is the ſame thing as the ſun's declination in the Ptolomaic ſyſtem.

REFLECTOIRE CURVE. See *Reflectoire* CURVE.

REFLEXIBILITY *of the rays of light*, is that property by which they are diſpoſed to be reflected. Or, it is their diſpoſition to be turned back into the ſame medium, from any other medium on whoſe ſurface they fall. Hence thoſe rays are ſaid to be more or leſs reflexible, which are returned back more or leſs eaſily under the ſame incidence. Thus, if light paſs out of glaſs into air, and by being inclined more and more to the common ſurface of the glaſs and air, begins at length to be totally reflected by that ſurface, thoſe ſorts of rays which at like incidences are reflected moſt copiouſly, or the rays which by being inclined begin ſooneſt to be totally reflected, are the moſt reflexible rays.

That rays of light are of different colours, and endued with different degrees of reflexibility, was firſt diſcovered by Sir I. Newton; and it is ſhewn by the following experiment. Applying a priſm DFE to



the aperture C of a darkened room in ſuch manner that the light be reflected from the baſe in G; the violet rays are ſeen firſt reflected into HG; the other rays continuing ſtill refracted to I and K. After the violet, the blue are all reflected; then the green, &c.——Hence it appears, that the differently coloured rays differ in degree of Reflexibility. And from other experiments it appears, that thoſe rays which are moſt reflexible, are alſo moſt refrangible.

REFLUX *of the Sea*, is the ebbing of the water, or its return from the ſhore; being ſo called, becauſe it is the oppoſite motion to the flood or flux. See TIDE.

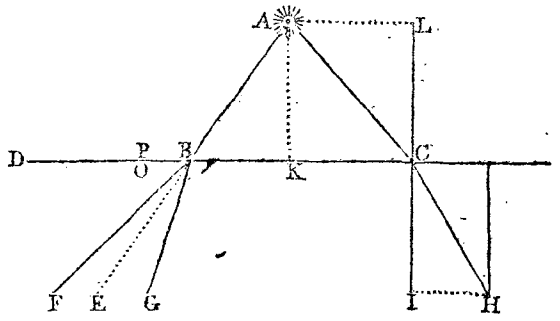
REFRACTED *Angle*, or *Angle of Refraction*, in Optics, is the angle which the refracted ray makes with the refracting ſurface; or ſometimes it denotes the complement of that, or the angle it makes with the perpendicular to the ſaid ſurface.

REFRACTED *Dials*, or *Refracting Dials*, are ſuch as ſhew the hour by means of ſome refracting tranſparent fluid.

REFRACTED *Ray*, or *Ray of* REFRACTION, is a

ray after it is broken or bent, at the common ſurface of two different mediums, where it paſſes from the one into the other. See RAY, and REFRACTION.

REFRACTION, in Mechanics, is the deviation of a moving body from its direct courſe, by reaſon of the different denſity of the medium it moves in; or a flexion and change of determination, occaſioned by a body's paſſing obliquely out of one medium into another of a different denſity.



Thus a ball A, moving in the air in the line AB, and falling obliquely on the ſurface of the water CD, does not proceed ſtraight in the ſame direction, as to E, but deviates or is deflected to F. Again, if the ball move in water in the line AB, and fall obliquely on a ſurface of air CD; it will in this caſe alſo deviate from the ſame continued direction BE, but now the contrary way, and will go to G, on the other ſide of it. Now the deflection in either caſe is called the *Refraction*, the Refraction being towards the denſer ſurface ED in the former caſe, but from it in the latter.

Theſe Refractions are ſuppoſed to ariſe from hence; that the ball arriving at B, in the firſt caſe finds more reſiſtance or oppoſition on the one ſide O, or from the ſide of the water, than it did from the ſide P, or that of the air; and in the latter more reſiſtance from the ſide P, which is now the ſide of the water, than the ſide O, which is that of the air. And ſo for any other different media: a viſible inſtance of which is often perceived in the falling of ſhot or ſhells into the earth, as clay &c, when the perforation is found to riſe a little upwards, toward the ſurface. However another reaſon is aſſigned for the Refraction of the rays of light, whoſe Refractions lie the contrary way to thoſe above, as will be ſeen in what follows, viz, that water by its greater attraction accelerates the motion of the rays of light more than air does.

REFRACTION *of Light*, in Optics, is an inflection or deviation of the rays from their rectilinear courſe on paſſing obliquely out of one medium into another, of a different denſity.

That a body may be refracted, it is neceſſary that it ſhould fall obliquely on the ſecond medium: in perpendicular incidence there is no Refraction. Yet Voſcius and Snellius imagined they had obſerved a perpendicular ray of light undergo a Refraction; a perpendicular object appearing in the water nearer than it really was: but this was attributing that to a Refraction of the perpendicular rays, which was owing to the divergency of the oblique rays after refraction, from a nearer point. Yet there is a manifeſt Refraction even of perpendicular rays found in iſland cryſtal.

Rohault adds, that though an oblique incidence be neceſſary in all other mediums we know of, yet the obliquity muſt not exceed a certain degree; if it do, the body will not penetrate the medium, but will be reflected inſtead of being refracted. Thus, cannon-balls, in ſea engagements, falling very obliquely on the ſurface of the water, are obſerved to bound or riſe from it, and to ſweep the men from off the enemy's decks. And the ſame thing happens to the little ſtones with which children make their ducks and drakes along the ſurface of the water.

The ancients confounded Refraction with Reflection; and it was Newton who firſt taught the true difference between them. He ſhews however that there is a good deal of analogy between them, and particularly in the caſe of light.

The laws of Refraction of the rays of light in mediums differently terminated, i. e. whoſe ſurfaces are plane, concave, and convex, make the ſubject of Dioptrics.—By Refraction it is, that convex glaſſes, or lenſes, collect the rays, magnify objects, burn, &c; and hence the foundation of microſcopes, teleſcopes, &c.—And by Refraction it is, that all remote objects are ſeen out of their real places; particularly, that the heavenly bodies are apparently higher than they are in reality. The Refraction of the air has many times ſo uncertain an influence on the places of celeſtial objects, near the horizon, that wherever Refraction is concerned, the concluſions deduced from obſervations that are much affected by it, will always remain doubtful, and ſometimes too precarious to be relied on. See Dr. Bradley in Philoſ. Tranſ. number 485.

As to the cauſe of Refraction, it does not appear that any perſon before Des Cartes attempted to explain it; this he undertook to do by the reſolution of forces, on the principles of mechanics; in conſequence of which, he was obliged to ſuppoſe that light paſſes with more eaſe through a denſe medium than a rare one: thus, the ray AC falling obliquely on a denſer medium at C is ſuppoſed to be acted on by two forces, one of them impelling it in the direction AL, and the other in AK, which alone can be affected by the change of medium: and ſince, after the ray has entered the denſer medium, it approaches the perpendicular CI, it is plain that this force muſt have received an increaſe, whilſt the other continued the ſame.

The firſt perſon who queſtioned the truth of this explanation of the cauſe of Refraction, was Fermat; he aſſerted, contrary to Des Cartes, that light ſuffers greater reſiſtance in water than in air, and greater in glaſs than in water; and he maintained that the reſiſtance of different mediums, with reſpect to light, is in proportion to their denſities. Leibnitz alſo adopted the ſame general idea; and they reaſoned upon the ſubject in the following manner. Nature, ſay they, accompliſhes her ends by the ſhorteſt methods; and therefore light ought to paſs from one point to another, either by the ſhorteſt courſe, or by that in which the leaſt time is required. But it is plain that the path in which light paſſes, when it falls obliquely upon a denſer

ſer medium, is not the moſt direct or the ſhorteſt; and therefore it muſt be that in which the leaſt time is ſpent. And whereas it is demonſtrable, that light falling obliquely upon a denſer medium (in order to take up the leaſt time poſſible, in paſſing from a point in one medium to a point in the other) muſt be refracted in ſuch a manner, that the ſine of the angles of incidence and Refraction muſt be to one another, as the different facilities with which light is tranſmitted in thoſe mediums; it follows that, ſince light approaches the perpendicular when it paſſes obliquely from air into water, the facility with which water ſuffers light to paſs through it, is leſs than that of the air; ſo that the light meets with greater reſiſtance in water than in air.

This method of arguing from final cauſes could not ſatisfy philoſophers. Dr. Smith obſerves, that it agrees only to the caſe of Refraction at a plane ſurface; and that the hypotheſis is altogether arbitrary.

Dechales, in explaining the law of Refraction, ſuppoſes that every ray of light is compoſed of ſeveral ſmaller rays, which adhere to one another; and that they are refracted towards the perpendicular, in paſſing into a denſer medium, becauſe one part of the ray meets with more reſiſtance than another part; ſo that the former traverſes a ſmaller ſpace than the latter; in conſequence of which the ray muſt neceſſarily bend a little towards the perpendicular. This hypotheſis was adopted by the celebrated Dr. Barrow, and indeed ſome ſay, he was the author of it. On this hypotheſis it is plain, that mediums of a greater refractive power, muſt give a greater reſiſtance to the paſſage of the rays of light, than mediums of a leſs refractive power; which is contrary to fact.

The Bernoullis, both father and ſon, have attempted to explain the cauſe of Refraction on mechanical principles; the former on the equilibrium of forces, and the latter on the ſame principles with the ſuppoſition of etherial vortices: but neither of theſe hypotheſes have gained much credit.

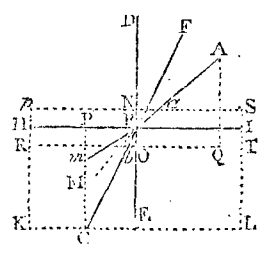
M. Mairan ſuppoſes a ſubtle fluid, filling the pores of all bodies, and extending, like an atmoſphere, to a ſmall diſtance beyond their ſurfaces; and then he ſuppoſes that the Refraction of light is nothing more than a neceſſary and mechanical effect of the incidence of a ſmall body in thoſe circumſtances. There is more, he ſays, of the refracting fluid, in water than in air, more in glaſs than in water, and in general more in a denſe medium than in one that is rarer.

Maupertuis ſuppoſes that the courſe which every ray takes, in paſſing out of one medium into another, is that which requires the leaſt quantity of action, which depends upon the velocity of the body and the ſpace it paſſes over; ſo that it is in proportion to the ſum of the products ariſing from the ſpaces multiplied by the velocities with which bodies paſs over them. From this principle he deduces the neceſſity of the ſine of the angle of incidence being in a conſtant proportion to that of Refraction; and alſo all the other laws relating to the propagation and reflection of light.

Dr. Smith (in his Optics, Remarks, p. 70) obſerves, that all other theories for explaining the reflection and Refraction of light, except that of Newton, ſuppoſe that it ſtrikes upon bodies and is reſiſted by them; which has never been proved by any deduction from experience. On the contrary, it appears by various conſiderations, and might be ſhewn by the obſervations of Mr. Molyneux and Dr. Bradley on the parallax of the fixed ſtars, that their rays are not at all impeded by the rapid motion of the earth's atmoſphere, nor by the object glaſs of the teleſcope, through which they paſs. And by Newton's theory of Refraction, which is grounded on experience only, it appears that light is ſo far from being reſiſted and retarded by Refraction into any denſe medium, that it is ſwifter there than in vacuo in the ratio of the ſine of incidence in vacuo to the ſine of Refraction into the denſe medium. Prieſtley's Hiſt. of Light, &c, p. 102 and 333.

Newton ſhews that the Refraction of light is not performed by the rays falling on the very ſurface of bodies; but that it is effected, without any contact, by the action of ſome power belonging to bodies, and extending to a certain diſtance beyond their ſurfaces; by which ſame power, acting in other circumſtances, they are alſo emitted and reflected.

The manner in which Refraction is performed by mere attraction, without contact, may be thus accounted for: Suppoſe HI the boundary of two mediums, N and O; the firſt the rarer, ex. gr. air; the ſecond the denſer, ex. gr. glaſs; the attraction of the mediums here will be as their denſities. Suppoſe p S to be the diſtance to which the attracting force of the denſer medium exerts itſelf within the rarer. Now let a ray of light Aa fall obliquely on the ſurface which ſeparates the mediums, or rather on the ſurface pS, where the action of the ſecond and more reſiſting medium commences: as the ray arrives at a, it will begin to be turned out of its rectilinear courſe by a ſuperior force, with which it is attracted by the medium O, more than by the medium N; hence the ray is bent out of its right line in every point of its paſſage between pS and RT, within which diſtance the attraction acts; and therefore between theſe lines it deſcribes a curve aBb; but beyond RT, being out of the ſphere of attraction of the medium N, it will proceed uniformly in a right line, according to the direction of the curve in the point b.



Again, ſuppoſe N the denſer and more attracting medium, O the rarer, and HI the boundary as before; and let RT be the diſtance to which the denſer medium exerts its attractive force within the rarer: even when the ray has paſſed the point B, it will be within the ſphere of the ſuperior attraction of the denſer medium; but that attraction acting in lines perpendicular to its ſurface, the ray will be continually drawn from its ſtraight courſe BM perpendicularly towards HI: thus, having two forces or directions, it will have a compound motion, by which, inſtead of BM, it will deſcribe Bm, which Bm will in ſtrictneſs be a curve. Laſtly, after it has arrived at m, being out of the influence of the medium N, it will perſiſt uniformly, in a right line, in the direction in which the extremity of

the curve leaves it.—Thus we ſee how Refraction is performed, both towards the perpendicular DE, and from it.

Refraction *in Dioptrics*, is the inflexion or bending of the rays of light, in paſſing the ſurfaces of glaſſes, leuſes, and other tranſparent bodies of different denſities. Thus, a ray, as AB, falling obliquely from the radiant A, upon a point B, in a diaphanous ſurface HI, rarer or denſer than the medium along which it was propagated from the radiant, has its direction there altered by the action of the new medium; and inſtead of proceeding to M, it deviates, as for ex. to C.

This deviation is called the *Refraction of the ray*; BC the *refracted ray*, or *line of Refraction*; and B the *point of Refraction*.—The line AB is alſo called the *line of incidence*; and in reſpect of it, B is alſo called the *point of incidence*. The plane in which both the incident and refracted ray are found, is called the *plane of Refraction*; alſo a right line BE drawn in the refracting medium perpendicular to the refracting ſurface at the point of Refraction B, is called the *axis of Refraction*; and its continuation DB along the medium through which the ray falls, is called the *axis of incidence*.—Farther, the angle ABI, made by the incident ray and the refracting ſurface, is uſually called the *angle of incidence*; and the angle ABD, between the incident ray and the axis of incidence, is the *angle of inclination*. Moreover, the angle MBC, between the refracted and incident rays, is called the *angle of Refraction*; and the angle CBE, between the refracted ray and the axis of Refraction, is the *refracted angle*. But it is alſo very common to call the angles ABD and CBE made by the perpendicular with the incident and refracted rays, the *angles of incidence and Refraction*.

General Laws of Refraction.—I. *A ray of light in its paſſage out of a rarer medium into a denſer*, ex. gr. *out of air into water or into glaſs, is refracted towards the perpendicular*, i. e. *towards the axis of Refraction*. Hence, the refracted angle is leſs than the angle of inclination; and the angle of Refraction leſs than that of incidence; as they would be equal were the ray to proceed ſtraight from A to M.

II. *The ratio of the ſines of the angles* ABD, CBE, *made by the perpendicular with the incident and refracted rays, is a conſtant and fixed ratio*; whatever be the obliquity of the incident ray, the mediums remaining. Thus, the Refraction out of air, into water, is nearly as 4 to 3, and into glaſs it is nearly as 3 to 2. As to air in particular, it is ſhewn by Newton, that a ray of light, in traverſing quite through the atmoſphere, is refracted the ſame as it would be, were it to paſs with the ſame obliquity out of a vacuum immediately into air of equal denſity with that in the loweſt part of the atmoſphere.

The true law of Refraction was firſt diſcovered by Willebrord Snell, profeſſor of Mathematics at Leyden; who found by experiment that the coſecants of the angles of incidence and Refraction, are always in the ſame ratio. It was commonly attributed however to Des Cartes; who, having ſeen it in a MS. of Snell's, firſt publiſhed it in his Dioptrics, without naming Snellius, as Huygens aſſerts; Des Cartes having only altered the form of the law, from the ratio of the coſecants, to that of the ſines, which is the ſame thing.

It is to be obſerved however, that as the rays of light are not all of the ſame degree of refrangibility, this conſtant ratio muſt be different in different kinds: ſo that the ratio mentioned by authors, is to be underſtood of rays of the mean refrangibility, i. e. of green rays. The difference of Refraction between the leaſt and moſt refrangible rays, that is, between violet and red rays, Newton ſhews, is about the $\frac{1}{35}$ of the whole Refraction of the mean refrangible; which difference, he allows, is ſo ſmall, that it ſeldom needs to be regarded.

Different tranſparent ſubſtances have indeed very different degrees of Refraction, and thoſe not according to any regular law; as appears by many experiments of Newton, Euler, Hawkſbee, &c. See Newton's Optics, 3d edit. pa. 247; Hawkſbee's Experim. pa. 292; Act. Berlin. 1762, pa. 302; Prieſtley's Hiſt. of Light &c, pa. 479.

Whence the different refractive powers in different fluids ariſe, has not been determined. Newton ſhews, that in many bodies, as glaſs, cryſtal, ſelenites, pſeudo-topaz, &c, the refractive power is indeed proportionable to their denſities; whilſt in ſulphureous bodies, as camphor, linſeed, and olive oil, amber, ſpirit of turpentine, &c, the power is two or three times greater than in other bodies of equal denſity; and yet even theſe have the refractive power with reſpect to each other, nearly as their denſities. Water has a refractive power in a medium degree between thoſe two kinds of ſubſtances; whilſt ſalts and vitriols have refractive powers in a middle degree between thoſe of earthy ſubſtances and water, and accordingly are compoſed of thoſe two ſorts of matter. Spirit of wine has a refractive power in a middle degree between thoſe of water and oily ſubſtances; and accordingly it ſeems to be compoſed of both, united by fermentation. It appears therefore, that all bodies ſeem to have their refractive powers nearly proportional to their denſities, excepting ſo far as they partake more or leſs of ſulphureous oily particles, by which thoſe powers are altered.

Newton ſuſpected that different degrees of heat might have ſome effect on the refractive power of bodies; but his method of determining the general Refraction was not ſufficiently accurate to aſcertain this circumſtance. Euler's method however was well adapted to this purpoſe: from his experiments he infers, that the focal diſtance of a ſingle lens of glaſs diminiſhes with the heat communicated to it; which diminution is owing to a change in the refractive power of the glaſs itſelf, which is probably increaſed by heat, and diminiſhed by cold, as well probably as that of all other tranſlucent ſubſtances.

From the law above laid down it follows, that one angle of inclination, and its correſponding refracted angle, being found by obſervation, the refracted angles correſponding to the ſeveral other angles of inclination are thence eaſily computed. Now, Zahnius and Kircher have found, that if the angle of inclination be 70°, the refracted angle, out of air into glaſs, will be 38° 50′; on which principle Zahnius has conſtructed a table of thoſe Refractions for the ſeveral degrees of the

angle of inclination; a ſpecimen of which here follows:

Angle of Inclination.	Refracted Angle.			Angle of Refraction.		
°	°	′	″	°	′	″
1	0	40	5	0	19	55
2	1	20	6	0	39	54
3	2	0	4	0	59	56
4	2	40	5	1	19	55
5	3	20	3	1	39	57
10	6	39	16	3	20	44
20	13	11	35	6	48	25
30	19	29	29	10	30	31
45	28	9	19	16	50	41
90	41	51	40	48	8	20

Hence it appears, that if the angle of inclination be leſs than 20°, the angle of Refraction out of air into glaſs is almoſt $\frac{1}{3}$ of the angle of inclination; and therefore a ray is refracted to the axis of Refraction by almoſt a third part of the quantity of its angle of inclination. And on this principle it is that Kepler, and moſt other dioptrical writers, demonſtrate the Refractions in glaſſes; though in eſtimating the law of theſe Refractions he followed the example of Alhazen and Vitello, and ſought to diſcover it in the proportion of the angles, and not in that of the ſines, or coſecants, as diſcovered by Snellius, as mentioned above.

The refractive powers of ſeveral ſubſtances, as determined by different philoſophers, may be ſeen in the following tables; in which the ray is ſuppoſed to paſs out of air into each of the ſubſtances, and the annexed numbers ſhew the proportion to unity or 1, between the ſines of the angles of incidence and Refraction.

III. *When a ray paſſes out of a denſer medium into a rarer, it is refracted from the perpendicular, or from the axis of Refraction.*

This is exactly the reverſe of the 2d law, and the quantity of Refraction is equal in both caſes, or both forwards and backwards; ſo that a ray would take the ſame courſe back, by which another paſſed forward, viz, if a ray would paſs from A by B to C, another would paſs from C by B to A. Hence, in this caſe, the angle of Refraction is greater than the angle of inclination. Hence alſo, if the angle of inclination be leſs than 30°, MBC is nearly equal to $\frac{1}{2}$ of MBE; therefore MBC is $\frac{1}{2}$ of CBE; conſequently, if the Refraction be out of glaſs into air, and the angle of inclination leſs than 30°, the ray is refracted from the axis of Refraction by almoſt the half of the angle of inclination. And this is the other dioptrical principle uſed by moſt authors after Kepler, to demonſtrate the Refractions of glaſſes.

If the Refraction be out of air into glaſs, the ratio of the ſines of inclination and Refraction is as 3 to 2, or more accurately as 17 to 11; if out of air into water as 4 to 3; therefore if the courſe be the contrary way, viz, out of glaſs or water into air, the ratio of the ſines will be, in the former caſe as 2 to 3 or 11 to 17, and in the latter as 3 to 4. So that, if the Refraction be from water or glaſs into air, and the angle of incidence

Mr. Mayer says his rule was deduced from theory, and, when reduced from French measure and Reaumur's thermometer, to English measure and Fahrenheit's thermometer, it is this,

$$r = \frac{74{\cdot}4b \times \text{cos. } a}{(1+{\cdot}00248t)^{\frac{3}{2}}}\left(\sqrt{1+\frac{17{\cdot}14 \text{ fin. } a}{1+{\cdot}00248t}} - \frac{17{\cdot}14 \text{ fin. } a}{(1+{\cdot}00248t)^{\frac{1}{2}}}\right)$$

or $r = \frac{74{\cdot}4b \times \text{cos. } a \times \text{tang. } \frac{1}{2}A}{(1+{\cdot}00248t)^{\frac{3}{2}}}$ the Refraction in seconds, corrected for both barometer and thermometer when the letters denote the same things as before, except A, which denotes the angle whose tangent is $\frac{\sqrt{1+{\cdot}00248t}}{17{\cdot}14 \text{ fin. } a}$.

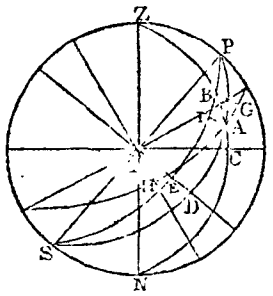
Mr. Simpson too (Differt. pa. 46 &c) has ingeniously determined by theory the astronomical Refractions, from which he brings out this rule, viz, As 1 to ·9986 or as radius to fine of 86° 58′ 30″, so is the fine of any given zenith distance, to the fine of an arc; then $\frac{2}{7}$ of the difference between this arc and the zenith distance, is the Refraction sought for that zenith distance. And by this rule Mr. Simpson computed a Table of the mean Refractions, which are not much different from those of Dr. Bradley and Mr. Mayer, and are as in the following Table.

Mr. Simpson's Table of Mean Refractions.

Apparent Altitude.	Refraction.		Apparent Altitude.	Refraction.		Apparent Altitude.	Refraction.	
0°	33′	0″	17°	2′	50″	38°	1′	7″
1	23	50	18	2	40	40	1	2
2	17	43	19	2	31	42	0	58
3	13	44	20	2	23	44	0	54
4	11	5	21	2	16	46	0	50
5	9	10	22	2	9	48	0	47
6	7	49	23	2	3	50	0	44
7	6	48	24	1	57	52	0	41
8	5	59	25	1	52	54	0	38
9	5	21	26	1	47	56	0	35
10	4	50	27	1	42	58	0	32
11	4	24	28	1	38	60	0	30
12	4	2	29	1	34	65	0	24
13	3	43	30	1	30	70	0	19
14	3	27	32	1	23	75	0	14
15	3	13	34	1	17	80	0	9
16	3	1	36	1	12	85	0	4½

It is evident that all observed altitudes of the heavenly bodies ought to be diminished by the numbers taken out of the foregoing Table. It is also evident that the Refraction diminishes the right and oblique ascensions of a star, and increases the descensions: it increases the northern declination and latitude, but decreases the southern: in the eastern part of the heavens it diminishes the longitude of a star, but in the western part of the heavens it increases the same.

REFRACTION *of Altitude*, is an arc of a vertical circle, as AB, by which the altitude of a star AC is increased by the Refraction.



REFRACTION *of Ascension and Descension*, is an arc DE of the equator, by which the ascension and descension of a star, whether right or oblique, is increased or diminished by the Refraction.

REFRACTION *of Declination*, is an arc BF of a circle of declination, by which the declination of a star DA or EF is increased or diminished by Refraction.

REFRACTION *of Latitude* is an arc AG of a circle of latitude, by which the latitude of a star AH is increased or diminished by the Refraction.

REFRACTION *of Longitude* is an arc IH of the ecliptic, by which the longitude of a star is increased or diminished by means of the Refraction.

Terrestrial REFRACTION, is that by which terrestrial objects appear to be raised higher than they really are, in observing their altitudes. The quantity of this Refraction is estimated by Dr. Maskelyne at one-tenth of the distance of the object observed, expressed in degrees of a great circle. So, if the distance be 10000 fathoms, its 10th part 1000 fathoms, is the 60th part of a degree of a great circle on the earth, or 1′, which therefore is the Refraction in the altitude of the object at that distance. (Requisite Tables, 1766, pa. 134).

But M. Le Gendre is induced, he says, by several experiments, to allow only $\frac{1}{13}$th part of the distance for the Refraction in altitude. So that, upon the distance of 10000 fathoms, the 14th part of which is 714 fathoms, he allows only 44″ of terrestrial Refraction, so many being contained in the 714 fathoms. See his Memoir concerning the Trigonometrical operations, &c.

Again, M. de Lambre, an ingenious French astronomer, makes the quantity of the Terrestrial Refraction to be the 11th part of the arch of distance. But the English measurers, Col. Edw. Williams, Capt. Mudge, and Mr. Dalby, from a multitude of exact observations made by them, determine the quantity of the medium Refraction to be the 12th part of the said distance.

The quantity of this Refraction, however, is found to vary considerably, with the different states of the weather and atmosphere, from the 15th part of the distance, to the 9th part of the same; the medium of which is the 12th part, as above mentioned.

Some whimsical effects of this Refraction are also related, arising from peculiar situations and circumstances. Thus, it is said, any person standing by the side of the river Thames at Greenwich, when it is high-

water

water there, he can ſee the cattle grazing on the Iſle of Dogs, which is the marſhy meadow on the other ſide of the river at that place; but when it is low-water there, he cannot ſee any thing of them, as they are hid from his view by the land wall or bank on the other ſide, which is raiſed higher than the marſh, to keep out the waters of the river. This curious effect is probably owing to the moiſt and denſe vapours, juſt above and riſing from the ſurface of the water, being raiſed higher or lifted up with the ſurface of the water at the time of high tide, through which the rays paſs, and are the more refracted.

Again, a ſimilar inſtance is related in a letter to me, from an ingenious friend, Mr. Abr. Crocker of Frome in Somerſetſhire, dated January 12, 1795. "My Devonſhire friend," ſays he, (whoſe ſeat is in the vicinity of the town of Modbury, 12 miles in a geographical line from Maker tower near Plymouth) "being on a pleaſure ſpot in his garden, on the 4th of December 1793, with ſome friends, viewing the ſurrounding country, with an achromatic teleſcope, deſcried an object like a perpendicular pole ſtanding up in the chaſm of a hedge which bounded their view at about 9 miles diſtance; which, from its direction, was conjectured to be the flagſtaff on Maker tower.—Directing the glaſs, on the morning of the next day, to the ſame part of the horizon, a flag was perceived on the pole; which corroborated the conjecture of the preceding day. This day's view alſo diſcovered the pinnacles and part of the ſhaft of the tower.—Viewing the ſame ſpot at 8 in the morning on the 9th of January 1794, the whole tower and part of the roof of the church, with other remote objects not before noticed, became viſible.

"It is neceſſary to give you the ſtate of the weather there, on thoſe days.

1793.	Barometer.	Thermom.	Wind	
Dec. 4	29·93, riſing	36·0	N. E.	Froſty morning, a miſt over the land below.
5	29·97, riſing	35·2	W.	Ditto.
1794.				
Jan. 9	30·01, falling	29·8	W.	Hard white froſt, a fog over the lowlands; clear in the ſurrounding country.

"The ſingularity of this phenomenon has occaſioned repeated obſervations on it; from all which it appears that the ſummer ſeaſon, and wet windy weather, are unfavourable to this refracted elevation; but that calm froſty weather, with the abſence of the ſun, are favourable to it.

"From hence a queſtion ariſes; what is the principal or moſt general cauſe of atmoſpheric Refraction, which produces ſuch extraordinary appearances?"

The following is alſo a copy of a letter to Mr. Crocker on this curious phenomenon, from his friend above mentioned, viz, Mr. John Andrews, of Traine, near Modbury, dated the 1ſt of February 1795.

"My good Friend,

"Finding, by your favour of laſt Sunday, the proceedings which are goin[illegible] obſervations on the phenomen[illegible] it neceſſary to beſtow al[illegible] what I am obliged to ca[illegible] illuſtrative of thoſe obſerva[illegible] diſtinguiſh, by different [illegible] which lie nearer or mor[illegible] be better explained by the letters of reference, which I have inſerted as they may be ſerviceable in future correſpondence.—I believe the drawings, rough as they are, give a tolerably exact repreſentation of the ſcenes: they may be properly copied to ſend to London by one of your ingenious ſons.—I have been attentive in my obſervations, or rather in looking out for obſervations, during the late hard froſts, which you will be ſurpriſed to learn, have (except on one or two days) been very unpropitious to the phenomenon; but they have compenſated for that diſappointment, by a diſcovery, that a dry froſt, though ever ſo intenſe, has no tendency to produce it. A hoar froſt, or that kind of dewy vapour which, in a ſufficient degree of cold, occaſions a hoar froſt, appears eſſentially neceſſary. This took place pretty favourably on the 6th of January, when the elevation was equal to that repreſented in the third drawing (*ſee plate* 25, *fig.* 3), much like what it was on the 9th of January 1794, and confirmed me as to the certainty of ſome peculiar appearances, hinted at in my letter of the 14th of that month, but not there deſcribed. What I allude to, was a fluctuating appearance of two horizons, one above the other, with a complete vacancy between them, exactly like what may be often obſerved looking through an uneven pane of glaſs. Divers inſtances of this were ſeen by my brother and myſelf on the 6th of laſt January; continually varying and intermitting, but not rapidly, ſo that they were capable of diſtinct obſervation.—Till that day I had formed, as I thought, a plauſible theory, to account for, as well this latter, as all the other phenomena; but now, unleſs my imagination deceives me, I am left in impenetrable darkneſs. The vacant line of ſeparation, you will take notice, would often increaſe ſo much in breadth, as to efface entirely the upper of the two horizons; forming then a kind of dent or gap in the remaining horizon, which horizon at the places contiguous to the extremities of the vacancy, ſeemed of the ſame height as the upper horizon was, before effaced. This vacancy was ſeveral times ſeen to approach and take in the tower, and immediately to admit a view of the whole or moſt part of its body (like that in the third drawing) which was not the caſe before: exactly, to all appearance, as if it had opened a gap for that purpoſe in the intercepted ground.—It remains therefore to be determined by future obſervations, whether the ſeparation is effected by an elevation of the upper, or depreſſion of the lower horizon; and if the latter, why the vacancy does not cauſe the tower to diſappear, as well as the intervening ground?—As an opportunity for this purpoſe may not ſoon occur, I hope you will not wait for it, in your communications to him who is, Dear Sir, yours very truly,

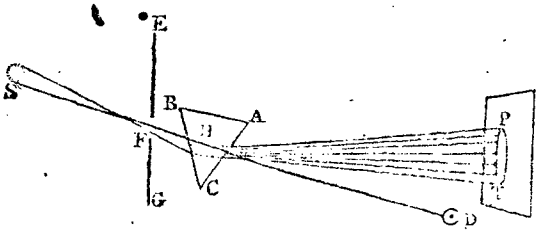
JOHN ANDREWS."

See the repreſentations in plate 25, of the appearances, in three different ſtates of the atmoſphere, with the explanations of them.

REFRAN.

REFRANGIBILITY *of Light*, the diſpoſition of the rays to be refracted. And a greater or leſs Refrangibility, is a diſpoſition to be more or leſs refracted, in paſſing at equal angles of incidence into the ſame medium.

That the rays of light are differently refrangible, is the foundation of Newton's whole theory of light and colours; and the truth and circumſtances of the principle he evinced from ſuch experiments as the following.



Let EG repreſent the window-ſhutter of a dark room, and F a hole in it, through which the light paſſes, from the luminous object S, to the glaſs priſm ABC within the room, which refracts it towards the oppoſite ſide, or a ſcreen, at PT, where it appears of an oblong form; its length being about five times the breadth, and exhibiting the various colours of the rainbow; whereas without the interpoſition of the priſm, the ray of light would have proceeded on in its firſt direction to D. Hence then it follows,

1. That the rays of light are refrangible. This appears by the ray being refracted from its original direction SHD, into another one, HP or HT, by paſſing through a different medium.

2. That the ray SFH is a compound one, which, by means of the priſm, is decompounded or ſeparated into its parts, HP, HT, &c, which it hence appears are all endued with different degrees of Refrangibility, as they are tranſmitted to all the intermediate points from T to P, and there painting all the different colours.

From this, and a great variety of other experiments, Newton proved, that the blue rays are more refracted than the red ones, and that there is likewiſe unequal refraction in the intermediate rays; and upon the whole it appears that the ſun's rays have not all the ſame Refrangibility, and conſequently are not of the ſame nature. It is alſo obſerved that thoſe rays which are moſt refrangible, are alſo moſt reflexible. See REFLEXIBILITY; alſo Newton's Optics, pa. 22 &c, 3d edit.

The difference between Refrangibility and reflexibility was firſt diſcovered by Sir Iſaac Newton, in 1671-2, and communicated to the Royal Society, in a letter dated Feb. 6 of that year, which was publiſhed in the Philoſ. Tranſ. numb. 80, pa. 3075; and from that time it was vindicated by him, from the objections of ſeveral authors; particularly Pardies, Mariotte, Linus or Lin, and other gentlemen of the Engliſh college at Liege; and at length it was more fully laid down, illuſtrated, and confirmed, by a great variety of experiments, in his excellent treatiſe on Optics.

But farther, as not only theſe colours of light produced by refraction in a priſm, but alſo thoſe reflected from opaque bodies, have their different degrees of Refrangibility and reflexibility; and as a white light ariſes from a mixture of the ſeveral coloured rays together, the ſame great author concluded that all homogeneous light has its proper colour, correſponding to its degree of Refrangibility, and not capable of being changed by any reflexions, or any refractions; that the ſun's light is compoſed of all the primary colours; and that all compound colours ariſe from the mixture of the primary ones, &c.

The different degrees of Refrangibility, he conjectures to ariſe from the different magnitude of the particles compoſing the different rays. Thus, the moſt refrangible rays, that is the red ones, he ſuppoſes may conſiſt of the largeſt particles; the leaſt refrangible, i. e. the violet rays, of the ſmalleſt particles; and the intermediate rays, yellow, green, and blue, of particles of intermediate ſizes. See COLOUR.

For the method of correcting the effect of the different Refrangibility of the rays of light in glaſſe, ſee ABERRATION and TELESCOPE.

REGEL, or RIGEL, a fixed ſtar of the firſt magnitude, in the left foot of Orion.

REGIOMONTANUS. See *John* MULLER.

REGION, of the Air or Atmoſphere. Authors divide the atmoſphere into three ſtages, called the upper, middle, and lower Regions.—The loweſt Region is that in which we breathe, and is bounded by the reflexion of the ſun's rays, that is, by the height to which they rebound from the earth.—The middle Region is that in which the clouds reſide, and where meteors are formed, &c; extending from the extremity of the loweſt, to the tops of the higheſt mountains.—The upper Region commences from the tops of the mountains, and reaches to the utmoſt limits of the atmoſphere. In this Region there probably reigns a perpetual equable calmneſs, clearneſs, and ſerenity.

Elementary REGION, according to the Ariſtotelians, is a ſphere terminated by the concavity of the moon's orb, comprehending the earth's atmoſphere.

Ethereal REGION, is the whole extent of the univerſe, compriſing all the heavens with the orbs of the fixed ſtars and other celeſtial bodies.

REGION, in Geography, a country or particular diviſion of the earth, or a tract of land inhabited by people of the ſame nation.

REGIONS *of the Moon*. Modern aſtronomers divide the moon into ſeveral Regions, or provinces, to each of which they give its proper name.

REGIONS *of the Sea*, are the two parts into which the whole depth of the ſea is conceived to be divided. The upper of theſe extends from the ſurface of the water, down as low as the rays of the ſun can pierce, and extend their influence; and the lower Region extends from thence to the bottom of the ſea.

Subterranean REGIONS. Theſe are three, into which the earth is divided, at different depths below the ſurface, according to different degrees of cold or warmth; and it is imagined that the 2d or middlemoſt of theſe Regions is the coldeſt of the three.

REGIS (PETER SYLVAIN), a French philoſopher, and great propagator of Carteſianiſm, was born in Agenois 1632.

He ſtudied the languages and philoſophy under the

Jeſuits at Cahors, and afterwards divinity in the univerſity of that town, being deſigned for the church. His progreſs in learning was ſo uncommon, that at the end of four years he was offered a doctor's degree without the uſual charges; but he did not think it became him till he ſhould ſtudy alſo in the Sorbonne at Paris. He accordingly repaired to the capital for that purpoſe; but he ſoon became diſguſted with theology; and, as the philoſophy of Des Cartes began at that time to make a noiſe through the lectures of Rohault, he conceived a taſte for it, and gave himſelf up entirely to it.

Having, by attending thoſe lectures, and by cloſe ſtudy, become an adept in that philoſophy, he went to Toulouſe in 1665, where he ſet up lectures in it himſelf. Having a clear and fluent manner, and a happy way of explaining his ſubject, he drew all ſorts of people to his diſcourſes; the magiſtrates, the literati, the eccleſiaſtics, and the very women, who all now affected to renounce the ancient philoſophy.

In 1671, he received at Montpellier the ſame applauſes for his lectures as at Toulouſe. Finally, in 1680 he returned to Paris; where the concourſe about him was ſuch, that the ſticklers for Peripateticiſm began to be alarmed. Theſe applying to the archbiſhop of Paris, he thought it expedient, in the name of the king, to put a ſtop to the lectures; which accordingly were diſcontinued for ſeveral months. Afterwards his whole life was ſpent in propagating the new philoſophy, both by lectures, and by publiſhing books. In defence of his ſyſtem, he had diſputes with Huet, Du Hamel, Malbranche, and others. His works, though abounding with ingenuity and learning, have been neglected in conſequence of the great diſcoveries and advancement in philoſophic knowledge that has been ſince made.—He was choſen a member of the Academy of Sciences in 1699; and died in 1707, at 75 years of age.

His works, which he publiſhed, are,

1. *A Syſtem of Philoſophy*; containing Logic, Metaphyſics, and Morals; in 1690, 3 vols in 4to. being a compilation of the different ideas of Des Cartes.—It was reprinted the year after at Amſterdam, with the addition of a Diſcourſe upon Ancient and Modern Philoſophy.

2. *The Uſe of Reaſon and of Faith.*

3. An Anſwer to Huet's Cenſures of the Carteſian Philoſophy; and an Anſwer to Du Hamel's Critical Reflections.

4. Some pieces againſt Malbranche, to ſhew that the apparent magnitude of an object depends ſolely on the magnitude of its image, traced on the retina.

5. A ſmall piece upon the queſtion, Whether Pleaſure makes our preſent happineſs?

REGRESSION, or RETROGRADATION *of Curves*, &c. See RETROGRADATION.

REGULAR *Figure*, in Geometry, is a figure that is both equilateral and equiangular, or having all its ſides and angles equal to one another.

For the dimenſions, properties, &c, of regular figures, ſee POLYGON.

REGULAR *Body*, called alſo *Platonic Body*, is a body or ſolid comprehended by like, equal, and regular plane figures, and whoſe ſolid angles are all equal.

The plane figures by which the ſolid is contained, are the faces of the [illegible] the plane figures are the [illegible] ſolid.

There are only five Regul[illegible]

The tetraedron, or regula[illegible] ing 4 triangular faces;

The hexaedron, or cube, [illegible]

The octaedron, having 8 t[illegible]

The dodecaedron, having [illegible]

The icoſaedron, having 20 [illegible]

Beſides theſe five, there can [illegible] dies in nature.

PROB. 1. *To conſtruct or form the Regular Solids.*—See the method of deſcribing th[illegible] figures under the article BODY.

2. *To find either the Surface or the Solid Content of any of the Regular Bodies.*—Multiply the proper tabular area or ſurface (taken from the following Table) by the ſquare of the linear edge of the ſolid, for the ſuperficies. And

Multiply the tabular ſolidity, in the laſt column of the Table, by the cube of the linear edge, for the ſolid content.

Surfaces and Solidities of Regular Bodies, the ſide being unity or 1.

No. of ſides.	Name.	Surface.	Solidity.
4	Tetraedron	1·7320508	0·1178513
6	Hexaedron	6·0000000	1·0000000
8	Octaedron	3·4641016	0·4714045
12	Dodecaedron	20·6457788	7·6631189
20	Icoſaedron	8·6602540	2·1816950

3. The Diameter of a Sphere being given, to find the ſide of any of the Platonic bodies, that may be either inſcribed in the ſphere, or circumſcribed about the ſphere, or that is equal to the ſphere.

Multiply the given diameter of the ſphere by the proper or correſponding number, in the following Table, anſwering to the thing ſought, and the product will be the ſide of the Platonic body required.

The diam. of a ſphere being 1, the ſide of a	That may be inſcribed in the ſphere, is	That may be circumſcribed about the ſphere, is	That is equal to the ſphere, is
Tetraedron	0·816497	2·44948	1·64417
Hexaedron	0·577350	1·00000	0·88610
Octaedron	0·707107	1·22474	1·03576
Dodecaedron	0·525731	0·66158	0·62153
Icoſaedron	0·356822	0·44903	0·40883

4. The ſide of any of the five Platonic bodies being given, to find the diameter of a ſphere, that may either be inſcribed in that body, or circumſcribed about it, or that is equal to it.—As the reſpective number in the Table above, under the title, *inſcribed*, *circumſcribed*, or *equal*, is to 1, ſo is the ſide of the given Platonic body,

body, to the diameter of the inſcribed, circumſcribed, or equal ſphere.

5. The ſide of any one of the five Platonic bodies being given; to find the ſide of any of the other four bodies, that may be equal in ſolidity to that of the given body.—As the number under the title *equal* in the laſt column of the table above, againſt the given Platonic body, is to the number under the ſame title, againſt the body whoſe ſide is ſought, ſo is the ſide of the given Platonic body, to the ſide of the body ſought.

See demonſtrations of many other properties of the Platonic bodies, in my Menſuration, part 3 ſect. 2 pa. 249, &c, 2d edition.

REGULAR *Curve*. See CURVE.

REGULATOR *of a Watch*, is a ſmall ſpring belonging to the balance, ſerving to adjuſt the going, and to make it go either faſter or ſlower.

REGULUS, in Aſtronomy, a ſtar of the firſt magnitude, in the conſtellation Leo; called alſo, from its ſituation, *Cor Leonis*, or the *Lion's Heart*; by the Arabs, *Alhabor*; and by the Chaldeans, *Kalbeleced*, or *Karbeleceid*; from an opinion of its influencing the affairs of the heavens; as Theon obſerves.

The longitude of Regulus, as fixed by Flamſteed, is 25° 31′ 21″, and its latitude 0° 26′ 38″ north. See LEO.

REINFORCE, in Gunnery, is that part of a gun next the breech, which is made ſtronger to reſiſt the force of the powder. There are uſually two Reinforces in each piece, called the firſt and ſecond Reinforce. The ſecond is ſomewhat ſmaller than the firſt, becauſe the inflamed powder in that part is leſs ſtrong.

REINFORCE *Rings* of a cannon, are flat mouldings, like iron hoops, placed at the breech end of the firſt and ſecond Reinforce, projecting beyond the reſt of the metal about a quarter of an inch.

REINHOLD (ERASMUS), an eminent aſtronomer and mathematician, was born at Salfeldt in Thuringia, a province in Upper Saxony, the 11th of October 1511. He ſtudied mathematics under James Milichi at Wittemberg, in which univerſity he afterwards became profeſſor of thoſe ſciences, which he taught with great applauſe. After writing a number of uſeful and learned works, he died the 19th of February 1553, at 42 years of age only. His writings are chiefly the following:

1. *Theoriæ novæ Planetarum G. Purbachii*, augmented and illuſtrated with diagrams and Scholia in 8vo, 1542; and again in 1580.—In this work, among other things worthy of notice, he teaches (pa. 75 and 76) that the centre of the lunar epicycle deſcribes an *oval figure* in each monthly period, and that the orbit of Mercury is alſo of the ſame oval figure.

2. *Ptolomy's Almageſt*, the firſt book, in Greek, with a Latin verſion, and Scholia, explaining the more obſcure paſſages; in 8vo, 1549.—At the end of pa. 123 he promiſes an edition of Theon's Commentaries, which are very uſeful for underſtanding Ptolomy's meaning; but his immature death prevented Reinhold from giving this and other works which he had projected.

3. *Prutenicæ Tabulæ Cœleſtium Motuum*, in 4to, 1551; again in 1571; and alſo in 1585.—Reinhold ſpent ſeven years labour upon this work, in which he was aſſiſted by the munificence of Albert, duke of Pruſſia, from whence the tables had their name. Reinhold compared the obſervations of Copernicus with thoſe of Ptolomy and Hipparchus, from whence he conſtructed theſe new tables, the uſes of which he has fully explained in a great number of precepts and canons, forming a complete introduction to practical aſtronomy.

4. *Primus liber Tabularum Directionum*; to which are added, the *Canon Fœcundus*, or Table of Tangents, to every minute of the quadrant; and New Tables of Climates, Parallels and Shadows, with an Appendix containing the ſecond Book of the Canon of Directions; in 4to, 1554.—Reinhold here ſupplies what was omitted by Regiomontanus in his Table of Directions, &c; ſhewing the finding of the ſines, and the conſtruction of the tangents, the ſines being found to every minute of the quadrant, to the radius 10,000,000; and he produced the Oblique Aſcenſions from 60 degrees to the end of the quadrant. He teaches alſo the uſe of theſe tables in the ſolution of ſpherical problems.

Reinhold prepared likewiſe an edition of many other works, which are enumerated in the Emperor's Privilege, prefixed to the Prutenic Tables. Namely, Ephemerides for ſeveral years to come, computed from the new tables. Tables of the Riſing and Setting of ſeveral Fixed Stars, for many different climates and times. The illuſtration and eſtabliſhment of Chronology, by the eclipſes of the luminaries, and the great conjunctions of the planets, and by the appearance of comets, &c. The Eccleſiaſtical Calendar. The Hiſtory of Years, or Aſtronomical Calendar. *Iſagoge Spherica*, or Elements of the Doctrine of the Primum Mobile. *Hypotypoſes Orbium Cœleſtium*, or the Theory of Planets. Conſtruction of a New Quadrant. The Doctrine of Plane and Spherical Triangles. Commentaries on the work of Copernicus. Alſo Commentaries on the 15 books of Euclid, on Ptolomy's Geography, and on the Optics of Alhazen the Arabian.—Reinhold alſo made Aſtronomical Obſervations, but with a wooden quadrant, which obſervations were ſeen by Tycho Brahe when he paſſed through Wittemberg in the year 1575, who wondered that ſo great a cultivator of aſtronomy was not furniſhed with better inſtruments.

Reinhold left a ſon, named alſo Eraſmus after himſelf, an eminent mathematician and phyſician at Salfeldt. He wrote a ſmall work in the German language, on Subterranean Geometry, printed in 4to at Erfurt 1575.—He wrote alſo concerning the New Star which appeared in Caſſiopeia in the year 1572; with an Aſtrological Prognoſtication, publiſhed in 1574, in the German language.

RELAIS, in Fortification, a French term, the ſame with berme.

RELATION, in Mathematics, is the habitude or reſpect of quantities of the ſame kind to each other, with regard to their magnitude; more uſually called *ratio*.—And the equality, identity, or ſameneſs of two ſuch Relations, is called proportion.

RELATION, *Inharmonical*, in Muſical Compoſition,

is that whoſe extremes form a falſe or unnatural interval, incapable of being ſung.—This is otherwiſe called a *falſe Relation*, and ſtands oppoſed to a juſt or true one.

RELATIVE *Gravity*, *Levity*, *Motion*, *Neceſſity*, *Place*, *Space*, *Time*, *Velocity*, *&c.* See the ſeveral ſubſtantives.

RELIEVO, in Architecture, denotes the ſally or projecture of any ornament.

REMAINDER, is the difference between two quantities, or that which is left after ſubtracting one from the other.

RENDERING, in Building. See PARGETING.

REPELLING *Power*, in Phyſics, is a certain power or faculty, reſiding in the minute particles of natural bodies, by which, under certain circumſtances, they mutually fly from each other. This is the reverſe or oppoſite of the attractive power. Newton ſhews, from obſervation, that ſuch a force does really exiſt; and he argues, that as in algebra, where poſitive quantities ceaſe, there negative ones begin; ſo in phyſics, where the attractive force ceaſes, there a Repelling force muſt begin.

As the Repelling power ſeems to ariſe from the ſame principle as the attractive, only exerciſed under different circumſtances, it is governed by the ſame laws. Now the attractive power we find is ſtronger in ſmall bodies, than in great ones, in proportion to the maſſes; therefore the Repelling is ſo too. But the rays of light are the moſt minute bodies we know of; and therefore their Repelling force muſt be the greateſt. It is computed by Newton, that the attractive force of the rays of light is above 1000000000000000, or one thouſand million of millions of times ſtronger than the force of gravity on the ſurface of the earth: hence ariſes that inconceivable velocity with which light muſt move to reach from the ſun to the earth in little more than 7 minutes of time. For the rays emitted from the body of the ſun, by the vibrating motion of its parts, are no ſooner got without the ſphere of attraction of the ſun, than they come within the action of the Repelling power.

The elaſticity or ſpringineſs of bodies, or that property by which, after having their figure altered by an external force, they return to their former ſhape again, follows from the Repelling power. See REPULSION.

REPERCUSSION. See REFLECTION.

REPETEND, in Arithmetic, denotes that part of an infinite decimal fraction, which is continually repeated ad infinitum. Thus in the numbers 2·13 13 13 &c. the figures 13 are the Repetend, and marked thus $\dot{1}\dot{3}$.

Theſe Repetends chiefly ariſe in the reduction of vulgar fractions to decimals. Thus, $\frac{1}{3} = 0{\cdot}333$ &c $= 0{\cdot}\dot{3}$; and $\frac{1}{6} = 01666$ &c $= 0{\cdot}1\dot{6}$; and $\frac{1}{7} = 0{\cdot}142857\ 142857$ &c $= 0{\cdot}\dot{1}42857\dot{}$. Where it is to be obſerved, that a point is ſet over the figure of a ſingle Repetend, and a point over the firſt and laſt figure when there are ſeveral that repeat.

Repetends are either *ſingle* or *compound*.

A *Single* REPETEND is that in which only one figure repeats; as $0{\cdot}\dot{3}$, or $0{\cdot}\dot{6}$, &c.

A *Compound* REPETEND is that in which two or more figures are repeated; as $0{\cdot}\dot{1}\dot{2}$, or $0{\cdot}\dot{2}\dot{3}$, &c.

Similar REPETENDS are thoſe which begin at the ſame place, and conſiſt of the ſame figures; as $0{\cdot}\dot{3}$ and $0{\cdot}\dot{6}$, or $1{\cdot}3\dot{4}$ and $2{\cdot}5\dot{4}$.

Diſſimilar REPETENDS are thoſe which begin at different places, and conſiſt of an unequal number of figures.

To find the finite Value of a Repetend, or reduce it to a Vulgar Fraction. Take the given repeating figure or figures for the numerator; and for the denominator, take as many 9's as there are recurring figures or places in the given Repetend.

So $0{\cdot}\dot{3} = \frac{3}{9} = \frac{1}{3}$; and $0{\cdot}0\dot{5} = 0{\cdot}0\frac{5}{9} = \frac{5}{90} = \frac{1}{18}$;

and $0{\cdot}\dot{1}2\dot{3} = \frac{123}{999} = \frac{41}{333}$; and $2{\cdot}\dot{6}\dot{3} = 2\frac{63}{99} = 2\frac{7}{11}$;

and $0{\cdot}0594405 = \frac{594405}{9999990} = \frac{17}{280}$;

and $0{\cdot}\dot{7}69230 = \frac{769230}{999999} = \frac{10}{13}$.

Hence it follows, that every ſuch infinite Repetend has a certain determinate and finite value, or can be expreſſed by a terminate vulgar fraction. And conſequently, that an infinite decimal which does not repeat or circulate, cannot be completely expreſſed by a finite vulgar fraction.

It may farther be obſerved, that if the numerator of a vulgar fraction be 1, and the denominator any prime number, except 2 and 5, the decimal which ſhall be equal to that vulgar fraction, will always be a Repetend, beginning at the firſt place of decimals; and this Repetend muſt neceſſarily be a ſubmultiple, or an aliquot part of a number expreſſed by as many 9's as the Repetend has figures; that is, if the Repetend have ſix figures, it will be a ſubmultiple of 999999; if four figures, a ſubmultiple of 9999 &c. From whence it follows, that if any prime number be called p, the ſeries 9999 &c, produced as far as is neceſſary, will always be diviſible by p, and the quotient will be the Repetend of the decimal fraction $= \frac{1}{p}$.

RESIDUAL *Figure*, in Geometry, the figure remaining after ſubtracting a leſs from a greater.

RESIDUAL *Root*, is a root compoſed of two parts or members, only connected together with the ſign — or minus. Thus, $a-b$, or $5-3$, is a reſidual root; and is ſo called, becauſe its true value is no more than the reſidue, or difference between the parts a and b, or 5 and 3, which in this caſe is 2.

RESIDUUM *of a Charge*, in Electricity, firſt diſcovered by Mr. Gralath, in Germany, in 1746, is that part of the charge that lay on the uncoated part of a Leyden phial, which does not part with all its electricity at once; ſo that it is afterwards gradually diffuſed to the coating.

RESISTANCE, or RESISTING *Force*, in Phyſics, any power which acts in oppoſition to another, ſo as to deſtroy or diminiſh its effect.

There

There are various kinds of Reſiſtance, ariſing from the various natures and properties of the reſiſting bodies, and governed by various laws: as, the Reſiſtance of ſolids, the Reſiſtance of fluids, the Reſiſtance of the air, &c. Of each of theſe in their order, as below.

RESISTANCE *of Solids*, in Mechanics, is the force with which the quieſcent parts of ſolid bodies oppoſe the motion of others contiguous to them.

Of theſe, there are two kinds. The firſt where the reſiſting and the reſiſted parts, i. e. the moving and quieſcent bodies, are only contiguous, and do not cohere; conſtituting ſeparate bodies or maſſes. This Reſiſtance is what Leibnitz calls *Reſiſtance of the ſurface*, but which is more properly called *friction*: for the laws of which, ſee the article FRICTION.

The ſecond caſe of Reſiſtance, is where the reſiſting and reſiſted parts are not only contiguous, but cohere, being parts of the ſame continued body or maſs. This Reſiſtance was firſt conſidered by Galileo, and may properly be called *renitency*.

As to what regards the Reſiſtance of bodies when ſtruck by others in motion, ſee PERCUSSION, and COLLISION.

Theory of the Reſiſtance of the Fibres of Solid Bodies. —To conceive an idea of this Reſiſtance, or renitency of the parts, ſuppoſe a cylindrical body ſuſpended vertically by one end. Here all its parts, being heavy, tend downwards, and endeavour to ſeparate the two contiguous planes or ſurfaces where the body is the weakeſt; but all the parts of them reſiſt this ſeparation by the force with which they cohere, or are bound together. Here then are two oppoſite powers; viz, the weight of the cylinder, which tends to break it; and the force of coheſion of the parts, which reſiſts the fracture.

If now the baſe of the cylinder be increaſed, without increaſing its length; it is evident that both the Reſiſtance and the weight will be increaſed in the ſame ratio as the baſe; and hence it appears that all cylinders of the ſame matter and length, whatever their baſes be, have an equal Reſiſtance, when vertically ſuſpended.

But if the length of the cylinder be increaſed, without increaſing its baſe, its weight is increaſed, while the Reſiſtance or ſtrength continues unaltered; conſequently the lengthening has the effect of weakening it, or increaſes its tendency to break.

Hence to find the greateſt length a cylinder of any matter may have, when it juſt breaks with the addition of another given weight, we need only take any cylinder of the ſame matter, and faſten to it the leaſt weight that is juſt ſufficient to break it; and then conſider how much it muſt be lengthened, ſo that the weight of the part added, together with the given weight, may be juſt equal to that weight, and the thing is done. Thus, let l denote the firſt length of the cylinder, c its weight, g the given weight the lengthened cylinder is to bear, and w the leaſt weight that breaks the cylinder l, alſo x the length ſought;

then as $l : x :: c : \frac{cx}{l}$ = the weight of the longeſt cylinder ſought; and this, together with the given weight g, muſt be equal to c together with the weight w; hence then

$\frac{cx}{l} + g = c + w$; therefore $x = \frac{c + w - g}{c} l$ = the whole length of the cylinder ſought. If the cylinder muſt juſt break with its own weight, then is $g = 0$, and in that caſe $x = \frac{c + w}{c} l$ is the whole length that juſt breaks by its own weight. By this means Galileo found that a copper wire, and of conſequence any other cylinder of copper, might be extended to 4801 braccios or fathoms of 6 feet each.

If the cylinder be fixed by one end into a wall, with the axis horizontally; the force to break it, and its Reſiſtance to fracture, will here be both different; as both the weight to cauſe the fracture, and the Reſiſtance of the fibres to oppoſe it, are combined with the effects of the lever; for the weight to cauſe the fracture, whether of the weight of the beam alone, or combined with an additional weight hung to it, is to be ſuppoſed collected into the centre of gravity, where it is conſidered as acting by a lever equal to the diſtance of that centre beyond the face of the wall where the cylinder or other priſm is fixed; and then the product of the ſaid whole weight and diſtance, will be the momentum or force to break the priſm. Again, the Reſiſtance of the fibres may be ſuppoſed collected into the centre of the tranſverſe ſection, and all acting there at the end of a lever equal to the vertical ſemidiameter of the ſection, the loweſt point of that diameter being immoveable, and about which the whole diameter turns when the priſm breaks; and hence the product of the adheſive force of the fibres multiplied by the ſaid ſemidiameter, will be the momentum of Reſiſtance, and muſt be equal to the former momentum when the priſm juſt breaks.

Hence, to find the length a priſm will bear, fixed ſo horizontally, before it breaks, either by its own weight, or by the addition of any adventitious weight; take any length of ſuch a priſm, and load it with weights till it juſt break. Then, put

l = the length of this priſm,
c = its weight,
w = the weight that breaks it,
a = diſtance of weight w,
g = any given weight to be borne,
d = its diſtance,
x = the length required to break.

Then $l : x :: c : \frac{cx}{l}$ the weight of the priſm x, and $\frac{cx}{l} \times \frac{1}{2} x = \frac{cx^2}{2l}$ = its momentum; alſo dg = the momentum of the weight g; therefore $\frac{cx^2}{2l} + dg$ is the momentum of the priſm x and its added weight. In like manner $\frac{1}{2}cl + aw$ is that of the former or ſhort priſm and the weight that brake it; conſequently $\frac{cx^2}{2l} + dg = \frac{1}{2}cl + aw$, and $x = \sqrt{\frac{aw + \frac{1}{2}cl - dg}{c}} \times 2l$ is the length ſought, that juſt

breaks

breaks with the weight g at the diſtance d. If this weight g be nothing, then $x = \sqrt{\frac{acw + \frac{1}{2}cl}{c}} \times 2l$ is the length of the priſm that juſt breaks with its own weight.

If two priſms of the ſame matter, having their baſes and lengths in the ſame proportion, be ſuſpended horizontally; it is evident that the greater has more weight than the leſſer, both on account of its length, and of its baſe; but it has leſs Reſiſtance on account of its length, conſidered as a longer arm of a lever, and has only more Reſiſtance on account of its baſe; therefore it exceeds the leſſer in its momentum more than it does in its Reſiſtance, and conſequently it muſt break more eaſily.

Hence appears the reaſon why, in making ſmall machines and models, people are apt to be miſtaken as to the Reſiſtance and ſtrength of certain horizontal pieces, when they come to execute their deſigns in large, by obſerving the ſame proportions as in the ſmall.

When the priſm, fixed vertically, is juſt about to break, there is an equilibrium between its poſitive and relative weight; and conſequently thoſe two oppoſite powers are to each other reciprocally as the arms of the lever to which they are applied, that is, as half the diameter to half the axis of the priſm. On the other hand, the Reſiſtance of a body is always equal to the greateſt weight which it will juſt ſuſtain in a vertical poſition, that is, to its abſolute weight. Therefore, ſubſtituting the abſolute weight for the Reſiſtance, it appears, that the abſolute weight of a body, ſuſpended horizontally, is to its relative weight, as the diſtance of its centre of gravity from the fixed point or axis of motion, is to the diſtance of the centre of gravity of its baſe from the ſame.

The diſcovery of this important truth, at leaſt of an equivalent to it, and to which this is reducible, we owe to Galileo. On this ſyſtem of Reſiſtance of that author, Mariotte made an ingenious remark, which gave birth to a new ſyſtem. Galileo ſuppoſes that where the body breaks, all the fibres break at once; ſo that the body always reſiſts with its whole abſolute force, or the whole force that all its fibres have in the place where it breaks. But Mariotte, finding that all bodies, even glaſs itſelf, bend before they break, ſhews that fibres are to be conſidered as ſo many little bent ſprings, which never exert their whole force, till ſtretched to a certain point, and never break till entirely unbent. Hence thoſe neareſt the fulcrum of the lever, or loweſt point of the fracture, are ſtretched leſs than thoſe farther off, and conſequently employ a leſs part of their force, and break later.

This conſideration only takes place in the horizontal ſituation of the body: in the vertical, the fibres of the baſe all break at once; ſo that the abſolute weight of the body muſt exceed the united Reſiſtance of all its fibres; a greater weight is therefore required here than in the horizontal ſituation, that is, a greater weight is required to overcome their united Reſiſtance, than to overcome their ſeveral Reſiſtances one after another.

Varignon has improved on the ſyſtem of Mariotte, and ſhewn that to Galileo's [illegible] ration of the centre of per[illegible] ſection, where the body [illegible] equilibrium, or line at the [illegible] ſection; but in the ſecon[illegible] are continually ſtretching [illegible] the ſame ratio, as they ar[illegible] from the axis of equilibrium, and conſequently ſtill exerting a greater and greater part of their whole force.

Theſe unequal extenſions, like all other forces, muſt have ſome common centre where they are united, making equal efforts on each ſide of it; and as they are preciſely in the ſame proportion as the velocities which the ſeveral points of a rod moved circularly would have to one another, the centre of extenſion of the ſection where the body breaks, muſt be the ſame as its centre of percuſſion. Galileo's hypotheſis, where fibres ſtretch equally, and break all at once, correſponds to the caſe of a rod moving parallel to itſelf, where the centre of extenſion or percuſſion does not appear, as being confounded with the centre of gravity.

Hence it follows, that the Reſiſtance of bodies in Mariotte's ſyſtem, is to that in Galileo's, as the diſtance of the centre of percuſſion, taken on the vertical diameter of the fracture, is to the whole of that diameter. Hence alſo, the Reſiſtance being leſs than what Galileo imagined, the relative weight muſt alſo be leſs, and in the ratio juſt mentioned. So that, after conceiving the relative weight of a body, and its Reſiſtance equal to its abſolute weight, as two contrary powers applied to the two arms of a lever, in the hypotheſis of Galileo, there needs nothing to change it into that of Mariotte, but to imagine that the Reſiſtance, or the abſolute weight, is become leſs, in the ratio above mentioned, every thing elſe remaining the ſame.

One of the moſt curious, and perhaps the moſt uſeful queſtions in this reſearch, is to find what figure a body muſt have, that its Reſiſtance may be equal or proportional in every part to the force tending to break it. Now to this end, it is neceſſary, ſome part of it being conceived as cut off by a plane parallel to the fracture, that the momentum of the part retrenched be to its Reſiſtance, in the ſame ratio as the momentum of the whole is to its Reſiſtance; theſe four powers acting by arms of levers peculiar to themſelves, and are proportional in the whole, and in each part, of a ſolid of equal Reſiſtance. From this proportion, Varignon eaſily deduces two ſolids, which ſhall reſiſt equally in all their parts, or be no more liable to break in one part than in another: Galileo had found one before. That diſcovered by Varignon is in the form of a trumpet, and is to be fixed into a wall at its greater end; ſo that its magnitude or weight is always diminiſhed in proportion as its length, or the arm of the lever by which its weight acts, is increaſed. It is remarkable that, howſoever different the two ſyſtems may be, the ſolids of equal Reſiſtance are the ſame in both.

For the Reſiſtance of a ſolid ſupported at each end, as of a beam between two walls, ſee BEAM.

RESISTANCE *of Fluids*, is the force with which bodies,

bodies, moving in fluid mediums, are impeded and retarded in their motion.

A body moving in a fluid is reſiſted from two cauſes. The firſt of theſe is the coheſion of the parts of the fluid. For a body, in its motion, ſeparating the parts of a fluid, muſt overcome the force with which thoſe parts cohere. The ſecond is the inertia, or inactivity of matter, by which a certain force is required to move the particles from their places, in order to let the body paſs.

The retardation from the firſt cauſe is always the ſame in the ſame ſpace, whatever the velocity be, the body remaining the ſame; that is, the Reſiſtance is as the ſpace run through, in the ſame time: but the velocity is alſo in the ſame ratio of the ſpace run over in the ſame time: and therefore the Reſiſtance, from this cauſe, is as the velocity itſelf.

The Reſiſtance from the ſecond cauſe, when a body moves through the ſame fluid with different velocities, is as the ſquare of the velocity. For, firſt the Reſiſtance increaſes according to the number of particles or quantity of the fluid ſtruck in the ſame time; which number muſt be as the ſpace run through in that time, that is, as the velocity: but the Reſiſtance alſo increaſes in proportion to the force with which the body ſtrikes againſt every part; which force is alſo as the velocity of the body, ſo as to be double with a double velocity, and triple with a triple one, &c: therefore, on both theſe accounts, the Reſiſtance is as the velocity multiplied by the velocity, or as the ſquare of the velocity. Upon the whole therefore, on account of both cauſes, viz, the tenacity and inertia of the fluid, the body is reſiſted partly as the velocity and partly as the ſquare of the velocity.

But when the ſame body moves through different fluids with the ſame velocity, the Reſiſtance from the ſecond cauſe follows the proportion of the matter to be removed in the ſame time, which is as the denſity of the fluid.

Hence therefore, if d denote the denſity of the fluid,
v the velocity of the body,
and a and b conſtant coefficients:
then $adv^2 + bv$ will be proportional to the whole Reſiſtance to the ſame body, moving with different velocities, in the ſame direction, through fluids of different denſities, but of the ſame tenacity.

But, to take in the conſideration of different tenacities of fluids; if t denote the tenacity, or the coheſion of the parts of the fluid, then $adv^2 + btv$ will be as the ſaid whole Reſiſtance.

Indeed the quantity of Reſiſtance from the coheſion of the parts of fluids, except in glutinous ones, is very ſmall in reſpect of the other Reſiſtance; and it alſo increaſes in a much lower degree, being only as the velocity, while the other increaſes as the ſquare of the velocity, and rather more. Hence then the term btv is very ſmall in reſpect of the other term adv^2; and conſequently the Reſiſtance is nearly as this latter term; or nearly as the ſquare of the velocity. Which rule has been employed by moſt authors, and is very near the truth in ſlow motions; but in very rapid ones, it differs conſiderably from the truth, as we ſhall perceive below; not indeed from the omiſſion of the ſmall term ctv, due to the coheſion, but from the want of the full counter preſſure on the hinder part of the body, a vacuum, either perfect or partial, being left behind the body in its motion; and alſo perhaps to ſome compreſſion or accumulation of the fluid againſt the fore part of the body. Hence,

To conceive the Reſiſtance of fluids to a body moving in them, we muſt diſtinguiſh between thoſe fluids which, being greatly compreſſed by ſome incumbent weight, always cloſe up the ſpace behind the body in motion, without leaving any vacuity there; and thoſe fluids which, not being much compreſſed, do not quickly fill up the ſpace quitted by the body in motion, but leave a kind of vacuum behind it. Theſe differences, in the reſiſting fluids, will occaſion very remarkable varieties in the laws of their Reſiſtance, and are abſolutely neceſſary to be conſidered in the determination of the action of the air on ſhot and ſhells; for the air partakes of both theſe affections, according to the different velocities of the projected body.

In treating of theſe Reſiſtances too, the fluids may be conſidered either as continued or diſcontinued, that is, having their particles contiguous or elſe as ſeparated and unconnected; and alſo either as elaſtic or non-elaſtic. If a fluid were ſo conſtituted, that all the particles compoſing it were at ſome diſtance from each other, and having no action between them, then the Reſiſtance of a body moving in it would be eaſily computed, from the quantity of motion communicated to thoſe particles; for inſtance, if a cylinder moved in ſuch a fluid in the direction of its axis, it would communicate to the particles it met with, a velocity equal to its own, and in its own direction, when neither the cylinder nor the parts of the fluid are elaſtic: whence, if the velocity and diameter of the cylinder be known, and alſo the denſity of the fluid, there would thence be determined the quantity of motion communicated to the fluid, which (as action and reaction are equal) is the ſame with the quantity loſt by the cylinder, and conſequently the Reſiſtance would thus be aſcertained.

In this kind of diſcontinued fluid, the particles being detached from each other, every one of them can purſue its own motion in any direction, at leaſt for ſome time, independent of the neighbouring ones; ſo that, inſtead of a cylinder moving in the direction of its axis, if a body with a ſurface oblique to its direction be ſuppoſed to move in ſuch a fluid, the motion which the parts of the fluid will hence acquire, will not be in the direction of the reſiſted body, but perpendicular to its oblique ſurface; whence the Reſiſtance to ſuch a body will not be eſtimated from the whole motion communicated to the particles of the fluid, but from that part of it only which is in the direction of the reſiſted body. In fluids then, where the parts are thus diſcontinued from each other, the different obliquities of that ſurface which goes foremoſt, will occaſion conſiderable changes in the Reſiſtance; although the tranſverſe ſection of the ſolid ſhould in all caſes be the ſame: And Newton has particularly determined that, in a fluid thus conſtituted, the Reſiſtance of a globe is but half the Reſiſtance of a cylinder of the ſame diameter, moving, in the direction of its axis, with the ſame velocity.

But though the hypotheſis of a fluid thus conſtituted

be

be of great uſe in explaining the nature of Reſiſtances, yet we know of no ſuch fluid exiſting in nature; all the fluids with which we are converſant being ſo formed, that their particles either lie contiguous to each other, or at leaſt act on each other in the ſame manner as if they did: conſequently, in theſe fluids, no one particle that is contiguous to the reſiſted body, can be moved, without moving at the ſame time a great number of others, ſome of which will be diſtant from it; and the motion thus communicated to a maſs of the fluid, will not be in any one determined direction, but different in all the particles, according to the different poſitions in which they lie in contact with thoſe from which they receive their impulſe; whence, great numbers of the particles being diverted into oblique directions, the Reſiſtance of the moving body, which will depend on the quantity of motion communicated to the fluid in its own direction, will be different in quantity from what it would be in the foregoing ſuppoſition, and its eſtimation becomes much more complicated and operoſe.

If the fluid be compreſſed by the incumbent weight of its upper parts (as all fluids are with us, except at their very ſurface), and if the velocity of the moving body be much leſs than that with which the parts of the fluid would ruſh into a void ſpace, in conſequence of their compreſſion; it is evident, that in this caſe the ſpace left by the moving body will be inſtantaneouſly filled up by the fluid; and the parts of the fluid againſt which the foremoſt part of the body preſſes in its motion, will, inſtead of being impelled forwards in the direction of the body, in ſome meaſure circulate towards the hinder part of the body, in order to reſtore the equilibrium, which the conſtant influx of the fluid behind the body would otherwiſe deſtroy; whence the progreſſive motion of the fluid, and conſequently the Reſiſtance of the body, which depends upon it, would in this inſtance be much leſs, than in the hypotheſis where each particle is ſuppoſed to acquire, from the ſtroke of the reſiſting body, a velocity equal to that with which the body moved, and in the ſame direction. Newton has determined, that the Reſiſtance of a cylinder, moving in the direction of its axis, in ſuch a compreſſed fluid as we have here treated of, is but one-fourth part of the Reſiſtance to the ſame cylinder, if it moved with the ſame velocity in a fluid conſtituted in the manner deſcribed in the firſt hypotheſis, each fluid being ſuppoſed of the ſame denſity.

But again, it is not only in the quantity of their Reſiſtance that theſe fluids differ, but alſo in the different manner in which they act upon ſolids of different forms moving in them. In the diſcontinued fluid, firſt deſcribed, the obliquity of the foremoſt ſurface of the moving body would diminiſh the Reſiſtance; but the ſame thing does not hold true in compreſſed fluids, at leaſt not in any conſiderable degree; for the chief Reſiſtance in compreſſed fluids ariſes from the greater or leſs facility with which the fluid, impelled by the fore part of the body, can circulate towards its hinder part; and this being little, if at all, affected by the form of the moving body, whether it be cylindrical, conical, or ſpherical, it follows, that while the tranſverſe ſection of the body is the ſame, and conſequently the quantity of impelled fluid alſo, the [illegible] the body will ſcarcely affect [illegible] Reſiſtance.

And this caſe, viz. the [illegible] of a compreſſed fluid to a ſolid, moving in it [illegible] than what the parts of the [illegible] their compreſſion, has been [illegible] Newton, who has aſcertained the quantity of ſuch a Reſiſtance, according to the different magnitudes of the moving body, and the denſity of the fluid. But he expreſsly informs us that the rules he has laid down, are not generally true, but only upon a ſuppoſition that the compreſſion of the fluid be increaſed in the greater velocities of the moving body: however, ſome unſkilful writers, who have followed him, overlooking this caution, have applied his determination to bodies moving with all ſorts of velocities, without attending to the different compreſſions of the fluids they are reſiſted by; and by this means they have accounted the Reſiſtance, for inſtance, of the air to muſket and cannon ſhot, to be but about one-third part of what it is found to be by experience.

It is indeed evident that the reſiſting power of the medium muſt be increaſed, when the reſiſted body moves ſo faſt that the fluid cannot inſtantaneouſly preſs in behind it, and fill the deſerted ſpace; for when this happens, the body will be deprived of the preſſure of the fluid behind it; which in ſome meaſure balanced its Reſiſtance, or at leaſt the fore preſſure, and muſt ſupport on its fore part the whole weight of a column of the fluid, over and above the motion it gives to the parts of the ſame; and beſides, the motion in the particles driven before the body, is leſs affected in this caſe by the compreſſion of the fluid, and conſequently they are leſs deflected from the direction in which they are impelled by the reſiſted ſurface; whence it happens that this ſpecies of Reſiſtance approaches more and more to that deſcribed in the firſt hypotheſis, where each particle of the fluid being unconnected with the neighbouring ones, purſued its own motion, in its own direction, without being interrupted or deflected by their contiguity; and therefore, as the Reſiſtance of a diſcontinued fluid to a cylinder, moving in the direction of its axis, is 4 times greater than the Reſiſtance of a fluid ſufficiently compreſſed of the ſame denſity, it follows that the Reſiſtance of a fluid, when a vacuity is left behind the moving body, may be near 4 times greater than that of the ſame fluid, when no ſuch vacuity is formed; for when a void ſpace is thus left, the Reſiſtance approaches in its nature to that of a diſcontinued fluid.

This then may probably be the caſe in a cylinder moving in the ſame compreſſed fluid, according to the different degrees of its velocity; ſo that if it ſet out with a great velocity, and moves in the fluid till that velocity be much diminiſhed, the reſiſting power of the medium may be near 4 times greater in the beginning of its motion than in the end.

In a globe, the difference will not be ſo great, becauſe, on account of its oblique ſurface, its Reſiſtance in a diſcontinued medium is but about twice as much as in one properly compreſſed; for its oblique ſurface diminiſhes its Reſiſtance in one caſe, and not in the other: however, as the compreſſion of the medium,

even

even when a vacuity is left behind the moving body, may ye confine the oblique motion of the parts of the fluid, which are driven before the body, and as in an elaſtic fluid, ſuch as our air is, there will be ſome degree of condenſation in thoſe parts; it is highly probable that the Reſiſtance of a globe, moving in a compreſſed fluid with a very great velocity, may greatly exceed the proportion of the Reſiſtance to ſlow motions.

And as this increaſe of the reſiſting power of the medium will take place, when the velocity of the moving body is ſo great, that a perfect vacuum is left behind it, ſo ſome degree of augmentation will be ſenſible in velocities much ſhort of this; for even when, by the compreſſion of the fluid, the ſpace left behind the body is inſtantaneouſly filled up; yet, if the velocity with which the parts of the fluid ruſh in behind, is not much greater than that with which the body moves, the ſame reaſons that have been urged above, in the caſe of an abſolute vacuity, will hold in a leſs degree in this inſtance; and therefore it is not to be ſuppoſed that, in the increaſed Reſiſtance which has been hitherto treated of, it immediately vaniſhes when the compreſſion of the fluid is juſt ſufficient to prevent a vacuum behind the reſiſted body; but we muſt conſider it as diminiſhing only according as the velocity, with which the parts of the fluid follow the body, exceeds that with which the body moves.

Hence then it may be concluded, that if a globe ſets out in a reſiſting medium, with a velocity much exceeding that with which the particles of the medium would ruſh into a void ſpace, in conſequence of their compreſſion, ſo that a vacuum is neceſſarily left behind the globe in its motion; the Reſiſtance of this medium to the globe will be much greater, in proportion to its velocity, than what we are ſure, from Sir I. Newton, would take place in a ſlower motion. We may farther conclude, that the reſiſting power of the medium will gradually diminiſh as the velocity of the globe decreaſes, till at laſt, when it moves with velocities which bear but a ſmall proportion to that with which the particles of the medium follow it, the Reſiſtance becomes the ſame with what is aſſigned by Newton in the caſe of a compreſſed fluid.

And from this determination may be ſeen, how falſe that poſition is, which aſſerts the Reſiſtance of any medium to be always in the duplicate ratio of the velocity of the reſiſted body; for it plainly appears, by what has been ſaid, that this can only be conſidered as nearly true in ſmall variations of velocity, and can never be applied in comparing together the Reſiſtances to all velocities whatever, without incurring the moſt enormous errors. See Robins's Gunnery, chap. 2 prop. 1, and my Select Exerciſes pa. 235 &c. See alſo the articles RESISTANCE *of the Air*, PROJECTILE, and GUNNERY.

Reſiſtance and retardation are uſed indifferently for each other, as being both in the ſame proportion, and the ſame Reſiſtance always generating the ſame retardation. But with regard to different bodies, the ſame Reſiſtance frequently generates different retardations; the Reſiſtance being as the quantity of motion, and the retardation that of the celerity. For the difference and meaſure of the two, ſee RETARDATION.

The retardations from this Reſiſtance may be compared together, by comparing the Reſiſtance with the gravity or quantity of matter. It is demonſtrated that the Reſiſtance of a cylinder, which moves in the direction of its axis, is equal to the weight of a column of the fluid, whoſe baſe is equal to that of the cylinder, and its altitude equal to the height through which a body muſt fall in vacuo, by the force of gravity, to acquire the velocity of the moving body. So that, if a denote the area of the face or end of the cylinder, or other priſm, v its velocity, and n the ſpecific gravity of the fluid; then, the altitude due to the velocity v being $\frac{v^2}{4g}$, the whole Reſiſtance, or motive force m, will be $a \times n \times \frac{v^2}{4g} = \frac{anv^2}{4g}$; the quantity g being $= 16\frac{1}{12}$ feet, or the ſpace a body falls, in vacuo, in the firſt ſecond of time. And the Reſiſtance to a globe of the ſame diameter would be the half of this.—Let a ball, for inſtance, of 3 inches diameter, be moved in water with a celerity of 16 feet per ſecond of time: now from experiments on pendulums, and on falling bodies, it has been found, that this is the celerity which a body acquires in falling from the height of 4 feet; therefore the weight of a cylinder of water of 3 inches diameter, and 4 feet high, that is a weight of about 12 lb 4 oz, is equal to the Reſiſtance of the cylinder; and conſequently the half of it, or 6 lb 2 oz is that of the ball. Or, the formula

$$\frac{anv^2}{4g} \text{ gives } \frac{\cdot 7854 \times 9 \times 1000 \times 16 \times 16}{144 \times 4 \times 16} = 196 \text{ oz},$$

or 12 lb 4 oz, for the Reſiſtance of the cylinder, or 6 lb 2 oz for that of the ball, the ſame as before.

Let now the Reſiſtance, ſo diſcovered, be divided by the weight of the body, and the quotient will ſhew the ratio of the retardation to the force of gravity. So if the ſaid ball, of 3 inches diameter, be of caſt iron, it will weigh nearly 61 ounces, or $3\frac{13}{16}$ lb; and the Reſiſtance being 6 lb 2 oz, or 98 ounces; therefore, the Reſiſtance being to the gravity as 98 to 61, the retardation, or retarding force, will be $\frac{98}{61}$ or $1\frac{37}{61}$, the force of gravity being 1. Or thus; becauſe a the area of a great circle of the ball, is $= p d^2$, where d is the diameter, and $p = \cdot 7854$, therefore the Reſiſtance to the ball is $m = \frac{pnd^2v^2}{8g}$; and becauſe its ſolid content is $w = \frac{1}{6}pd^3$, and its weight $\frac{1}{6}Npd^3$, where N denotes its ſpecific gravity; therefore, dividing the Reſiſtance or motive force m by the weight w, gives $\frac{m}{w} = \frac{3nv^2}{16Ndg} = f$ the retardation, or retarding force, that of gravity being 1; which is therefore as the ſquare of the velocity directly, and as the diameter inverſely; and this is the reaſon why a large ball overcomes the Reſiſtance better than a ſmall one, of the ſame denſity. See my Select Exerciſes, pa. 225 &c.

RESISTANCE *of Fluid Mediums to the Motion of Falling Bodies*.—A body freely deſcending in a fluid, is accelerated by the relative gravity of the body, (that is, the difference between its own abſolute gravity and that of a like bulk of the fluid), which continually acts upon it, yet not equably, as in a vacuum: the Reſiſtance of the fluid occaſions a retardation, or diminution

of acceleration, which diminution increaſes with the velocity of the body. Hence it happens, that there is a certain velocity, which is the greateſt that a body can acquire by falling; for if its velocity be ſuch, that the Reſiſtance ariſing from it becomes equal to the relative weight of the body, its motion can be no longer accelerated; for the motion here continually generated by the relative gravity, will be deſtroyed by the Reſiſtance, or the force of Reſiſtance is equal to the relative gravity, and the body forced to go on equably: for after the velocity is arrived at ſuch a degree, that the reſiſting force is equal to the weight that urges it, it will increaſe no longer, and the globe muſt afterward continue to deſcend with that velocity uniformly. A body continually comes nearer and nearer to this greateſt celerity, but can never attain accurately to it. Now, N and n being the ſpecific gravities of the globe and fluid, $N - n$ will be the relative gravity of the globe in the fluid, and therefore $w = \frac{1}{6}pd^3(N - n)$ is the weight by which it is urged downward; alſo $m = \frac{pnd^2v^2}{8g}$ is the Reſiſtance, as above; therefore theſe two muſt be equal when the velocity can be no farther increaſed, or $m = w$, that is $\frac{pnd^2v^2}{8g} = \frac{1}{6}pd^3(N - n)$, or $nv^2 = \frac{4}{3}dg(N - n)$; and hence $v = \sqrt{\frac{4}{3}dg \times \frac{N-n}{n}}$ is the ſaid uniform or greateſt velocity to which the body may attain; which is evidently the greater in the ſubduplicate proportion of v the diameter of the ball. But v is always $= \sqrt{4gfs}$, the velocity generated by any accelerative force f in deſcribing the ſpace s; which being compared with the former, it gives $s = \frac{1}{3}d$, when f is $= \frac{N-n}{n}$; that is, the greateſt velocity is that which is generated by the accelerating force $\frac{N-n}{n}$ in paſſing over the ſpace $\frac{1}{3}d$ or $\frac{4}{3}$ of the diameter of the ball, or it is equal to the velocity generated by gravity in deſcribing the ſpace $\frac{N-n}{n} \times \frac{4}{3}d$. For ex. if the ball be of lead, which is about $11\frac{1}{4}$ times the denſity of water; then $N = 11\frac{1}{4}$, $n = 1$, $N - n = \frac{N-n}{n} = 10\frac{1}{4} = \frac{41}{4}$, and $\frac{N-n}{n} \times \frac{4}{3}d = \frac{41}{3}d = 13\frac{2}{3}d$; that is, the uniform or greateſt velocity of a ball of lead, deſcending in water, is equal to that which a heavy body acquired by falling in vacuo through a ſpace equal to $13\frac{2}{3}$ of the diameter of the ball, which velocity is $v = 2\sqrt{\frac{1}{3}dg \times \frac{N-n}{n}} = 2\sqrt{13\frac{2}{3}dg} = 8\sqrt{13\frac{2}{3}d}$ nearly, or 8 times the root of the ſame ſpace.

Hence it appears, how ſoon ſmall bodies come to their greateſt or uniform velocity in deſcending in a fluid, as water, and how very ſmall that velocity is: which explains the reaſon of the ſlow precipitation of mud, and ſmall particles, in water, as alſo why, in precipitations, the larger and groſs particles [illegible] ſooneſt, and the loweſt.

Farther, where $N = n$, or the denſity of the [illegible] is equal to that of the body, then $N - n = 0$, conſequently the velocity and diſtance [illegible] nothing, and the body will juſt float in any part of the fluid.

Moreover, when the body is lighter than the fluid, then N is leſs than n, and $N - n$ becomes a negative quantity, or the force and motion tend the contrary way, that is, the ball will aſcend up towards the top of the fluid by a motive force which is as $n - N$. In this caſe then, the body aſcending by the action of the fluid, is moved exactly by the ſame laws as a heavier body falling in the fluid. Wherever the body is placed, it is ſuſtained by the fluid, and carried up with a force equal to the difference of the weight of a quantity of the fluid of the ſame bulk as the body, from the weight of the body; there is therefore a force which continually acts equably upon the body; by which not only the action of gravity of the body is counteracted, ſo as that it is not to be conſidered in this caſe; but the body is alſo carried upwards by a motion equably accelerated, in the ſame manner as a body heavier than a fluid deſcends by its relative gravity: but the equability of acceleration is deſtroyed in the ſame manner by the Reſiſtance, in the aſcent of a body lighter than the fluid, as it is deſtroyed in the deſcent of a body that is heavier.

For the circumſtances of the correſpondent velocity, ſpace, and time, &c, of a body moving in a fluid in which it is projected with a given velocity, or deſcending by its own weight, &c, ſee my Select Exercifes, prop. 29, 30, 31, and 32, pag. 221 &c.

Resistance *of the Air*, in Pneumatics, is the force with which the motion of bodies, particularly of projectiles, is retarded by the oppoſition of the air or atmoſphere. See Gunnery, Projectiles, &c.

The air being a fluid, the general laws of the Reſiſtance of fluids obtain in it; ſubject only to ſome variations and irregularities from the different degrees of denſity in the different ſtations or regions of the atmoſphere.

The Reſiſtance of the air is chiefly of uſe in military projectiles, in order to allow for the differences cauſed in their flight and range by it. Before the time of Mr. Robins, it was thought that this Reſiſtance to the motion of ſuch heavy bodies as iron balls and ſhells, was too inconſiderable to be regarded, and that the rules and concluſions derived from the common parabolic theory, were ſufficiently exact for the common practice of gunnery. But that gentleman ſhewed, in his New Principles of Gunnery, that, ſo far from being inconſiderable, it is in reality enormouſly great, and by no means to be rejected without incurring the groſſeſt errors; ſo much ſo, that balls or ſhells which range, at the moſt, in the air, to the diſtance of two or three miles, would in a vacuum range to 20 or 30 miles, or more. To determine the quantity of this Reſiſtance, in the caſe of different velocities, Mr. Robins diſcharged muſket balls, with various degrees of known velocity, againſt his balliſtic pendulums, placed at ſeveral different diſtances, and ſo diſcovered by experiment the quantity of velocity loſt, when paſſing through thoſe diſtances

or ſpaces of air, with the ſeveral known degrees of celerity. For having thus known, the velocity loſt or deſtroyed, in paſſing over a certain ſpace, in a certain time, (which time is very nearly equal to the quotient of the ſpace divided by the medium velocity between the greateſt and leaſt, or between the velocity at the mouth of the gun and that at the pendulum); that is, knowing the velocity v, the ſpace s, and time t, the reſiſting force is thence eaſily known, being equal to $\frac{vb}{2gt}$ or $\frac{vVb}{2gs}$, where b denotes the weight of the ball, and V the medium velocity above-mentioned. The balls employed upon this occaſion by Mr. Robins, were leaden ones, of $\frac{1}{71}$ of a pound weight, and $\frac{3}{4}$ of an inch diameter; and to the medium velocity of

1600 feet the Reſiſtance was 11 lb,
1065 feet - - - - - - - it was $2\frac{4}{5}$;

but by the theory of Newton, before laid down, the former of theſe ſhould be only $4\frac{1}{2}$ lb, and the latter 2 lb: ſo that, in the former caſe the real Reſiſtance is more than double of that by the theory, being increaſed as 9 to 22; and in the leſſer velocity the increaſe is from 2 to $2\frac{4}{5}$, or as 5 to 7 only.

Mr. Robins alſo invented another machine, having a whirling or circular motion, by which he meaſured the Reſiſtances to larger bodies, though with much ſmaller velocities: it is deſcribed, and a figure of it given, near the end of the 1ſt vol. of his works.

That this reſiſting power of the air to ſwift motions is very ſenſibly increaſed beyond what Newton's theory for ſlow motions makes it, ſeems hence to be evident. By other experiments it appears that the Reſiſtance is very ſenſibly increaſed, even in the velocity of 400 feet. However, this increaſed power of Reſiſtance diminiſhes as the velocity of the reſiſted body diminiſhes, till at length, when the motion is ſufficiently abated, the actual Reſiſtance coincides with that ſuppoſed in the theory nearly. For theſe varying Reſiſtances Mr. Robins has given a rule, extending to 1670 feet velocity.

Mr. Euler has ſhewn, that the common doctrine of Reſiſtance anſwers pretty well when the motion is not very ſwift, but in ſwift motions it gives the Reſiſtance leſs than it ought to be, on two accounts. 1. Becauſe in quick motions, the air does not fill up the ſpace behind the body faſt enough to preſs on the hinder parts, to counterbalance the weight of the atmoſphere on the fore part. 2. The denſity of the air before the ball being increaſed by the quick motion, will preſs more ſtrongly on the fore part, and ſo will reſiſt more than lighter air in its natural ſtate. He has ſhewn that Mr. Robins has reſtrained his rule to velocities not exceeding 1670 feet per ſecond; whereas had he extended it to greater velocities, the reſult muſt have been erroneous; and he gives another formula himſelf, and deduces concluſions differing from thoſe of Mr. Robins. See his Principles of Gunnery inveſtigated, tranſlated by Brown in 1777, pa. 224 &c.

Mr. Robins having proved that, in very great changes of velocity, the Reſiſtance does not accurately follow the duplicate ratio of the velocity, lays down two poſitions, which he thought might be of ſome ſervice in the practice of artillery, till a more complete and accurate theory of Reſiſtance, and the changes of its augmentation, may be obtained. The firſt of theſe is, that till the velocity of the projectile ſurpaſs 1100 or 1200 feet in a ſecond, the Reſiſtance may be eſteemed to be in the duplicate ratio of the velocity: and the ſecond is, that when the velocity exceeds 1100 or 1200 feet, then the abſolute quantity of the Reſiſtance will be near 3 times as great as it ſhould be by a compariſon with the ſmaller velocities. Upon theſe principles he proceeds in approximating to the actual ranges of pieces with ſmall angles of elevation, viz, ſuch as do not exceed 8° or 10°, which he ſets down in a table, compared with their correſponding potential ranges. See his Mathematical Tracts, vol. 1 pa. 179 &c. But we ſhall ſee preſently that theſe poſitions are both without foundation; that there is no ſuch thing as a ſudden or abrupt change in the law of Reſiſtance, from the ſquare of the velocity to one that gives a quantity three times as much; but that the change is ſlow and gradual, continually from the ſmalleſt to the higheſt velocities; and that the increaſed real Reſiſtance no where riſes higher than to about double of that which Newton's theory gives it.

Mr. Glenie, in his Hiſtory of Gunnery, 1776, pa. 49, obſerves, in conſequence of ſome experiments with a rifled piece, properly fitted for experimental purpoſes, that the Reſiſtance of the air to a velocity ſomewhat leſs than that mentioned in the firſt of the above propoſitions, is conſiderably greater than in the duplicate ratio of the velocity; and that, to a celerity ſomewhat greater than that ſtated in the ſecond, the Reſiſtance is conſiderably leſs than that which is treble the Reſiſtance in the ſaid ratio. Some of Robins's own experiments ſeem neceſſarily to make it ſo; ſince, to a velocity no quicker than 400 feet in a ſecond, he found the Reſiſtance to be ſomewhat greater than in that ratio. But the true value of the ratio, and other circumſtances of this Reſiſtance, will more fully appear from what follows.

The ſubject of the Reſiſtance of the air, as begun by Robins, has been proſecuted by myſelf, to a very great extent and variety, both with the whirling machine, and with cannon balls of all ſizes, from 1 lb to 6 lb weight, as well as with figures of many other different ſhapes, both on the fore part and hind part of them, and with planes ſet at all varieties of angles of inclination to the path or motion of the ſame; from all which I have obtained the real Reſiſtance to bodies for all velocities, from 1 up to 2000 feet per ſecond; together with the law of the Reſiſtance to the ſame body for all different velocities, and for different ſizes with the ſame velocity, and alſo for all angles of inclination; a full account of which would make a book of itſelf, and muſt be reſerved for ſome other occaſion. In the mean time, ſome general tables of concluſions may be taken as below.

In this Table are contained the Reſiſtances to ſeveral forms of bodies, when moved with ſeveral degrees of velocity, from 3 feet per ſecond to 20. The names of the bodies are at the tops of the columns, as alſo which end went foremoſt through the air; the different velocities are in the firſt column, and the Reſiſtances on the ſame line, in their ſeveral columns, in avoirdupois ounces and decimal parts. So on the firſt line are contained the Reſiſtances when the bodies move with a velocity of 3 feet in a ſecond, viz, in the 2d column for the ſmall hemiſphere, of 4¾ inches diameter, its Reſiſtance ·028 oz when the flat ſide went foremoſt; in the 3d and 4th columns the Reſiſtances to a larger hemiſphere, firſt with the flat ſide, and next the round ſide foremoſt, the diameter of this, as well as all the following figures being 6⅛ inches, and therefore the area of the great circle = 32 ſq. inches, or ⅔ of a ſq. foot; then in the 5th and 6th columns are the Reſiſtances to a cone, firſt its vertex and then its baſe foremoſt, the altitude of the cone being 6⅛ inches, the ſame as the diameter of its baſe; in the 7th column the Reſiſtance to the end of the cylinder, and in the 8th that againſt the whole globe or ſphere. All the numbers ſhew the real weights which are equal to the Reſiſtances; and at the bottoms of the columns are placed proportional numbers, which ſhew the mean proportions of the Reſiſtances of all the figures to one another, with any velocity. Laſtly, in the 9th column are placed the exponents of the power of the velocity which the Reſiſtances in the 8th column bear to each other, viz, which that of the 10 feet velocity bears to each of the following ones, the medium of all of them being as the 2·04 power of the velocity, that is, very little above the ſquare or ſecond power of the velocity, ſo far as the velocities in this Table extend.

From this Table the following inferences are eaſily deduced.

1. That the Reſiſtance is nearly in the ſame proportion as the ſurfaces; a ſmall increaſe only taking place in the greater ſurfaces, and for the greater velocities. Thus, by comparing together the numbers in the 2d and 3d columns, for the baſes of the two hemiſpheres, the areas of which baſes are in the proportion of 17¼ to 32, or 5 to 9 very nearly, it appears that the numbers in thoſe two columns, expreſſing the Reſiſtances, are nearly as 1 to 2 or 5 to 10, as far as the velocity of 12 feet; but after that, the Reſiſtances on the greater ſurface increaſe gradually more and more above that proportion.

2. The Reſiſtance to the ſame ſurface, with different velocities, is, in theſe ſlow motions, nearly as the ſquare of the velocity; but gradually increaſes more and more above that proportion as the velocity increaſes. This is manifeſt from all the columns; and the index of the power of the velocity is ſet down in the 9th column, for the Reſiſtances in the 8th, the medium being 2·04; by which it appears that the Reſiſtance to the ſame body is, in theſe ſlow motions, as the 2·04 power of the velocity, or nearly as the ſquare of it.

3. The round ends, and ſharp ends, of ſolids, ſuffer leſs Reſiſtance than the flat or plane ends, of the ſame diameter; but the ſharper end has not always the leſs Reſiſtance. Thus, the cylinder, and the flat ends of the hemiſphere and cone, have more Reſiſtance, than the round or ſharp ends of the ſame; but the round ſide of the hemiſphere has leſs Reſiſtance than the ſharper end of the cone.

4. The Reſiſtance on the baſe of the hemiſphere, is to that on the round, or whole ſphere, as 2¼ to 1, inſtead of 2 to 1, as the theory gives that relation. Alſo the experimented Reſiſtance, on each of theſe, is nearly ¼ more than the quantity aſſigned by the theory.

5. The Reſiſtance on the baſe of the cone, is to that on the vertex, nearly as $2\frac{3}{10}$ to 1; and in the ſame ratio is radius to the ſine of the angle of inclination of the ſide of the cone to its path or axis. So that, in this inſtance, the Reſiſtance is directly as the ſine of the angle of incidence, the tranſverſe ſection being the ſame.

6. When the hinder parts of bodies are of different forms, the Reſiſtances are different, though the fore-parts be exactly alike and equal; owing probably to the different preſſures of the air on the hinder parts. Thus, the Reſiſtance to the fore part of the cylinder, is leſs than on the equal flat ſurface of the cone, or of the hemiſphere; becauſe the hinder part of the cylinder is more preſſed or puſhed, by the following air than thoſe of the other two figures; alſo, for the ſame reaſon, the baſe of the hemiſphere ſuffers a leſs Reſiſtance than that of the cone, and the round ſide of the hemiſphere leſs than the whole ſphere.

2000	1569	786	2·00	2·098

In the firſt column of this Table are contained the ſeveral velocities, gradually from 0 up to the great velocity of 2000 feet per ſecond, with which a ball or globe moved. In the 2d column are the experimented Reſiſtances, in averdupois ounces. In the 3d column are the correſpondent Reſiſtances, as computed by the foregoing theory. In the 4th column are the ratios of theſe two Reſiſtances, or the quotients of the former divided by the latter. And in the 5th or laſt, the indexes of the power of the velocity which is proportional to the experimented Reſiſtance; which are found by comparing the Reſiſtance of 20 feet velocity with each of the following ones.

From the 2d, 3d and 4th columns it appears, that at the beginning of the motion, the experimented Reſiſtance is nearly equal to that computed by theory; but that, as the velocity increaſes, the experimented Reſiſtance gradually exceeds the other more and more, till at the velocity of 1300 feet the former becomes juſt double the latter; after which the difference increaſes a little farther, till at the velocity of 1600 or 1700, where that exceſs is the greateſt, and is rather leſs than $2\frac{1}{10}$; after this, the difference decreaſes gradually as the velocity increaſes, and at the velocity of 2000, the former Reſiſtance again becomes juſt double the latter.

From the laſt column it appears that, near the beginning, or in ſlow motions, the Reſiſtances are nearly as the ſquare of the velocities; but that the ratio gradually increaſes, with ſome ſmall variation, till at the velocity of 1500 or 1600 feet it becomes as the $2\frac{1}{9}$ power of the velocity nearly, which is its higheſt aſcent; and after that it gradually decreaſes again, as the velocity goes higher. And ſimilar concluſions have alſo been derived from experiments with larger balls or globes.

And hence we perceive that Mr. Robins's poſitions are erroneous on two accounts, viz., both in ſtating that the Reſiſtance changes ſuddenly, or all at once, from being as the ſquare of the velocity, ſo as then to become as ſome higher and conſtant power; and alſo when he ſtates the Reſiſtance as riſing to the height of 3 times that which is given by the theory: ſince the ratio of the Reſiſtance both increaſes gradually from the beginning, and yet never aſcends higher than $2\frac{9}{100}$ of the theory.

In the 2d column of this Table are contained the actual experimented Reſiſtances, in ounces, to a plane of 32 ſquare inches, or $\frac{2}{9}$ of a ſquare foot, moved through the air with a velocity of exactly 12 feet per ſecond, when the plane was ſet ſo as to make, with the direction of its path, the correſponding angles in the firſt column.

And from theſe I have deduced this formula, or theorem, viz, $\cdot 84 s^{1\cdot 842c}$, which brings out very nearly the ſame numbers, and is a general theorem for every angle, for the ſame plane of $\frac{2}{9}$ of a foot, and moved with the ſame velocity of 12 feet in a ſecond of time; where s is the ſine, and c the coſine of the angles of inclination in the firſt column.

If

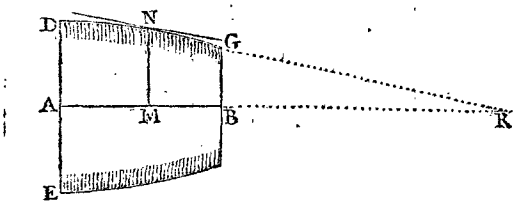
If a theorem be desired for any other velocity v, and any other plane whose area is a, it will be this: $\frac{1}{3\frac{1}{8}} a v^{3} s^{1\cdot 842c}$, or more nearly $\frac{1}{2\frac{1}{2}} a v^{2\cdot 04} s^{1\cdot 842c}$; which denotes the Resistance nearly to any plane surface whose area is a, moved through the air with the velocity v, in a direction making with that plane an angle, whose sine is s, and cosine c.

If it be water or any other fluid, different from air, this formula will be varied in proportion to the density of it.

By this theorem were computed the numbers in the 3d column; which it is evident agree very nearly with the experiment Resistances in the 2d column, excepting in two or three of the small numbers near the beginning, which are of the least consequence. In all other cases, the theorem gives the true Resistance very nearly. In the 4th or last column are entered the sines of the angles of the first column, to the radius ·84, in order to compare them with the Resistances in the other columns. From whence it appears, that those Resistances bear no sort of analogy to the sines of the angles, nor yet to the squares of the sines, nor to any other power of them whatever. In the beginning of the columns, the sines much exceed the Resistances all the way till the angle be between 55 and 60 degrees; after which the sines are less than the Resistances all the way to the end, or till the angle become of 90 degrees.

Mr. James Bernoulli gave some theorems for the Resistances of different figures, in the Acta Erud. Lipsi. for June 1693, pa. 252 &c. But as these are deduced from theory only, which we find to be so different from experiment, they cannot be of much use. Messieurs Euler, D'Alembert, Gravesande, and Simpson, have also written pretty largely on the theory of Resistances, besides what had been done by Newton.

Solid of Least Resistance. Sir Isaac Newton, from his general theory of Resistance, deduces the figure of a solid which shall have the least Resistance of the same base, height and content.



The figure is this. Suppose DNG to be a curve of such a nature, that if from any point N the ordinate NM be drawn perpendicular to the axis AB; and from a given point G there be drawn GR parallel to a tangent at N, and meeting the axis produced in R; then if MN be to GR, as GR^3 to $4BR \times BG^2$, a solid described by the revolution of this figure about its axis AB, moving in a medium from A towards B, is less resisted than any other circular solid of the same base, &c.

This theorem, which Newton gave without a demonstration, has been demonstrated by several mathematicians, as Facio, Bernoulli, Hospital, &c. See Maclaurin's Flux. sect. 606 and 607; also Horsley's edit. of Newton, vol. 2, pag. 390. See also Act. Erud. 1699, pa. 514; and Mem. de l'Acad. &c; also Robins's View of Newton's method for comparing the Resistance of Solids, 8vo, 1734; and Simpson's Fluxions, art. 413; or my Principles of Bridges, prop. 11 and 12.

M. Bouguer has resolved this problem in a very general manner; not in supposing the solid to be formed by a revolution, of any figure whatever. The problem, as enunciated and resolved by M. Bouguer, is this: Any base being given, to find what kind of solid must be formed upon it, so that the impulse upon it may be the least possible. Properly however it ought to be the retardive force, or the impulse divided by the weight or mass of matter in the body, that ought to be the minimum.

RESOLUTION, in Physics, the reduction of a body into its original or natural state, by a dissolution or separation of its aggregated parts. Thus, snow and ice are said to be resolved into water; water resolves in vapour by heat; and vapour is again resolved into water by cold; also any compound is resolved into its ingredients, &c.

Some of the modern philosophers, particularly Boyle, Mariotte, Boerhaave, &c, maintain, that the natural state of water is to be congealed, or in ice; in as much as a certain degree of heat, which is a foreign and violent agent, is required to make it fluid: so that near the pole, where this foreign agent is wanting, it constantly retains its fixed or icy state.

Resolution, or Solution, in Mathematics, is an orderly enumeration of several things to be done, to obtain what is required in a problem.

Wolfius makes a problem to consist of three parts: The *proposition* (or what is properly called the *problem*), the *Resolution*, and the *demonstration*.

As soon as a problem is demonstrated, it is converted into a theorem; of which the Resolution is the hypothesis; and the proposition the thesis.

For the process of a mathematical Resolution, see the following article.

Resolution in *Algebra*, or *Algebraical* Resolution, is of two kinds; the one practised in numerical problems, the other in geometrical ones.

In Resolving a Numerical Problem Algebraically, the method is this. First, the given quantities are distinguished from those that are sought; and the former denoted by the initial letters of the alphabet, but the latter by the last letters.—2. Then as many equations are formed as there are unknown quantities. If that cannot be done from the proposition or data, the problem is indeterminate; and certain arbitrary assumptions must be made, to supply the defect, and which can satisfy the question. When the equations are not contained in the problem itself, they are to be found by particular theorems concerning equations, ratios, proportions, &c.—Since, in an equation, the known and unknown quantities are mixed together, they must be separated in such a manner, that the unknown one remain alone on one side, and the known ones on the other. This reduction, or separation, is made by addition, subtraction, multiplication, division, extraction

of

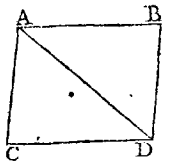
of roots, and raiſing of powers; reſolving every kind of combination of the quantities, by their counter or reverſe ones, and performing the ſame operation on all the quantities or terms, on both ſides of the equation, that the equality may ſtill be preſerved.

To Reſolve a Geometrical Problem Algebraically.—The ſame ſort of operations are to be performed, as in the former article; beſides ſeveral others, that depend upon the nature of the diagram, and geometrical properties. As 1ſt, the thing required or propoſed, muſt be ſuppoſed done, the diagram being drawn or conſtructed in all its parts, both known and unknown. 2. We muſt then examine the geometrical relations which the lines of the figure have among themſelves, without regarding whether they are known or unknown, to find what equations ariſe from thoſe relations, for finding the unknown quantities. 3. It is often neceſſary to form ſimilar triangles and rectangles, ſometimes by producing of lines, or drawing parallels and perpendiculars, and forming equal angles, &c; till equations can be formed, from them, including both the known and unknown quantities.

If we do not thus arrive at proper equations, the thing is to be tried in ſome other way. And ſometimes the thing itſelf, that is required, is not to be ſought directly, but ſome other thing, bearing certain relations to it, by means of which it may be found.

The final equation being at laſt arrived at, the geometrical conſtruction is to be deduced from it, which is performed in various ways according to the different kinds of equations.

RESOLUTION *of Forces*, or *of Motion*, is the reſolving or dividing of any one force or motion, into ſeveral others, in other directions, but which, taken together, ſhall have the ſame effect as the ſingle one; and it is the reverſe of the compoſition of forces or motions. See theſe articles.



Any ſingle direct force AD, may be reſolved into two oblique forces, whoſe quantities and directions are AB, AC, having the ſame effect, by deſcribing any parallelogram ABDC, whoſe diagonal is AD. And each of theſe may, in like manner, be reſolved into two others; and ſo on, as far as we pleaſe. And all theſe new forces, or motions, ſo found, when acting together, will produce exactly the ſame effect as the ſingle original one. See alſo COLLISION, PERCUSSION, MOTION, &c.

REST, in Phyſics, the continuance of a body in the ſame place; or its continual application or contiguity to the ſame parts of the ambient and contiguous bodies.—See SPACE.

Reſt is either *abſolute* or *relative*, as place is.

Some define Reſt to be the ſtate of a thing without motion; and hence again Reſt becomes either abſolute or relative, as motion is.

Newton defines true or abſolute Reſt to be the continuance of a body in the ſame part of abſolute and immoveable ſpace; and relative Reſt to be the continuance of a body in the ſame part of relative ſpace.

Thus, in a ſhip under ſail, relative Reſt is the continuance of a body in the ſame part of the ſhip. But true or abſolute Reſt is its continuance in the ſame part of univerſal ſpace in which the ſhip itſelf is contained.

Hence, if the earth be really and abſolutely at Reſt, the body relatively at Reſt in the ſhip will really and abſolutely move, and that with the ſame velocity as the ſhip itſelf. But if the earth do likewiſe move, there will then ariſe a real and abſolute motion of the body at Reſt; partly from the real motion of the earth in abſolute ſpace, and partly from the relative motion of the ſhip on the ſea. Laſtly, if the body be likewiſe relatively moved in the ſhip, its real motion will ariſe partly from the real motion of the earth in immoveable ſpace, and partly from the relative motion of the ſhip on the ſea, and of the body in the ſhip.

It is an axiom in philoſophy, that matter is indifferent as to Reſt or motion. Hence Newton lays it down, as a law of nature, that every body perſeveres in its ſtate, either of Reſt or uniform motion, except ſo far as it is diſturbed by external cauſes.

The Carteſians aſſert, that firmneſs, hardneſs, or ſolidity of bodies, conſiſts in this, that their parts are at Reſt with regard to each other; and this Reſt they eſtabliſh as the great nexus, or principle of coheſion, by which the parts are connected together. On the other hand, they make fluidity to conſiſt in a perpetual motion of the parts, &c. But the Newtonian philoſophy furniſhes us with much better ſolutions.

Maupertuis aſſerts, that when bodies are in equilibrio, and any ſmall motion is impreſſed on them, the quantity of action reſulting will be the leaſt poſſible. This he calls the law of *Reſt*; and from this law he deduces the fundamental propoſition of ſtatics. See Berlin Mem. tom. 2, pa. 294. And from the ſame principle too he deduces the laws of percuſſion.

RESTITUTION, in Phyſics, the returning of elaſtic bodies, forcibly bent, to their natural ſtate; by ſome called the *motion of Reſtitution*.

RETARDATION, in Phyſics, the act of retarding, that is, of delaying the motion or progreſs of a body, or of diminiſhing its velocity.

The Retardation of moving bodies ariſes from two great cauſes, the reſiſtance of the medium, and the force of gravity.

The RETARDATION *from the Reſiſtance* is often confounded with the reſiſtance itſelf; becauſe, with reſpect to the ſame moving body, they are in the ſame proportion.

But with reſpect to different bodies, the ſame reſiſtance often generates different Retardations. For if bodies of equal bulk, but different denſities, be moved through the ſame fluid with equal velocity, the fluid will act equally on each; ſo that they will have equal reſiſtances, but different Retardations; and the Retardations will be to each other, as the velocities which might be generated by the ſame forces in the bodies propoſed; that is, they are inverſely as the quantities of matter in the bodies, or inverſely as the denſities.

Suppoſe then bodies of equal denſity, but of unequal bulk, to move equally faſt through the ſame fluid; then their reſiſtances increaſe according to their ſuperficies, that is as the ſquares of their diameters; but the quantities of matter are increaſed according to their maſs or magnitude, that is as the cubes of their diameters: the reſiſtances are the quantities of motion; the

the Retardations are the celerities arising from them; and dividing the quantities of motion by the quantities of matter, we shall have the celerities; therefore the Retardations are directly as the squares of the diameters, and inversely as the cubes of the diameters, that is inversely as the diameters themselves.

If the bodies be of equal magnitude and denſity, and moved through different fluids, with equal celerity, their Retardations are as the denſities of the fluids. And when equal bodies are carried through the ſame fluid with different velocities, the Retardations are as the ſquares of the velocities.

So that, if s denote the ſuperficies of a body, w its weight, d its diameter, v the velocity, and n the denſity of the fluid medium, and N that of the body; then, in ſimilar bodies, the reſiſtance is as nsv^2 or as nd^2v^2, and the Retardation, or retarding force,

$$\text{as } \frac{nsv^2}{w}, \text{ or as } \frac{nd^2v^2}{Nd^3} = \frac{nv^2}{Nd}.$$

The RETARDATION *from Gravity* is peculiar to bodies projected upwards. A body thrown upwards is retarded after the ſame manner as a falling body is accelerated; only in the one caſe the force of gravity conſpires with the motion acquired, and in the other it acts contrary to it.

As the force of gravity is uniform, the Retardation from that cauſe will be equal in equal times. Hence, as it is the ſame force which generates motion in the falling body, and diminiſhes it in the riſing one, a body riſes till it loſe all its motion; which it does in the ſame time in which a body falling would have acquired a velocity equal to that with which the body was thrown up.

Alſo, a body thrown up, will riſe to the ſame height from which, in falling, it would acquire the ſame velocity with which it was thrown up: therefore the heights which bodies can riſe to, when thrown up with different velocities, are to each other as the ſquares of the velocities.

Hence, the Retardations of motions may be compared together. For they are, firſt, as the ſquares of the velocities; 2dly, as the denſities of the fluids through which the bodies are moved; 3dly, inverſely as the diameters of thoſe bodies; 4thly, inverſely as the denſities of the bodies themſelves; as expreſſed by the theorem above, viz, $\frac{nv^2}{Nd}$.

The Laws of RETARDATION, are the very ſame as thoſe for acceleration; motion and velocity being deſtroyed in the one caſe, in the very ſame quantity and proportion as it is generated in the other.

RETICULA, or RETICULE, in Aſtronomy, a contrivance for meaſuring very nicely the quantity of eclipſes, &c.

This inſtrument, introduced ſome years ſince by the Paris Acad. of Sciences, is a little frame, conſiſting of 13 fine ſilken threads, parallel to, and equidiſtant from each other; placed in the focus of object-glaſſes of teleſcopes; that is, in the place where the image of the luminary is painted in its full extent. Conſequently the diameter of the ſun or moon is thus ſeen divided into 12 equal parts or digits: ſo that, to find the quantity of the eclipſe, there is nothing to do but to number the parts that are dark, or that are luminous.

As a ſquare Reticule is only proper for the diameter of the luminary, not for the circumference of it, it is ſometimes made circular, by drawing 6 concentric equidiſtant circles; which repreſents the phaſes of the eclipſe perfectly.

But it is evident that the Reticule, whether ſquare or circular, ought to be perfectly equal to the diameter or circumference of the ſun or ſtar, ſuch as it appears in the focus of the glaſs; otherwiſe the diviſions cannot be juſt. Now this is no eaſy matter to effect, becauſe the apparent diameter of the ſun and moon differs in each eclipſe; nay that of the moon differs from itſelf in the progreſs of the ſame eclipſe.—Another imperfection in the Reticule is, that its magnitude is determined by that of the image in the focus; and of conſequence it will only fit one certain magnitude.

But M. de la Hire has found a remedy for all theſe inconveniences, and contrived that the ſame Reticule ſhall ſerve for all teleſcopes, and all magnitudes of the luminary in the ſame eclipſe. The principle upon which his invention is founded, is that two object-glaſſes applied againſt each other, having a common focus, and theſe forming an image of a certain magnitude, this image will increaſe in proportion as the diſtance between the two glaſſes is increaſed, as far as to a certain limit. If therefore a Reticule be taken of ſuch a magnitude, as juſt to comprehend the greateſt diameter the ſun or moon can ever have in the common focus of two object-glaſſes applied to each other, there needs nothing but to remove them from each other, as the ſtar comes to have a leſs diameter, to have the image ſtill exactly comprehended in the ſame Reticule.

Farther, as the ſilken threads are ſubject to ſwerve from the parallelism, &c, by the different temperature of the air, another improvement is, to make the Reticule of a thin looking-glaſs, by drawing lines or circles upon it with the fine point of a diamond. See MICROMETER.

RETIRED FLANK, in Fortification. See FLANK.

RETROCESSION *of Curves*, &c. See RETROGRADATION.

RETROCESSION *of the Equinox*. See PRECESSION.

RETROGRADATION, or RETROGRESSION, in Aſtronomy, is an apparent motion of the planets, by which they ſeem to go backwards in the ecliptic, and to move contrary to the order or ſucceſſion of the ſigns.

When a planet moves in conſequentia, or according to the order of the ſigns, as from Aries to Taurus, from Taurus to Gemini, &c, which is from weſt to eaſt, it is ſaid to be *direct*.—When it appears for ſome days in the ſame place, or point of the heavens, it is ſaid to be *ſtationary*.—And when it goes in antecedentia, or backwards to the following ſigns, or contrary to the order of the ſigns, which is from eaſt to weſt, it is ſaid to be *retrograde*. All theſe different affections or circumſtances, may happen in all the planets, except the ſun and moon, which are ſeen to go direct only. But the times of the ſuperior and inferior planets being retrograde are different; the former appearing ſo about their oppoſition, and the latter about their conjunction.

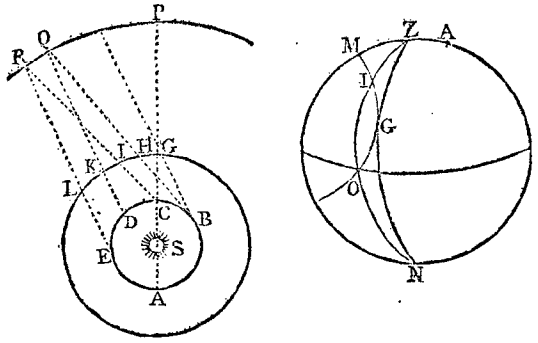
tion. The intervals of time alſo between two Retrogradations of the ſeveral planets, are very unequal:

In Saturn	it is	1 year	13 days,
In Jupiter	- -	1 - -	43
In Mars	- -	2 - -	50
In Venus	- -	1 - -	220
In Mercury	-	0 - -	115

Again, Saturn continues retrograde 140 days, Jupiter 120, Mars 73, Venus 42, and Mercury 22; or nearly ſo; for the ſeveral Retrogradations of the ſame planet are not conſtantly equal.

Theſe various circumſtances however in the motions of the planets are not real, but only apparent; as the inequalities ariſe from the motion and poſition of the earth, from whence they are viewed; for when they are conſidered as ſeen from the ſun, their motions appear always uniform and regular. Theſe inequalities are thus explained:

Let S denote the ſun; and ABCD &c the path or orbit of the earth, moving from weſt to eaſt, and in that order; alſo GK &c the orbit of a ſuperior planet, as Saturn for inſtance, moving the ſame way, or in the direction GKLG, but with a much leſs celerity than



the earth's motion. Now when the earth is at the point A of its orbit, let Saturn be at G, in conjunction with the ſun, when it will be ſeen at P in the zodiac, or among the ſtars; and when the earth has moved from A to B, let Saturn have moved from G to H in its orbit, when it will be ſeen in the line BHQ, and will appear to have moved from P to Q in the zodiac; alſo when the earth has got to C, let Saturn be arrived at I, but found at R in the zodiac, where being ſeen in the line CIR, it appears ſtationary, or without motion in the zodiac at R. But after this, Saturn will appear for ſome time in Retrogradation, viz, moving backwards, or the contrary way: for when the earth has moved to D, Saturn will have got to K, and, being ſeen in the line DKQ, will appear to have moved retrograde in the zodiac from R to Q; about which place the planet, ceaſing to recede any farther, again becomes ſtationary, and afterward proceeds forward again; for while the earth moves from D to E, and Saturn from K to L, this latter, being now ſeen in the line ELR, appears to have moved forward in the zodiac from Q to R. And ſo on; the ſuperior planets always becoming retrograde a little before they are in oppoſition to the ſun, and continuing ſo till ſome time after the oppoſition: the retrograde motion being ſwifteſt when the planet is in the very oppoſition itſelf; and the direct motion ſwifteſt when in the conjunction. The arch RQ which the planet deſcribes while thus retrograde, is called the arch of Retrogradation. Theſe arches are unequal in all the planets, being greateſt in the moſt diſtant, and gradually leſs in the nearer ones.

In like manner may be ſhewn the circumſtances of the Retrogradations of the inferior planets; by which it will appear, they become ſtationary a little before their inferior conjunction, and go retrograde till a little time after it; moving the quickeſt retrograde juſt at that conjunction, and the quickeſt direct juſt at the ſuperior or further conjunction.

Retrogradation *of the Nodes of the Moon*, is a motion of the line of the nodes of her orbit, by which it continually ſhifts its ſituation from eaſt to weſt, contrary to the order of the ſigns, completing its retrograde circulation in the period of about 19 years: after which time, either of the nodes, having receded from any point of the ecliptic, returns to the ſame again.—Newton has demonſtrated, in his Principia, that the Retrogradation of the moon's nodes is cauſed by the action of the ſun, which continually drawing this planet from her orbit, deflects this orbit from a plane, and cauſes its interſection with the ecliptic continually to vary; and his determinations on this point have been confirmed by obſervation.

Retrogradation *of the Sun*, a motion by which in ſome ſituations, in the torrid zone, he ſeems to move retrograde or backwards.

When the ſun is in the torrid zone, and has his declination AM greater than the latitude of the place AZ, but either northern or ſouthern as that is (laſt fig. above), the ſun will appear to go retrograde, or backwards, both before and after noon. For draw the vertical circle ZGN to be a tangent to the ſun's diurnal circle MGO in G, and another ZON through the ſun's riſing, at O: then it is evident, that all the intermediate vertical circles cut the ſun's diurnal circle twice: firſt in the arc GO, and the ſecond time in the arc GI. So that, as the ſun aſcends through the arc GO, he continually arrives at farther and farther verticals. But as he continues his aſcent through the arc GI, he returns to his former verticals; and therefore is ſeen retrograde for ſome time before noon. And in like manner it may be ſhewn that he does the ſame thing for ſome time after noon. Hence, as the ſhadow always tends oppoſite to the ſun, the ſhadow will be retrograde twice every day in all places of the torrid zone, where the ſun's declination exceeds the latitude.

But the ſame thing can never happen without the tropics, in a natural way.

Retrogradation, or Retrogreſſion, in the Higher Geometry, is the ſame with what is otherwiſe called *contrary flexion* or *flexure*. See Flexure, and Inflexion.

RETROGRADE, denotes backward, or contrary to the forward or natural direction. See RETROGRADATION.

RETROGRESSION, or RETROCESSION. The ſame with RETROGRADATION.

RETURNING *Stroke*, in Electricity, is an expreſſion uſed by lord Mahon (now earl Stanhope) to denote the effect produced by the return of the electric fire into a body from which, in certain circumſtances, it has been expelled.

To underſtand properly the meaning of theſe terms, it muſt be premiſed that, according to the noble author's experiments, an inſulated ſmooth body, immerged within the electrical atmoſphere, but beyond the ſtriking diſtance of another body, charged poſitively, is at the ſame time in a ſtate of threefold electricity. The end next to the charged body acquires negative electricity, the farther end is poſitively electrified; while a certain part of the body, ſomewhere between its two extremes, is in a natural, unelectrified, or neutral ſtate; ſo that the two contrary electricities balance each other. It may farther be added, that if the body be not inſulated, but have a communication with the earth the whole of it will be in a negative ſtate. Suppoſe then a braſs ball, which may be called A, to be conſtantly placed at the ſtriking diſtance of a prime conductor; ſo that the conductor, the inſtant when it becomes fully charged, explodes into it. Let another large or ſecond conductor be ſuſpended, in a perfectly inſulated ſtate, farther from the prime conductor than the ſtriking diſtance, but within its electrical atmoſphere: let a perſon ſtanding on an inſulated ſtool touch this ſecond conductor very lightly with a finger of his right hand; while, with a finger of his left hand, he communicates with the earth, by touching very lightly a ſecond braſs ball fixed at the top of a metallic ſtand, on the floor, which may be called B. Now while the prime conductor is receiving its electricity, ſparks paſs (at leaſt if the diſtance between the two conductors is not too great) from the ſecond conductor to the right hand of the inſulated perſon; while ſimilar and ſimultaneous ſparks paſs out from the finger of his left hand into the ſecond metallic ball B, communicating with the earth. At length however the prime conductor, having acquired its full charge, ſuddenly ſtrikes into the ball A, of the firſt metallic ſtand, placed for that purpoſe at the ſtriking diſtance. The exploſion being made, and the prime conductor ſuddenly robbed of its elaſtic atmoſphere, its preſſure or action on the ſecond conductor, and on the inſulated perſon, as ſuddenly ceaſes; and the latter inſtantly feels a ſmart Returning Stroke, though he has no direct or viſible communication (except by the floor) with either of the two bodies, and is placed at the diſtance of 5 or 6 feet from both of them. This Returning Stroke is evidently occaſioned by the ſudden re-entrance of the electric fire naturally belonging to his body and to the ſecond conductor, which had before been expelled from them by the action of the charged prime conductor upon them; and which returns to its former place in the inſtant when that action or elaſtic preſſure ceaſes. When the ſecond conductor and the inſulated perſon are placed in the denſeſt part of the electrical atmoſphere of the prime conductor, or juſt beyond the ſtriking diſtance, the effects are ſtill more conſiderable; the Returning Stroke being extremely ſevere and pungent, and appearing conſiderably ſharper than even the main ſtroke itſelf, received directly from the prime conductor. Lord Mahon obſerves, that perſons and animals may be deſtroyed, and particular parts of buildings may be much damaged, by an electrical Returning Stroke, occaſioned even by ſome very diſtant exploſion from a thunder cloud; poſſibly at the diſtance of a mile or more. It is certainly not difficult to conceive that a charged extenſive thunder cloud muſt be productive of effects ſimilar to thoſe produced by the prime conductor; but perhaps the effects are not ſo great, nor the danger ſo terrible, as it ſeems have been apprehended. If the quantity of electric fluid naturally contained, for example, in the body of a man, were immenſe or indefinite, then the eſtimate between the effects producible by a cloud, and thoſe cauſed by a prime conductor, might be admitted; but ſurely no electrical cloud can expel from a body more than the natural quantity of electricity which this contains. On the ſudden removal therefore of the preſſure by which this natural quantity had been expelled, in conſequence of the exploſion of the cloud into the earth, no more (at the utmoſt) than his whole natural ſtock of electricity can re-enter his body, provided it be ſo ſituated, that the returning fire of other bodies muſt neceſſarily paſs through his body. But perhaps we have no reaſon to ſuppoſe that this quantity is ſo great, as that its ſudden re-entrance into his body ſhould deſtroy or injure him.

Allowing therefore the exiſtence of the Returning Stroke, as ſufficiently aſcertained, and well illuſtrated, in a variety of circumſtances, by the author's experiments, the magnitude and danger of it do not ſeem to be ſo alarming as he apprehends. See Lord Mahon's Principles of Electricity, &c. 4to. 1779, pa. 76, 113, and 131. Alſo Monthly Review, vol. 62, pa. 436.

REVERSION *of Series*, in Algebra, is the finding the value of the root, or unknown quantity, whoſe powers enter the terms of an infinite ſeries, by means of another infinite ſeries in which it is not contained. As, in the infinite ſeries $z = ax + bx^2 + cx^3 + dx^4$ &c; then if there be found $x = Az + Bz^2 + Cz^3$ &c, that ſeries is inverted, or its root x is found in an infinite ſeries of other terms.

This was one of Newton's improvements in analyſis, the firſt ſpecimen of which was given in his Analyſis per Æquationes Numero Terminorum Infinitas; and it is of great uſe in reſolving many problems in various parts of the mathematics.

The moſt uſual and general way of Reverſion, is to aſſume a ſeries, of a proper form, for the value of the required unknown quantity; then ſubſtitute the powers of this value, inſtead of thoſe of that quantity into the given ſeries; laſtly compare the reſulting terms with the ſaid given ſeries, and the values of the aſſumed coefficients will thus be obtained. So, to revert the ſeries $z = ax + bx^2 + cx^3$, &c, or to find the value of x in terms of z; aſſume it thus, $x = Az + Bz^2 + Cz^3$ &c.

&c; then by involving this ſeries, for the ſeveral powers of x, and multiplying the correſponding powers by a, b, c, &c, there reſults

$$z = aAz + aBz^2 + aCz^3 + aDz^4, \text{ &c.}$$
$$+ bA^2z^2 + 2bABz^3 + 2bACz^4$$
$$+ bB^2z^4$$
$$+ cA^3z^3 + 3cA^2Bz^4$$
$$+ dA^4z^4$$

Then by comparing the correſponding terms of this laſt ſeries, or making their coefficients equal, there are obtained theſe equations, viz,

$aA = 1$, and $aB + bA^2 = 0$, and $aC + 2bAB + cA^3 = 0$, &c, which give theſe values of the aſſumed coefficients, viz,

$$A = \frac{1}{a}; \quad B = -\frac{bA^2}{a} = -\frac{b}{a^3};$$

$$C = -\frac{2bAB + cA^3}{a} = \frac{2bb - ac}{a^5};$$

$$D = -\frac{2bAC + bB^2 + 3cA^2B + dA^4}{a}$$

$$= -\frac{5abc - 5b^3 - a^2d}{a^7}; \text{ &c.}$$

and conſequently

$$x = \frac{1}{a}z - \frac{b}{a^3}z^2 + \frac{2bb - ac}{a^5}z^3 - \frac{5abc - 5b^3 - a^2d}{a^7}z^4$$

&c; which is therefore a general formula or theorem for every ſeries of the ſame kind, as to the powers of the quantity x. Thus, for

Ex. Suppoſe it were required to revert the ſeries $z = x - x^2 + x^3 - x^4$, &c.

Here $a = 1$, $b = -1$, $c = 1$, $d = -1$, &c; which values of theſe letters being ſubſtituted in the theorem, there reſults $x = z + z^2 + z^3 + z^4$, &c, which is that ſeries reverted, or the value of x in it.

In the ſame way it will be found that the theorem for reverting the ſeries $z = ax + bx^3 + cx^5 + dx^7$ &c, is

$$x = \frac{1}{a}z - \frac{b}{a^4}z^3 + \frac{3bb - ac}{a^7}z^5 - \frac{a^2d + 12b^3 - 8abc}{a^{10}},$$

&c.

And if $z = ax^m + bx^{m+n} + cx^{m+2n}$ + &c, then is

$$x = y^{\frac{1}{m}} - \frac{b}{ma}y^{\frac{1+n}{m}} + \frac{(1 + 2n + m)\,bb - 2mac}{2mma^2}$$
$$\times y^{\frac{1+2n}{m}} \text{ &c. where } y \text{ is } = \frac{z}{a}.$$

Various methods of Reverſion may be ſeen as given by De Moivre in the Philoſ. Tranſ. number 240; or Maclaurin's Algebra pa. 263; or Stuart's Explanation of Newton's Analyſis, &c. pa. 455; or Coulſon's Comment on Newton's Flux. pa. 219; or Horſley's ed. of Newton's works vol. 1, pa. 291; or Simpſon's Flux. vol. 2, pa. 302; or moſt authors on Algebra.

REVETEMENT, in Fortification, a ſtrong wall built on the outſide of the rampart and parapet, to ſupport the earth, and prevent its rolling into the ditch.

REVOLUTION, in Geometry, the motion of rotation of a line about a fixed point or centre, or of any figure about a fixed axis, or upon any line or ſurface. Thus, the Revolution of a given line about a fixed centre, generates a circle; and that of a right-angled triangle about one ſide, as an axis, generates a cone; and that of a ſemicircle about its diameter, generates a ſphere or globe, &c.

REVOLUTION, in Aſtronomy, is the period of a ſtar, planet, or comet, &c; or its courſe from any point of its orbit, till it return to the ſame again.

The planets have a twofold Revolution. The one about their own axis, uſually called their *diurnal rotation*, which conſtitutes their day. The other about the ſun, called their *annual Revolution*, or *period*, conſtituting their year.

REYNEAU (CHARLES-RENE), commonly called Father Reyneau, a noted French mathematician, was born at Briſſac in the province of Anjou, in the year 1656. At 20 years of age he entered himſelf among the Oratorians, a kind of religious order, in which the members lived in community without making any vows, and applied themſelves chiefly to the education of youth. He was ſoon after ſent, by his ſuperiors, to teach philoſophy at Pezenas, and then at Toulon. This requiring ſome acquaintance with geometry, he contracted a great affection for this ſcience, which he cultivated and improved to a great extent; in conſequence he was called to Angers in 1683, to fill the mathematical chair; and the Academy of Angers elected him a member in 1694.

In this occupation Father Reyneau, not content with making himſelf maſter of every thing worth knowing, which the modern analyſis, ſo fruitful in ſublime ſpeculations and ingenious diſcoveries, had already produced, undertook to reduce into one body, for the uſe of his ſcholars, the principal theories ſcattered here and there in Newton, Deſcartes, Leibnitz, Bernoulli, the Leipſic Acts, the Memoirs of the Paris Academy, and in other works; treaſures which by being ſo widely diſperſed, proved much leſs uſeful than they otherwiſe might have been. The fruit of this undertaking, was his *Analyſe Demontrée*, or Analyſis Demonſtrated, which he publiſhed in 2 volumes 4to, 1708.

Father Reyneau called this uſeful work, Analyſis Demonſtrated, becauſe he demonſtrates in it ſeveral methods which had not been demonſtrated by the authors of them, or at leaſt not with ſufficient perſpicuity and exactneſs; for it often happens that, in matters of this kind, a perſon is clear in a thing, without being able to demonſtrate it. Some perſons too have been ſo miſtakingly fond of glory as to make a ſecret of their demonſtrations, in order to perplex thoſe, whom it would become them much better to inſtruct. This book of Reyneau's was ſo well approved, that it ſoon became a maxim, at leaſt in France, that to follow him was the beſt, if not the only way, to make any extra-

ordinary progreſs in the mathematics. This was conſidering him as the firſt maſter, as the Euclid of the ſublime geometry.

Reyneau, after thus giving leſſons to thoſe who underſtood ſomething of geometry, thought proper to draw up ſome for ſuch as were utterly unacquainted with that ſcience. This was in ſome meaſure a condeſcenſion in him, but his paſſion to be uſeful made it eaſy and agreeable. In 1714 he publiſhed a volume in 4to on calculation, under the title of *Science du Calcul des Grandeurs*, of which the then Cenſor Royal, a moſt intelligent and impartial judge, ſays, in his approbation of it, that "though ſeveral books had already appeared upon the ſame ſubject, ſuch a treatiſe as that before him was ſtill wanting, as in it every thing was handled in a manner ſufficiently extenſive, and at the ſame time with all poſſible exactneſs and perſpicuity." In fact, though moſt branches of the mathematics had been well treated of before that period, there were yet no good elements, even of practical geometry. Thoſe who knew no more than what preciſely ſuch a book ought to contain, knew too little to complete a good one; and thoſe who knew more, thought themſelves probably above the taſk; whereas Reyneau poſſeſſed at once all the learning and modeſty neceſſary to undertake and execute ſuch a work.

As ſoon as the Royal Academy of Sciences at Paris, in conſequence of a regulation made in the year 1716, opened its doors to other learned men, under the title of *Free Aſſociates*, Father Reyneau was admitted of the number. The works however which we have already mentioned, beſides a ſmall piece upon *Logic*, are the only ones he ever publiſhed, or probably ever compoſed, except moſt of the materials for a ſecond volume of his *Science du Calcul*, which he left behind him in manuſcript. The laſt years of his life were attended with too much ſickneſs to admit of any extraordinary application. He died in 1728, at 72 years of age, not more regretted on account of his great learning, than of his many virtues, which all conſpired in an eminent degree to make that learning agreeable to thoſe about him, and uſeful to the world. The firſt men in France deemed it an honour and a happineſs to count him among their friends. Of this number were the chancellor of that kingdom, and Father Mallebranche, of whom Reyneau was a zealous and faithful diſciple.

RHABDOLOGY, or Rabdology, in Arithmetic, a name given by Napier to a method of performing ſome of the more difficult operations of numbers by means of certain ſquare little rods. Upon theſe are inſcribed the ſimple numbers; then by ſhifting them according to certain rules, thoſe operations are performed by ſimply adding or ſubtracting of the numbers as they ſtand upon the rods. See Napier's Rabdologia, printed in 1617. See alſo the article Napier's *Bones*.

RHEO-STATICS, is uſed by ſome for the ſtatics, or the ſcience of the equilibrium of fluids.

RHETICUS (George Joachim), a noted German aſtronomer and mathematician, who was the colleague of Reinhold in the univerſity of Wittemberg, being joint profeſſors of mathematics there together. He was born at Feldkirk in Tyrol the 15th of February 1514. After imbibing the elements of the mathematics at Tiguri with Oſwald Mycone, he went to Wittemberg, where he diligently cultivated that ſcience. Here he was made maſter of philoſophy in 1535, and profeſſor in 1537. He quitted this ſituation however two years after, and went to Fruenburg to put him under the aſſiſtance of the celebrated Copernicus, being induced to this ſtep by his zeal for aſtronomical purſuits, and the great fame which Copernicus had then acquired. Rheticus aſſiſted this aſtronomer for ſome years, and conſtantly exhorted him to perfect his work, *De Revolutionibus*, which was publiſhed after the death of Copernicus, viz. in 1543, folio, at Norimberg, together with an illuſtration of the ſame in a narration, dedicated to Schoner. Here too, to render aſtronomical calculations more accurate, he began his very elaborate canon of ſines, tangents and ſecants, to 15 places of figures, and to every 10 ſeconds of the quadrant, a deſign which he did not live quite to complete. The canon of ſines however to that radius, for every 10 ſeconds, and for every ſingle ſecond in the firſt and laſt degree of the quadrant, computed by him, was publiſhed in folio at Francfort 1613 by Pitiſcus, who himſelf added a few of the firſt ſines computed to 22 places of figures. But the larger work, or canon of ſines, tangents and ſecants, to every 10 ſeconds, was perfected and publiſhed after his death, viz, in 1596, by his diſciple Valentine Otho, mathematician to the Electoral Prince Palatine; a particular account and analyſis of which work may be ſeen in the Hiſtorical Introduction to my Logarithms, pa. 9.

After the death of Copernicus, Rheticus returned to Wittemberg, viz, in 1541 or 1542, and was again admitted to his office of profeſſor of mathematics. The ſame year, by the recommendation of Melancthon, he went to Norimberg, where he found certain manuſcripts of Werner and Regiomontanus. He afterwards taught mathematics at Leipſic. From Saxony he departed a ſecond time, for what reaſon is not known, and went to Poland; and from thence to Caſſovia in Hungary, where he died December the 4th, 1576, near 63 years of age.

His *Narratio de Libris Revolutionum Copernici*, was firſt publiſhed at Gedunum in 4to, 1540; and afterwards added to the editions of Copernicus's work. He alſo compoſed and publiſhed *Ephemerides*, according to the doctrine of Copernicus, till the year 1551.

Rheticus alſo projected other works, and partly executed them, though they were never publiſhed, of various kinds, aſtronomical, aſtrological, geographical, chemical, &c; as they are more particularly mentioned in his letter to Peter Ramus in the year 1568, which Adrian Romanus inſerted in the preface to the firſt part of his Idea of Mathematics.

RHOMB Solid, conſiſts of two equal and right cones joined together at their baſes.

RHOMBOID, or Rhomboides, in Geometry, a quadrilateral figure, whoſe oppoſite ſides and angles are equal; but which is neither equilateral nor equiangular.

RHOMBUS, is an oblique equilateral parallelogram;

or

or a quadrilateral figure, whose sides are equal and parallel, but the four angles not all equal, two of the opposite ones being obtuse, and the other two opposite ones acute.

The two diagonals of a Rhombus intersect at right angles; but not of a rhomboides.

As to the area of the Rhombus or rhomboides, it is found, like that of all other parallelograms, by multiplying the length or base by the perpendicular breadth.

Rhombus-*Solid*. See Rhomb-*Solid*.

RHUMB, Romb, or Rum, in Navigation, a vertical circle of any given place; or the intersection of a part of such a circle with the horizon. Rhumbs therefore coincide with points of the world, or of the horizon. And hence mariners distinguish the Rhumbs by the same names as the points and winds. But we may observe, that the Rhumbs are denominated from the points of the compass in a different manner from the winds: thus, at sea, the north-east wind is that which blows from the north-east point of the horizon towards the ship in which we are; but we are said to sail upon the north-east Rhumb, when we go towards the north-east.

They usually reckon 32 Rhumbs, which are represented by the 32 lines in the rose or card of the compass.

Aubin defines a Rhumb to be a line on the terrestrial globe, or sea-compass, or sea-chart, representing one of the 32 winds which serve to conduct a vessel. So that the Rhumb a vessel pursues is conceived as its route, or course.

Rhumbs are divided and subdivided like points of the compass. Thus, the whole Rhumb answers to the cardinal point. The half Rhumb to a collateral point, or makes an angle of 45 degrees with the former. And the quarter Rhumb makes an angle of 22° 30′ with it. Also the half-quarter Rhumb makes an angle of 11° 15′ with the same.

For a table of the Rhumbs, or points, and their distances from the meridian, see Wind.

Rhumb-Line, *Loxodromia*, in Navigation, is a line prolonged from any point of the compass in a nautical chart, except the four cardinal points: or it is the line which a ship, keeping in the same collateral point, or rhumb, describes throughout its whole course.

The chief property of the Rhumb-line, or loxodromia, and that from which some authors define it, is, that it cuts all the meridians in the same angle.

This angle is called the *angle of the Rhumb*, or the *loxodromic* angle. And the angle which the Rhumb-line makes with any parallel to the equator, is called the *complement of the Rhumb*.

An idea of the origin and properties of the Rhumb-line, the great foundation of Navigation, may be conceived thus: a vessel beginning its course, the wind by which it is driven makes a certain angle with the meridian of the place; and as we shall suppose that the vessel runs exactly in the direction of the wind, it makes the same angle with the meridian which the wind makes. Supposing then the wind to continue the same, as each point or instant of the progress may be esteemed the beginning, the vessel always makes the same angle with the meridian of the place where it is each moment, or in each point of its course which the wind makes.

Now a wind, for example, that is north-east, and which consequently makes an angle of 45 degrees with the meridian, is equally north-east wherever it blows, and makes the same angle of 45 degrees with all the meridians it meets. And therefore a vessel, driven by the same wind, always makes the same angle with all the meridians it meets with on the surface of the earth.

If the vessel sail north or south, it describes the great circle of a meridian. If it runs east or west, it cuts all the meridians at right angles, and describes either the circle of the equator, or else a circle parallel to it.

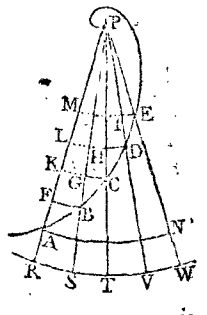
But if the vessel sails between the two, it does not then describe a circle; since a circle, drawn obliquely to a meridian, would cut all the meridians at unequal angles, which the vessel cannot do. It describes therefore another curve, the essential property of which is, that it cuts all the meridians in the same angle, and it is called the *loxodromy*, or *loxodromic curve*, or *Rhumb-line*.

This curve, on the globe, is a kind of spiral, tending continually nearer and nearer to the pole, and making an infinite number of circumvolutions about it, but without ever arriving exactly at it. But the spiral Rhumbs on the globe become proportional spirals in the stereographic projection on the plane of the equator.

The length of a part of this Rhumb-line, or spiral, then, is the distance run by the ship while she keeps in the same course. But as such a spiral line would prove very perplexing in the calculation, it was necessary to have the ship's way in a right line; which right line however must have the essential properties of the curve line, viz, to cut all the meridians at right angles. The method of effecting which, see under the article Chart.

The arc of the Rhumb-line is not the shortest distance between any two places through which it passes; for the shortest distance, on the surface of the globe, is an arc of the great circle passing through those places; so that it would be a shorter course to sail on the arc of this great circle: but then the ship cannot be kept in the great circle, because the angle it makes with the meridians is continually varying, more or less.

Let P be the pole, RW the equator, ABCDEP a spiral Rhumb, divided into an indefinite number of equal parts at the points B, C, D, &c, through which are drawn the meridians, PS, PT, PV, &c, and the parallels FB, KC, LD, &c, also draw the parallel AN. Then, as a ship sails along the Rhumb-line towards the pole, or in the direction ABCD &c, from A to E, the distance sailed AE



is

is made up of all the ſmall equal parts of the Rhumb AB + BC + CD + DE; and

the ſum of all the ſmall differences of latitude AF + BG + CH + DI make up the whole difference of latitude AM or EN; and

the ſum of all the ſmall parallels FB + GC + HD + IE is what is called the departure in plane ſailing; and ME is the meridional diſtance, or diſtance between the firſt and laſt meridians, meaſured on the laſt parallel; alſo RW is the difference of longitude, meaſured on the equator. So that theſe laſt three are all different, viz. the departure, the meridional diſtance, and the difference of longitude.

If the ſhip ſail towards the equator, from E to A; the departure, difference of latitude, and difference of longitude, will be all three the ſame as before; but the meridional diſtance will now be AN, inſtead of ME; the one of theſe AN being greater than the departure FB + GC + HD + IE, and the other ME is leſs than the ſame; and indeed that departure is nearly a mean proportional between the two meridional diſtances ME, AN. Other properties are as below.

1. All the ſmall elementary triangles ABF, BCG, CDH, &c, are mutually ſimilar and equal in all their parts. For all the angles at A, B, C, D, &c are equal, being the angles which the Rhumb makes with the meridians, or the angles of the courſe; alſo all the angles F, G, H, I, are equal, being right angles; therefore the third angles are equal, and the triangles all ſimilar. Alſo the hypotenuſes AB, BC, CD, &c, are all equal by the hypotheſis; and conſequently the triangles are both ſimilar and equal.

2. As radius : diſtance run AE
:: ſine of courſe ∠A : departure FB + GC &c,
:: coſin. of courſe ∠A : dif. of lat. AM.

For in any one ABF of the equal elementary triangles, which may be conſidered as ſmall right-angled plane triangles, it is, as rad. or ſin. ∠F : ſin. courſe A :: AB : FB :: (by compoſition) the ſum of all the diſtances AB + BC + CD &c : the ſum of all the departures FB + GC + HD &c.

And, in like manner, as radius : coſ. courſe A :: AB : AF :: AB + BC &c : AF + BG &c.

Hence, of theſe four things, the courſe, the difference of latitude, the departure, and the diſtance run, having any two given, the other two are found by the proportions above in this article.

By means of the departure, the length of the Rhumb, or diſtance run, may be connected with the longitude and latitude, by the following two theorems.

3. As radius : half the ſum of the coſines of both the latitudes, of A and E :: dif. of long. RW : departure.

Becauſe RS : FB :: radius : ſine of PA or coſ. RA,
and VW : IE :: radius : ſine of PE or coſ. EW.

4. As radius : coſ. middle latitude :: dif. of longitude : departure.—Becauſe coſine of middle latitude is nearly equal to half the ſum of the coſines of the two extreme latitudes.

RICCIOLI (Joannes Baptista), a learned Italian aſtronomer, philoſopher, and mathematician, was born in 1598, at Ferrara, a city in Italy, in the dominions of the Pope. At 16 years of age he was admitted into the ſociety of the Jeſuits. He was endowed with uncommon talents, which he cultivated with extraordinary application; ſo that the progreſs he made in every branch of literature and ſcience was ſurpriſing. He was firſt appointed to teach rhetoric, poetry, philoſophy, and ſcholaſtic divinity, in the Jeſuits colleges at Parma and Bologna; yet applied himſelf in the mean time to making obſervations in geography, chronology, and aſtronomy. This was his natural bent, and at length he obtained leave from his ſuperiors to quit all other employment, that he might devote himſelf entirely to thoſe ſciences.

He projected a large work, to be divided into three parts, and to contain as it were a complete ſyſtem of philoſophical, mathematical, and aſtronomical knowledge. The firſt of theſe parts, which regards aſtronomy, came out at Bologna in 1651, 2 vols. folio, with this title, *J. B. Riccioli Almageſtum Novum, Aſtronomiam veterem novamque complectens, obſervationibus aliorum et propriis, noviſque theorematibus, problematibus ac tabulis promotam.* Riccioli imitated Ptolomy in this work, by collecting and digeſting into proper order, with obſervations, every thing ancient and modern, which related to his ſubject; ſo that Gaſſendus very juſtly called his work, "Promptuarium et theſaurum ingentem Aſtronomiæ."

In the firſt volume of this work, he treats of the ſphere of the world, of the ſun and moon, with their eclipſes; of the fixed ſtars, of the planets, of the comets and new ſtars, of the ſeveral mundane ſyſtems, and ſix ſections of general problems ſerving to aſtronomy, &c. —In the ſecond volume, he treats of trigonometry, or the doctrine of plane and ſpherical triangles; propoſes to give a treatiſe of aſtronomical inſtruments, and the optical part of aſtronomy (which part was never publiſhed); treats of geography, hydrography, with an epitome of chronology.—The third, comprehends obſervations of the ſun, moon, eclipſes, fixed ſtars and planets, with precepts and tables of the primary and ſecondary motions, and other aſtronomical tables.

Riccioli printed alſo, two other works, in folio, at Bologna, viz,

2. *Aſtronomia Reformata*, 1665: the deſign of which was, that of conſidering the various hypotheſes of ſeveral aſtronomers, and the difficulty thence ariſing of concluding any thing certain, by comparing together all the beſt obſervations, and examining what is moſt certain in them, thence to reform the principles of aſtronomy.

3. *Chronologia Reformata*, 1669.

Riccioli died in 1671, at 73 years of age.

RICOCHET Firing, in the Military Art, is a method of firing with ſmall charges, and pieces elevated but in a ſmall degree, as from 3 to 6 degrees. The word ſignifies duck-and-drake, or rebounding, becauſe the ball or ſhot, thus diſcharged, goes bounding and rolling along, and killing or deſtroying every thing in its way, like the bounding of a flat ſtone along the ſurface of water when thrown almoſt horizontally.

RIDEAU,

RIDEAU, in Fortification, a ſmall elevation of earth, extending itſelf lengthways on a plain; ſerving to cover a camp, or give an advantage to a poſt.

RIDEAU is ſometimes alſo uſed for a trench, the earth of which is thrown up on its ſide, to ſerve as a parapet for covering the men.

RIFLE GUNS, in the Military Art, are thoſe whoſe barrels, inſtead of being ſmooth on the inſide, are grooved with a number of ſpiral channels, making each about a turn and a half in the length of the barrel. Theſe carry their balls both farther and truer than the common pieces. For the nature and qualities of them, ſee Robins's Tracts, vol. 1 pa. 328 &c.

RIGEL, in Aſtronomy. See REGEL.

RIGHT, in Geometry, ſomething that lies evenly or equally, without inclining or bending one way or another. Thus, a Right-line is that whoſe ſmall parts all tend the ſame way. In this ſenſe, Right means the ſame as ſtraight, as oppoſed to curved or crooked.

RIGHT-*Angle*, that which one line makes with another upon which it ſtands ſo as to incline neither to one ſide nor the other. And in this ſenſe the word Right ſtands oppoſed to oblique.

RIGHT-*angled*, is ſaid of a figure when its ſides are at Right angles or perpendicular to each other.—This ſometimes holds in all the angles of the figure, as in ſquares and rectangles; ſometimes only in part, as in right-angled triangles.

RIGHT *Cone*, or *Cylinder*, or priſm, or pyramid, one whoſe axis is at right-angles to the baſe.

RIGHT-*lined Angle*, one formed by Right lines.

RIGHT *Sine*, one that ſtands at Right-angles to the diameter; as oppoſed to verſed ſine.

RIGHT *Sphere*, is that where the equator cuts the horizon at Right angles; or that which has the poles in the horizon, and the equinoctial in the zenith.

Such is the poſition of the ſphere with regard to thoſe who live at the equator, or under the equinoctial. The conſequences of which are; that they have no latitude, nor elevation of the pole; they ſee both poles of the world, and all the ſtars riſe, culminate and ſet; alſo the ſun always riſes and deſcends at Right angles, and makes their days and nights equal. In a Right ſphere, the horizon is a meridian; and if the ſphere be ſuppoſed to revolve, all the meridians ſucceſſively become horizons, one after another.

RIGHT Aſcenſion, Deſcenſion, Parallax, &c. See the reſpective Articles.

RIGHT *Circle*, in the Stereographic Projection of the Sphere, is a circle at Right angles to the plane of projection, or that is projected into a Right line.

RIGHT *Sailing*, is that in which a voyage is performed on ſome one of the four cardinal points, eaſt, weſt, north, or ſouth.

If the ſhip ſail on a meridian, that is, north or ſouth, ſhe does not alter her longitude, but only changes the latitude, and that juſt as much as the number of degrees ſhe has run.

But if ſhe ſail on the equator, directly eaſt or weſt, ſhe varies not her latitude, but only changes the longitude, and that juſt as much as the number of degrees ſhe has run.

And if ſhe ſail directly eaſt or weſt upon any parallel, ſhe again does not change her latitude, but only the longitude; yet not the ſame as the number of degrees of a great circle ſhe hath ſailed, as on the equator, but more, according as the parallel is remoter from the equinoctial towards the pole. For the leſs any parallel is, the greater is the difference of longitude anſwering to the diſtance run.

RIGIDITY, a brittle hardneſs; or that kind of hardneſs which is ſuppoſed to ariſe from the mutual indentation of the component particles within one another. Rigidity is oppoſed to ductility, malleability, &c.

RING, in Aſtronomy and Navigation, an inſtrument uſed for taking the ſun's altitude &c. It is uſually of braſs, about 9 inches diameter, ſuſpended by a little ſwivel, at the diſtance of 45° from the point of which is a perforation, which is the centre of a quadrant of 90° divided in the inner concave ſurface.

To uſe it, let it be held up by the ſwivel, and turned round to the ſun, till his rays, falling through the hole, make a ſpot among the degrees, which marks the altitude required.

This inſtrument is preferred before the aſtrolabe, becauſe the diviſions are here larger than on that inſtrument.

RING, of Saturn, is a thin, broad, opaque circular arch, encompaſſing the body of that planet, like the wooden horizon of an artificial globe, without touching it, and appearing double, when ſeen through a good teleſcope.

This Ring was firſt diſcovered by Huygens, who, after frequent obſervation of the planet, perceived two lucid points, like anſæ or handles, ariſing out from the body in a right line. Hence as in ſubſequent obſervations he always found the ſame appearance, he concluded that Saturn was encompaſſed with a permanent Ring; and accordingly produced his New Syſtem of Saturn, in 1659. However, Galileo firſt diſcovered that the figure of Saturn was not round.

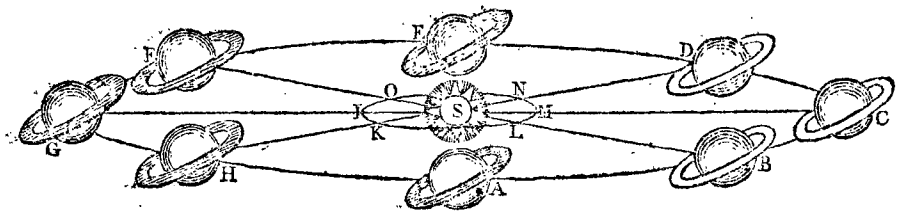
Huygens makes the ſpace between the globe of Saturn and the Ring equal to the breadth of the Ring, or rather more, being about 22000 miles broad; and the greateſt diameter of the Ring, in proportion to that of the globe, as 9 to 4. But Mr. Pound, by an excellent micrometer applied to the Huygenian glaſs of 123 feet, determined this proportion, more exactly, to be as 7 to 3.

Obſervations have alſo determined, that the plane of the Ring is inclined to the plane of the ecliptic in an angle of 30 degrees; that the Ring probably turns, in the direction of its plane, round its axis, becauſe when it is almoſt edgewiſe to us, it appears rather thicker on one ſide of the planet than on the other; and the thickeſt edge has been ſeen on different ſides at different times: the ſun ſhines almoſt 15 of our years together on one ſide of Saturn's Ring without ſetting, and as long on the other in its turn; ſo that the Ring is viſible to the inhabitants of that planet for almoſt 15

of our years, and as long invisible, by turns, if its axis has no inclination to its Ring; but if the axis of the planet be inclined to the Ring, ex. gr. about 30 degrees, the Ring will appear and disappear once every natural day to all the inhabitants within 30 degrees of the equator, on both sides, frequently eclipsing the sun in a Saturnian day. Moreover, if Saturn's axis be so inclined to his Ring, it is perpendicular to his orbit; by which the inconvenience of different seasons to that planet is avoided.

This Ring, seen from Saturn, appears like a large luminous arch in the heavens, as if it did not belong to the planet.

When we see the Ring most open, its shadow upon the planet is broadest; and from that time the shadow grows narrower, as the Ring appears to do to us; until, by Saturn's annual motion, the sun comes to the plane of the Ring, or even with its edge; which, being directed towards us, becomes invisible, on account of its thinness.



The phenomena of Saturn's Ring are illustrated by a view of this figure. Let S be the sun, ABCDEFGH Saturn's orbit, and IKLMNO the earth's orbit. Both Saturn and the earth move according to the order of the letters; and when Saturn is at A, his Ring is turned edgewise to the sun S, and he is then seen from the earth as if he had lost his Ring, let the earth be in any part of its orbit whatever, except between N and O; for whilst it describes that space, Saturn is apparently so near the sun as to be hid in his beams. As Saturn goes from A to C, his Ring appears more and more open to the earth; at C the Ring appears most open of all; and seems to grow narrower and narrower as Saturn goes from C to E; and when he comes to E, the Ring is again turned edgewise both to the sun and earth; and as neither of its sides is illuminated, it is invisible to us, because its edge is too thin to be perceptible; and Saturn appears again as if he had lost his Ring. But as he goes from E to G, his Ring opens more and more to our view on the under side; and seems just as open at G as it was at C, and may be seen in the night time from the earth in any part of its orbit, except about M, when the sun hides the planet from our view.

As Saturn goes from G to A, his Ring turns more and more edgewise to us, and, therefore, it seems to grow narrower and narrower; and at A it disappears as before.

Hence, while Saturn goes from A to E, the sun shines on the upper side of his Ring, and the under side is dark; and whilst he goes from E to A, the sun shines on the under side of his Ring, and the upper side is dark. The Ring disappears twice in every annual revolution of Saturn, viz, when he is in the 19th degree of Pisces and of Virgo, and when Saturn is in the middle between these points, or in the 19th degree either of Gemini or of Sagittarius, his Ring appears most open to us; and then its longest diameter is to its shortest, as 9 to 4. Ferguson's Astr. sect. 204.

There are various hypotheses concerning this Ring. Kepler, in his Epitom. Astron. Copern. and after him Dr. Halley, in his Enquiry into the Causes of the Variation of the Needle, Phil. Trans. No 195, suppose our earth may be composed of several crusts or shells, one within another, and concentric to each other. If this be the case, it is possible the Ring of Saturn may be the fragment or remaining ruin of his formerly exterior shell, the rest of which is broken or fallen down upon the body of the planet. And some have supposed that the Ring may be a congeries or series of moons revolving about the planet.

Later observations have thrown much more light upon this curious phenomenon, especially respecting its dimensions, and rotation, and division into two or more parts. De la Lande and De la Place say, that Cassini saw the breadth of the Ring divided into two separate parts that are equal, or nearly so. Mr. Short assured M. De la Lande, that he had seen many divisions upon the Ring, with his 12 feet telescope. And Mr. Hadley, with an excellent $5\frac{1}{2}$ feet reflector, saw the Ring divided into two parts. Several excellent theories have been given in the French Memoirs, particularly by De la Place, contending for the division of the Ring into many parts. But finally the observations of Dr. Herschel, in several volumes of the Philos. Trans. seem to confirm the division into two concentric parts only. The dimensions of these two Rings, and the space between them, he states in the following proportion to each other.

	Miles.
Inner diam. of smaller Ring	146345
Outside diam. of ditto	184393
Inner diam. of larger Ring	190248
Outside diam. of ditto	204883
Breadth of the inner Ring	20000
Breadth of the outer Ring	7200
Breadth of the vacant space	2839

Ring revolves in its own plane, in $10^h\ 32'\ 15''.4$.

So that the outside diameter of the larger Ring is almost 26 times the diameter of the earth.

Dr. Herschel adds, Some theories and observations, of

of other perſons, "lead us to conſider the queſtion, whether the conſtruction of this Ring is of a nature ſo as permanently to remain in its preſent ſtate? or whether it be liable to continual and frequent changes, in ſuch a manner as in the courſe of not many years, to be ſeen ſubdivided into narrow ſlips, and then again as united into one or two circular planes only. Now, without entering into a diſcuſſion, the mind ſeems to revolt, even at firſt ſight, againſt an idea of the chaotic ſtate in which ſo large a maſs as the Ring of Saturn muſt needs be, if phenomena like theſe can be admitted. Nor ought we to indulge a ſuſpicion of this being a reality, unleſs repeated and well-confirmed obſervations had proved, beyond a doubt, that this Ring was actually in ſo fluctuating a condition." But from his own obſervations he concludes, "It does not appear to me that there is a ſufficient ground for admitting the Ring of Saturn to be of a very changeable nature, and I gueſs that its phenomena will hereafter be ſo fully explained as to reconcile all obſervations. In the mean while, we muſt withhold a final judgment of its conſtruction, till we can have more obſervations. Its diviſion however into two very unequal parts, can admit of no doubt." See Philoſ. Tranſ. vol. 80 pa. 4, 481 &c, and the vol. for 1792, pa. 1 &c. alſo Hiſt. de l'Acad. des Scienc. de Paris, 1787, pa. 249 &c.

Rings *of Colours*, in Optics, a phenomenon firſt obſerved in thin plates of various ſubſtances, by Boyle, and Hook, but afterwards more fully explained by Newton.

Mr. Boyle having exhibited a variety of colours in colourleſs liquors, by ſhaking them till they roſe in bubbles, as well as in bubbles of ſoap and water, and alſo in turpentine, procured glaſs blown ſo thin as to exhibit ſimilar colours; and he obſerves, that a feather of a proper ſhape and ſize, and alſo a black ribband, held at a proper diſtance between his eye and the ſun, ſhewed a variety of little rainbows, as he calls them, with very vivid colours. Boyle's Works by Shaw, vol. 2, p. 70. Dr. Hook, about nine years after the publication of Mr. Boyle's Treatiſe on Colours, exhibited the coloured bubbles of ſoap and water, and obſerved, that though at firſt it appeared white and clear, yet as the film of water became thinner, there appeared upon it all the colours of the rainbow. He alſo deſcribed the beautiful colours that appear in thin plates of Muſcovy glaſs; which appeared, through the microſcope, to be ranged in Rings ſurrounding the white ſpecks or flaws in them, and with the ſame order of colours as thoſe of the rainbow, and which were often repeated ten times. He alſo took two thin pieces of glaſs, ground plane and poliſhed, and putting them one upon another, preſſed them till there began to appear a red coloured ſpot in the middle; and preſſing them cloſer, he obſerved ſeveral Rings of colours encompaſſing the firſt place, till, at laſt, all the colours diſappeared out of the middle of the circles, and the central ſpot appeared white. The firſt colour that appeared was red, then yellow, then green, then blue, then purple; then again red, yellow, green, blue, and purple; and again in the ſame order; ſo that he ſometimes counted nine or ten of theſe circles, the red immediately next to the purple; and the laſt colour that appeared before the white was blue; ſo that it began with red, and ended with purple. Theſe Rings, he ſays, would change their places, by changing the poſition of the eye, ſo that, the glaſſes remaining the ſame, that part which was red in one poſition of the eye, was blue in a ſecond, green in the third, &c. Birch's Hiſt. of the Royal Society, vol. 3, pa. 54.

Newton, having demonſtrated that every different colour conſiſts of rays which have a different and ſpecific degree of refrangibility, and that natural bodies appear of this or that colour, according to their diſpoſition to reflect this or that ſpecies of rays (ſee Colour), purſued the hint ſuggeſted by the experiments of Dr. Hook, already recited, and caſually noticed by himſelf, with regard to thin tranſparent ſubſtances. Upon compreſſing two priſms hard together, in order to make their ſides touch one another, he obſerved, that in the place of contact they were perfectly tranſparent, which appeared like a dark ſpot, and when it was looked through, it ſeemed like a hole in that air, which was formed into a thin plate, by being impreſſed between the glaſſes. When this plate of air, by turning the priſms about their common axis, became ſo little inclined to the incident rays, that ſome of them began to be tranſmitted, there aroſe in it many ſlender arcs of colours, which increaſed, as the motion of the priſms was continued, and bended more and more about the tranſparent ſpot, till they were completed into circles, or Rings, ſurrounding it; and afterwards they became continually more and more contracted.

By another experiment, with two object glaſſes, he was enabled to obſerve diſtinctly the order and quality of the colours from the central ſpot, to a very conſiderable diſtance. Next to the pellucid central ſpot, made by the contact of the glaſſes, ſucceeded blue, white, yellow, and red. The next circuit immediately ſurrounding theſe, conſiſted of violet, blue, green, yellow, and red. The third circle of colours was purple, blue, green, yellow, and red. The fourth circle conſiſted of green and red. All the ſucceeding colours became more and more imperfect and dilute, till, after three or four revolutions, they ended in perfect whiteneſs.

When theſe Rings were examined in a darkened room, by the coloured light of a priſm caſt on a ſheet of white paper, they became more diſtinct, and viſible to a far greater number than in the open air. He ſometimes ſaw more than twenty of them, whereas in the open air he could not diſcern above eight or nine.

From other curious obſervations on theſe Rings, made by different kinds of light thrown upon them, he inferred, that the thickneſſes of the air between the glaſſes, where the Rings are ſucceſſively made, by the limits of the ſeven colours, red, orange, yellow, green, blue, indigo, and violet, in order, are one to another as the cube roots of the ſquares of the eight lengths of a chord, which ſound the notes in an octave, ſol, la, fa, ſol, la, mi, fa, ſol; that is, as the cube roots of the ſquares of the numbers 1, $\frac{8}{9}$, $\frac{5}{6}$, $\frac{3}{4}$, $\frac{2}{3}$, $\frac{3}{5}$, $\frac{9}{16}$, $\frac{1}{2}$. Theſe Rings appeared of that priſmatic colour, with which they were illuminated, and by projecting the priſmatic colours immediately upon the glaſſes, he found that the light, which fell on the dark ſpaces between

the coloured Rings, was tranſmitted through the glaſſes without any change of colour. From this circumſtance he thought that the origin of theſe Rings is manifeſt; becauſe the air between the glaſſes is diſpoſed according to its various thickneſs, in ſome places to reflect, and in others to tranſmit the light of any particular colour, and in the ſame place to reflect that of one colour, where it tranſmits that of another.

In examining the phenomena of colours made by a denſer medium ſurrounded by a rarer, ſuch as thoſe which appear in plates of Muſcovy glaſs, bubbles of ſoap and water, &c, the colours were found to be much more vivid than the others, which were made with a rarer medium ſurrounded by a denſer.

From the preceding phenomena it is an obvious deduction, that the tranſparent parts of bodies, according to their ſeveral ſeries, reflect rays of one colour and tranſmit thoſe of another; on the ſame account that thin plates, or bubbles, reflect or tranſmit thoſe rays, and this Newton ſuppoſed to be the reaſon of all their colours. Hence alſo he has inferred, that the ſize of thoſe component parts of natural bodies that affect the light, may be conjectured by their colours. See Colour and Reflection.

Newton, purſuing his diſcoveries concerning the colours of thin ſubſtances, found that the ſame were alſo produced by plates of a conſiderable thickneſs, diviſible into leſſer thicknefſes. The Rings formed in both caſes have the ſame origin, with this difference, that thoſe of the thin plates are made by the alternate reflexions and tranſmiſſions of the rays at the ſecond ſurface of the plate, after one paſſage through it; but that, in the caſe of a glaſs ſpeculum, concave on one ſide, and convex on the other, and quickſilvered over on the convex ſide, the rays go through the plate and return before they are alternately reflected and tranſmitted. Newton's Optics, p. 169, &c. or Newton's Opera, Horſley's edit. vol. 4, p. 121, &c. p. 184, &c.

The abbé Mazeas, in his experiments on the Rings of colours that appear in thin plates, has diſcovered ſeveral important circumſtances attending them, which were overlooked by the ſagacious Newton, and which tend to invalidate his theory for explaining them. In rubbing the flat ſide of an object-glaſs againſt another piece of flat and ſmooth glaſs, he found that they adhered very firmly together after this friction, and that the ſame colours were exhibited between theſe plane glaſſes, which Newton had obſerved between the convex object glaſs of a teleſcope, and another that was plane; and that the colours were in proportion to their adheſion. When the ſurfaces of pieces of glaſs, that are tranſparent and well poliſhed, are equally preſſed, a reſiſtance will be perceived; and wherever this is felt, two or three very fine curve lines will be diſcovered, ſome of a pale red, and others of a faint green. If the friction be continued, the red and green lines increaſe in number at the place of contact; the colours being ſometimes mixed without any order, and ſometimes diſpoſed in a regular manner; in which caſe the coloured lines are generally concentric circles, or ovals, more or leſs elongated, as the ſurfaces are more or leſs united.

When the colours are formed, the glaſſes adhere with conſiderable force; but if the glaſſes be ſeparated ſuddenly, the colours will appear immediately upon their being put together, without the leaſt friction. Beginning with the ſlighteſt touch, and increaſing the preſſure by inſenſible degrees, there firſt appears an oval plate of a faint red, and in the centre of it a ſpot of light green, which enlarges by the preſſure, and becomes a green oval, with a red ſpot in the centre; and this enlarging in its turn, diſcovers a green ſpot in its centre. Thus the red and green ſucceed one another in turn, aſſuming different ſhades, and having other colours mixed with them. The greateſt difference between theſe colours exhibited between plane ſurfaces, and thoſe by curve ones, is, that, in the former caſe, preſſure alone will not produce them, except in the caſe above mentioned.

In rubbing together two priſms, with very ſmall refracting angles, which were joined ſo as to form a parallelopiped, the colours appeared with a ſurpriſing luſtre at the places of contact, and differently coloured ovals appeared.

In the centre there was a black ſpot, bordered by a deep purple; next to this appeared violet, blue, orange, red tinged with purple, light green, and faint purple.

The other Rings appeared to the naked eye to conſiſt of nothing but faint reds and greens. When theſe coloured glaſſes were ſuſpended over the flame of a candle, the colours diſappeared ſuddenly, though they ſtill adhered; but being ſuffered to cool, the colours returned to their former places, in the ſame order as before. At firſt the abbé Mazeas had no doubt but that theſe colours were owing to a thin plate of air between the glaſſes, to which Newton has aſcribed them; but the remarkable difference in the circumſtances attending thoſe produced by the flat plates and thoſe produced by the object glaſſes of Newton, convinced him that the air was not the cauſe of this appearance. The colours of the flat plates vaniſhed at the approach of flame, but thoſe of the object glaſſes did not. Nor was this difference owing to the plane glaſſes being leſs compreſſed than the convex ones; for though the former were compreſſed ever ſo much by a pair of forceps, it did not in the leaſt hinder the effect of the flame. Afterwards he put both the plane glaſſes and the convex ones into the receiver of an air-pump, ſuſpending the former by a thread, and keeping the latter compreſſed by two ſtrings; but he obſerved no change in the colours of either of them, in the moſt perfect vacuum that he could make. Suſpecting ſtill that the air adhered to the ſurface of the glaſſes, ſo as not to be ſeparated from them by the force of the pump, he had recourſe to other experiments, which rendered it ſtill more improbable that the air ſhould be the cauſe of theſe colours. Having laid the coloured plates, after warming them gradually, on burning coals; and thus, when they were nearly red, rubbing them together, he obſerved the ſame coloured circles and ovals as before. When he ceaſed to preſs upon them, the colours ſeemed to vaniſh; but they returned, as he renewed the friction. In order to determine whether the colours were owing to the thickneſs of ſome matter interpoſed between the glaſſes, he rubbed them toge-

the

ther with ſuet and other ſoft ſubſtances between them; yet his endeavour to produce the colours had no effect. However by continuing the friction with ſome degree of violence, he obſerved, that a candle appeared through them encompaſſed with two or three concentric greens, and with a lively red inclining to yellow, and a green like that of an emerald, and at length the Rings aſſumed the colours of blue, yellow, and violet. The abbé was confirmed in his opinion that there muſt be ſome error in Newton's hypotheſis, by conſidering that, according to his meaſures, the colours of the plates varied with the difference of a miſſionth part of an inch; whereas he was ſatisfied that there muſt have been much greater differences in the diſtance between his glaſſes, when the colours remained unchanged. From other experiments he concluded, that the plate of water introduced between the glaſſes was not the cauſe of their colours, as Newton apprehended; and that the coloured Rings could not be owing to the compreſſion of the glaſſes. After all, he adds, that the theory of light, thus reflected from thin plates, is too delicate a ſubject to be completely aſcertained by a ſmall number of obſervations. Berlin Mem. for 1752, or Memoires Preſentes, vol. 2, pa. 28—43. M. du Tour repeated the experiments of the abbé Mazeas, and added ſome obſervations of his own. See Mem. Pref. vol. 4, pa. 288.

Muſſchenbroeck is alſo of opinion, that the colours of thin plates do not depend upon the air; but as to the cauſe of them, he acknowledges that he could not ſatisfy himſelf about it. Introd. ad Phil. Nat. vol. 2, p. 738.

See on this ſubject Prieſtley's Hiſt. of Light, &c. per. 6, ſect. 5, pa. 498, &c.

For an account of the Rings of colours produced by electrical exploſions, ſee *Colours* of *natural bodies*, CIRCULAR *ſpots*, and FAIRY *circles*.

RISING, in Aſtronomy, the appearance of the ſun, or a ſtar, or other luminary, above the horizon, which before was hid beneath it.

By reaſon of the refraction of the atmoſphere, the heavenly bodies always appear to riſe before their time; that is, they are ſeen above the horizon, while they are really below it, by about 33′ of a degree.

There are three poetical kinds of Riſing of the ſtars. See ACRONICAL, COSMICAL, and HELIACAL.

RIVER, in Geography, a ſtream or current of freſh water, flowing in a bed or channel, from a ſource or ſpring, into the ſea.

When the ſtream is not large enough to bear boats, or ſmall veſſels, loaden, it is properly called by the diminutive, *rivulet* or *brook*; but when it is conſiderable enough to carry larger veſſels, it is called by the general name River.

Rivulets have their riſe ſometimes from great rains, or great quantities of thawed ſnow, eſpecially in mountainous places; but they more uſually ariſe from ſprings.

Rivers themſelves all ariſe either from the confluence of ſeveral rivulets, or from lakes.

RIVER, in Phyſics, denotes a ſtream of water running by its own gravity, from the more elevated parts of the earth towards the lower parts, in a natural bed or channel open above.

When the channel is artificial, or cut by art, it is called a canal; of which there are two kinds, viz, that whoſe channel is every where open, without ſluices, called an artificial River, and that whoſe water is kept up and let off by means of ſluices, which is properly a *canal*.

Modern philoſophers endeavour to reduce the motion and flux of Rivers to preciſe laws; and with this view they have applied geometry and mechanics to the ſubject; ſo that the doctrine of Rivers is become a part of the new philoſophy.

The authors who have moſt diſtinguiſhed themſelves in this branch, are the Italians, the French, and the Dutch, but eſpecially the firſt, and among them more eſpecially Gulielmini, and Ximenes.

Rivers, ſays Gulielmini, uſually have their ſources in mountains or elevated grounds; in the deſcent from which it is moſtly that they acquire the velocity, or acceleration, which maintains their future current. In proportion as they advance farther, this velocity diminiſhes, on account of the continual friction of the water againſt the bottom and ſides of the channel; as well as from the various obſtacles they meet with in their progreſs, and from their arriving at length in plains where the deſcent is leſs, and conſequently their inclination to the horizon greater. Thus the Reno, a River in Italy, which he ſays gave occaſion, in ſome meaſure, to his ſpeculations, is found to have near its mouth a declivity of ſcarce 52 ſeconds.

When the acquired velocity is quite ſpent, through the many obſtacles, ſo that the current becomes horizontal, there will then nothing remain to propagate the motion, and continue the ſtream, but the depth, or the perpendicular preſſure of the water, which is always proportional to the depth. And, happily for us, this reſource increaſes, as the occaſion for it increaſes; for in proportion as the water loſes of the velocity acquired by the deſcent, it riſes and increaſes in its depth.

It appears from the laws of motion pertaining to bodies moved on inclined planes, that when water flows freely upon an inclined bed, it acquires a velocity, which is always as the ſquare root of the quantity of deſcent of the bed. But in an horizontal bed, opened by ſluices or otherwiſe, at one or both ends, the water flows out by its gravity alone.

The upper parts of the water of a River, and thoſe at a diſtance from the banks, may continue to flow, from the ſimple cauſe or principle of declivity, how ſmall ſoever it be; for not being detained by any obſtacle, the minuteſt difference of level will have its effect; but the lower parts, which roll along the bottom, will ſcarce be ſenſible of ſo ſmall a declivity; and will only have what motion they receive from the preſſure of the ſuperincumbent waters.

The greateſt velocity of a River is about the middle of its depth and breadth, or that point which is the fartheſt poſſible from the ſurface of the water, and from the bottom and ſides of the bed or channel. Whereas, on the contrary, the leaſt velocity of the water is at the bottom and ſides of the bed, becauſe there the reſiſtance ariſing from friction is the greateſt, which is communicated to the other parts of the ſection of the

River inverſely as the diſtances from the bottom and ſides.

To find whether the water of a River, almoſt horizontal, flows by means of the velocity acquired in its deſcent, or by the preſſure of its depth; ſet up an obſtacle perpendicular to it; then if the water riſe and ſwell immediately againſt the obſtacle, it runs by virtue of its fall; but if it firſt ſtop a little while, in virtue of its preſſure.

Rivers, according to this author, almoſt always make their own beds. If the bottom have originally been a large declivity, the water, hence falling with a great force, will have ſwept away the moſt elevated parts of the ſoil, and carrying them lower down, will gradually render the bottom more nearly horizontal.

The water having made its bed horizontal, becomes ſo itſelf, and conſequently rakes with the leſs force againſt the bottom, till at length that force becomes only equal to the reſiſtance of the bottom, which is now arrived at a ſtate of permanency, at leaſt for a conſiderable time; and the longer according to the quality of the ſoil, clay and chalk reſiſting longer than ſand or mud.

On the other hand, the water is continually wearing away the brims of its channel, and this with the more force, as, by the direction of its ſtream, it impinges more directly againſt them. By this means it has a continual tendency to render them parallel to its own courſe. At the ſame time that it has thus rectified its edges, it has widened its own bed, and thence becoming leſs deep, it loſes part of its force and preſſure: this it continues to do till there is an equilibrium between the force of the water and the reſiſtance of its banks, and then they will remain without farther change. And it appears by experience that theſe equilibriums are all real, as we find that Rivers only dig and widen to a certain pitch.

The very reverſe of all theſe things does alſo on ſome occaſions happen. Rivers, whoſe waters are thick and muddy, raiſe their bed, by depoſiting part of the heterogeneous matters contained in them: they alſo contract their banks, by a continual oppoſition of the ſame matter, in bruſhing over them. This matter, being thrown aſide far from the ſtream of water, might even ſerve, by reaſon of the dullneſs of the motion, to form new banks.

If theſe various cauſes of reſiſtance to the motion of flowing waters did not exiſt, viz, the attraction and continual friction of the bottom and ſides, the inequalities in both, the windings and angles that occur in their courſe, and the diminution of their declivity the farther they recede from their ſprings, the velocity of their currents would be accelerated to 10, 15, or even 20 times more than it is at preſent in the ſame Rivers, by which they would become abſolutely unnavigable.

The union of two Rivers into one, makes the whole flow the ſwifter, becauſe, inſtead of the friction of four ſhores, they have only two to overcome, and one bottom inſtead of two; alſo the ſtream, being farther diſtant from the banks, goes on with the leſs interruption, beſides, that a greater quantity of water, moving with a greater velocity, digs deeper in the bed, and of courſe retrenches of its former width. Hence alſo it is, that Rivers, by being united, take up leſs ſpace on the ſurface of the earth, and are more advantageous to low grounds, which drain their ſuperfluous moiſture into them, and have alſo leſs occaſion for dykes to prevent their overflowing.

A very good and ſimple method of meaſuring the velocity of the current of a River, or canal, is the following. Take a cylindrical piece of dry, light wood, and of a length ſomething leſs than the depth of the water in the River; about one end of it let there be ſuſpended as many ſmall weights, as may keep the cylinder in a vertical or upright poſition, with its head juſt above water. To the centre of this end fix a ſmall ſtraight rod, preciſely in the direction of the cylinder's axis; to the end that, when the inſtrument is ſuſpended in the water, the deviations of the rod from a perpendicularity to the ſurface of it, may indicate which end of the cylinder goes foremoſt, by which may be diſcovered the different velocities of the water at different depths; for when the rod inclines forward, according to the direction of the current, it is a proof that the ſurface of the water has the greateſt velocity; but when it reclines backward, it ſhews that the ſwifteſt current is at the bottom; and when it remains perpendicular, it is a ſign that the velocities at the top and bottom are equal.

This inſtrument, being placed in the current of a River or canal, receives all the percuſſions of the water throughout the whole depth, and will have an equal velocity with that of the whole current from the ſurface to the bottom at the place where it is put in, and by that means may be found, both with exactneſs and eaſe, the mean velocity of that part of the River for any determinate diſtance and time.

But to obtain the mean velocity of the whole ſection of the River, the inſtrument muſt be put ſucceſſively both in the middle and towards the ſides, becauſe the velocities at thoſe places are often very different from each other. Having by this means found the ſeveral velocities, from the ſpaces run over in certain times, the arithmetical mean proportional of all theſe trials, which is found by dividing the common ſum of them all by the number of the trials, will be the mean velocity of the River or canal. And if this medium velocity be multiplied by the area of the tranſverſe ſection of the waters at any place, the product will be the quantity running through that place in a ſecond of time.

If it be required to find the velocity of the current only at the ſurface, or at the middle, or at the bottom, a ſphere of wood loaded, or a common bottle corked with a little water in it, of ſuch a weight as will remain ſuſpended in equilibrium with the water at the ſurface or depth which we want to meaſure, will be better for the purpoſe than the cylinder, becauſe it is only affected by the water of that ſole part of the current where it remains ſuſpended.

It follows from what has been ſaid in the former part of this article, that the deeper the waters are in their bed in proportion to its breadth, the more their motion is accelerated; ſo that their velocity increaſes in the inverſe ratio of the breadth of the bed, and alſo

of

of the magnitude of the ſection; whence, in order to augment the velocity of water in a River or canal, without augmenting the declivity of the bed, we muſt increaſe the depth of the channel, and diminiſh its breadth. And theſe principles are agreeable to obſervation; as it is well known, that the velocity of flowing waters depends much more on the quantity and depth of the water, and on the compreſſion of the upper parts on the lower, than on the declivity of the bed; and therefore the declivity of a River muſt be made much greater in the beginning than toward the end of its courſe; where it ſhould be almoſt inſenſible. If the depth or volume of water in a River or canal be conſiderable, it will ſuffice, in the part next the mouth, to allow one foot of declivity through 6000, or 8000, or even (according to Dechales, De Fontibus et Fluviis, prop. 49) 10000 feet in horizontal extent; at moſt it need not be above 1 in 6 or 7 thouſand. From hence the quantity of declivity in equal ſpaces muſt ſlowly and gradually increaſe as far as the current is to be made fit for navigation; but in ſuch a manner, as that at this upper end there may not be above one foot of perpendicular declivity in 4000 feet of horizontal extent.

To conclude this article, M. de Buffon obſerves, that people accuſtomed to Rivers can eaſily foretell when there is going to be a ſudden increaſe of water in the bed from floods produced by ſudden falls of rain in the higher countries through which the Rivers paſs. This they perceive by a particular motion in the water, which they expreſs by ſaying, that the River's bottom moves, that is, the water at the bottom of the channel runs off faſter than uſual; and this increaſe of motion at the bottom of a River always announces a ſudden increaſe of water coming down the ſtream. Nor, ſays he, is their opinion ill grounded; becauſe the motion and weight of the waters coming down, though not yet arrived, muſt act upon the waters in the lower parts of the River, and communicate by impulſion part of their motion to them, within a certain diſtance.

On the ſubject of this article, ſee an elaborate treatiſe on Rivers and canals, in the Philoſ. Tranſ. vol. 69, pa. 555 &c, by Mr. Mann, who has availed himſelf of the obſervations of Gulielmini, and moſt other writers.

RIXDOLLAR, a ſilver coin, ſtruck in ſeveral ſtates and free cities in Germany, as alſo in Flanders, Poland, Denmark, Sweden, &c.

There is but little difference between the Rixdollar and the dollar, another ſilver coin ſtruck in Germany, each being nearly equal to the French crown of three livres, or the Spaniſh piece of eight, or 4s. 6d. ſterling.

ROBERVAL (GILES-PERSONNE), an eminent French mathematician, was born in 1602, at Roberval, a pariſh in the dioceſe of Beauvais. He was firſt profeſſor of mathematics at the College of Maitre-Gervais, and afterwards at the College-royal. A ſimilarity of taſte connected him with Gaſſendi and Morin; the latter of whom he ſucceeded in the mathematical chair at the Royal College, without quitting however that of Ramus.

Roberval made experiments on the Torricellian vacuum: he invented two new kinds of balance, one of which was proper for weighing air; and made many other curious experiments. He was one of the firſt members of the ancient Academy of Sciences of 1666; but died in 1675, at 73 years of age. His principal works are,

I. A treatiſe on Mechanics.

II. A work entitled Ariſtarchus Samos.

He had ſeveral memoirs inſerted in the volumes of the Academy of Sciences of 1666, viz,

1. Experiments concerning the Preſſure of the Air.

2. Obſervations on the Compoſition of Motion, and on the Tangents of Curvè Lines.

3. The Recognition of Equations.

4. The Geometrical Reſolution of Plane and Cubic Equations.

5. Treatiſe on Indiviſibles.

6. On the Trochoid, or Cycloid.

7. A Letter to Father Merſenne.

8. Two Letters from Torricelli.

9. A new kind of Balance.

ROBERVALLIAN *Lines*, a name given to certain lines, uſed for the transformation of figures: thus called from their inventor Roberval.

Theſe lines bound ſpaces that are infinitely extended in length, which are nevertheleſs equal to other ſpaces that are terminated on all ſides.

The abbot Gallois, in the Memoirs of the Royal Academy, anno 1693, obſerves, that the method of transforming figures, explained at the latter end of Roberval's treatiſe of Indiviſibles, was the ſame with that afterwards publiſhed by James Gregory, in his Geometria Univerſalis, and alſo by Barrow in his Lectiones Geometricæ; and that, by a letter of Torricelli, it appears, that Roberval was the inventor of this manner of transforming figures, by means of certain lines, which Torricelli therefore called Robervallian Lines.

He adds, that it is highly probable, that J. Gregory firſt learned the method in the journey he made to Padua in 1668, the method itſelf having been known in Italy from the year 1646, though the book was not publiſhed till the year 1692.

This account David Gregory has endeavoured to refute, in vindication of his uncle James. His anſwer is inſerted in the Philoſ. Tranſ. of 1694, and the abbot rejoined in the French Memoirs of the Academy of 1703.

ROBINS (BENJAMIN), an Engliſh mathematician and philoſopher of great genius and eminence, was born at Bath in Somerſetſhire, 1707. His parents were of low condition, and Quakers; and conſequently neither able from their circumſtances, nor willing from their religious profeſſion, to have him much inſtructed in that kind of learning which they are taught to deſpiſe as human. Nevertheleſs, he made an early and ſurpriſing progreſs in various branches of ſcience and literature, particularly in the mathematics; and his friends being deſirous that he might continue his purſuits, and that his merit might not be buried in obſcurity, wiſhed that he could be properly recommended

to

to teach that ſcience in London. Accordingly, a ſpecimen of his abilities in this way was ſent up thither, and ſhewn to Dr. Pemberton, the author of the "View of Sir Iſaac Newton's Philoſophy;" who, thence conceiving a good opinion of the writer, for a farther trial of his ſkill ſent him ſome problems, which Robins reſolved very much to his ſatisfaction. He then came to London, where he confirmed the opinion which had been preconceived of his abilities and knowledge.

But though Robins was poſſeſſed of much more ſkill than is uſually required in a common teacher; yet being very young, it was thought proper that he ſhould employ ſome time in peruſing the beſt writers upon the ſublimer parts of the mathematics, before he ſhould undertake publicly the inſtruction of others. In this interval, beſides improving himſelf in the modern languages, he had opportunities of reading in particular the works of Archimedes, Apollonius, Fermat, Huygens, De Witt, Sluſius, Gregory, Barrow, Newton, Taylor, and Cotes. Theſe authors he readily underſtood without any aſſiſtance, of which he gave frequent proofs to his friends: one was, a demonſtration of the laſt propoſition of Newton's treatiſe on Quadratures, which was thought not undeſerving a place in the Philoſophical Tranſactions for 1727.

Not long after, an opportunity offered him of exhibiting to the public a ſpecimen alſo of his knowledge in Natural Philoſophy. The Royal Academy of Sciences at Paris had propoſed, among their prize queſtions in 1724 and 1726, to demonſtrate the laws of motion in bodies impinging on one another. John Bernoulli here condeſcended to be a candidate; and as his diſſertation loſt the reward, he appealed to the learned world by printing it in 1727. In this piece he endeavoured to eſtabliſh Leibnitz's opinion of the force of bodies in motion from the effects of their ſtriking againſt ſpringy materials; as Poleni had before attempted to evince the ſame thing from experiments of bodies falling on ſoft and yielding ſubſtances. But as the inſufficiency of Poleni's arguments had been demonſtrated in the Philoſophical Tranſactions, for 1722; ſo Robins publiſhed in the Preſent State of the Republic of Letters, for May 1728, a Confutation of Bernoulli's performance, which was allowed to be unanſwerable.

Robins now began to take ſcholars; and about this time he quitted the garb and profeſſion of a Quaker; for, having neither enthuſiaſm nor ſuperſtition in his nature, as became a mathematician, he ſoon ſhook off the prejudices of ſuch early habits. But though he profeſſed to teach the mathematics only, he would frequently aſſiſt particular friends in other matters; for he was a man of univerſal knowledge: and the confinement of this way of life not ſuiting his diſpoſition, which was active, he gradually declined it, and went into other courſes, that required more exerciſe. Hence he tried many laborious experiments in gunnery; believing that the reſiſtance of the air had a much greater effect on ſwift projectiles, than was generally ſuppoſed. And hence he was led to conſider thoſe mechanic arts that depend upon mathematical principles, in which he might employ his invention: as, the conſtructing of mills, the building of bridges, draining of fens, rendering of rivers navigable, and making of harbours. Among other arts of this kind, fortification very much engaged his attention; in which he met with opportunities of perfecting himſelf, by a view of the principal ſtrong places of Flanders, in ſome journeys he made abroad with perſons of diſtinction.

On his return home from one of theſe excurſions, he found the learned here amuſed with Dr. Berkeley's treatiſe, printed in 1734, entitled, "The Analyſt;" in which an examination was made into the grounds of the doctrine of Fluxions, and occaſion thence taken to explode that method. Robins was therefore adviſed to clear up this affair, by giving a full and diſtinct account of Newton's doctrines, in ſuch a manner, as to obviate all the objections, without naming them, which had been advanced by Berkeley; and accordingly he publiſhed, in 1735, *A Diſcourſe concerning the Nature and Certainty of Sir Iſaac Newton's Method of Fluxions, and of Prime and Ultimate Ratios.* This is a very clear, neat, and elegant performance: and yet ſome perſons, even among thoſe who had written againſt The Analyſt, taking exception at Robins's manner of defending Newton's doctrine, he afterwards wrote two or three additional diſcourſes.

In 1738, he defended Newton againſt an objection, contained in a note at the end of a Latin piece, called "Matho, ſive Coſmotheoria puerilis," written by Baxter, author of the "Inquiry into the Nature of the Human Soul:" and the year after he printed *Remarks on Euler's Treatiſe of Motion*, on *Smith's Syſtem of Optics*, and on *Jurin's Diſcourſe of Diſtinct and Indiſtinct Viſion*, annexed to Dr. Smith's work.

In the mean time Robins's performances were not confined to mathematical ſubjects: for, in 1739, there came out three pamphlets upon political affairs, which did him great honour. The firſt was entitled, *Obſervations on the preſent Convention with Spain:* the ſecond, *A Narrative of what paſſed in the Common Hall of the Citizens of London, aſſembled for the Election of a Lord Mayor:* the third, *An Addreſs to the Electors and other free Subjects of Great Britain, occaſioned by the late Succeſſion; in which is contained a Particular Account of all our Negociations with Spain, and their Treatment of us for above ten years paſt.* Theſe were all publiſhed without our author's name; and the firſt and laſt were ſo univerſally eſteemed, that they were generally reputed to have been the production of the great man himſelf, who was at the head of the oppoſition to Sir Robert Walpole. They proved of ſuch conſequence to Mr. Robins, as to occaſion his being employed in a very honourable poſt; for, the patriots at length gaining ground againſt Sir Robert, and a committee of the Houſe of Commons being appointed to examine into his paſt conduct, Robins was choſen their ſecretary. But after the committee had preſented two reports of their proceedings, a ſudden ſtop was put to their farther progreſs, by a compromiſe between the contending parties.

In 1742, being again at leiſure, he publiſhed a ſmall treatiſe, entitled, *New Principles of Gunnery;* containing the reſult of many experiments he had made, by which are diſcovered the force of gunpowder, and the difference in the reſiſting power of the air to ſwift and

ſlow

ſlow motions. To this treatiſe was prefixed a full and learned account of the progreſs which modern fortification had made from its firſt riſe; as alſo of the invention of gunpowder, and of what had already been performed in the theory of gunnery. It ſeems that the occaſion of this publication, was the diſappointment of a ſituation at the Royal Military Academy at Woolwich. On the new modelling and eſtabliſhing of that Academy, in 1741, our author and the late Mr. Muller were competitors for the place of profeſſor of fortification and gunnery. Mr. Muller held then ſome poſt in the Tower of London, under the Board of Ordnance, ſo that, notwithſtanding the great knowledge and abilities of our author, the intereſt which Mr. Muller had with the Board of Ordnance carried the election in his favour. Upon this diſappointment Mr. Robins, indignant at the affront, determined to ſhew them, and the world, by his military publications, what ſort of a man he was that they had rejected.

Upon a diſcourſe containing certain experiments being publiſhed in the Philoſophical Tranſactions, with a view to invalidate ſome of Robins's opinions, he thought proper, in an account he gave of his book in the ſame Tranſactions, to take notice of thoſe experiments: and in conſequence of this, ſeveral diſſertations of his on the reſiſtance of the air were read, and the experiments exhibited before the Royal Society, in 1746 and 1747; for which he was preſented with the annual gold medal by that Society.

In 1748 came out Anſon's Voyage round the World; which, though it bears Walter's name in the title-page, was in reality written by Robins. Of this voyage the public had for ſome time been in expectation of ſeeing an account, compoſed under that commander's own inſpection: for which purpoſe the reverend Richard Walter was employed, as having been chaplain on board the Centurion the greateſt part of the expedition. Walter had accordingly almoſt finiſhed his taſk, having brought it down to his own departure from Macao for England; when he propoſed to print his work by ſubſcription. It was thought proper however that an able judge ſhould firſt review and correct it, and Robins was appointed; when, upon examination, it was reſolved, that the whole ſhould be written entirely by Robins, and that what Walter had done, being moſtly taken verbatim from the journals, ſhould ſerve as materials only. Hence it was that the whole of the introduction, and many diſſertations in the body of the work, were compoſed by Robins, without receiving the leaſt hint from Walter's manuſcript; and what he had tranſcribed from it regarded chiefly the wind and weather, the currents, courſes, bearings, diſtances, offings, ſoundings, moorings, the qualities of the ground they anchored on, and ſuch particulars as uſually fill up a ſeaman's account. No production of this kind ever met with a more favourable reception, four large impreſſions having been ſold off within a year: it was alſo tranſlated into moſt of the European languages; and it ſtill ſupports its reputation, having been repeatedly reprinted in various ſizes. The fifth edition at London in 1749 was reviſed and corrected by Robins himſelf; and the 9th edition was printed there in 1761.

Thus becoming famous for his elegant talents in writing, he was requeſted to compoſe an apology for the unfortunate affair at Preſtonpans in Scotland. This was added as a preface to the Report of the Proceedings and Opinion of the Board of General Officers on their Examination into the Conduct of Lieutenant General Sir John Cope, &c, printed at London in 1749; and this preface was eſteemed a maſter-piece in its kind.

Robins had afterwards, by the favour of lord Anſon, opportunities of making farther experiments in Gunnery; which have been publiſhed ſince his death, in the edition of his works by his friend Dr. Wilſon. He alſo not a little contributed to the improvements made in the Royal Obſervatory at Greenwich, by procuring for it, through the intereſt of the ſame noble perſon, a ſecond mural quadrant, and other inſtruments; by which it became perhaps the completeſt of any obſervatory in the world.

His reputation being now arrived at its full height, he was offered the choice of two very conſiderable employments. The firſt was to go to Paris, as one of the commiſſaries for adjuſting the limits in Acadia; the other, to be engineer general to the Eaſt India Company, whoſe forts, being in a moſt ruinous condition, wanted an able perſon to put them into a proper ſtate of defence. He accepted the latter, as it was ſuitable to his genius, and as the Company's terms were both advantageous and honourable. He deſigned, if he had remained in England, to have written a ſecond part of the Voyage round the World; as appears by a letter from lord Anſon to him, dated Bath, Oct. 22, 1749, as follows.

"Dear Sir, when I laſt ſaw you in town, I forgot to aſk you, whether you intended to publiſh the ſecond volume of my Voyage before you leave us; which I confeſs I am very ſorry for. If you ſhould have laid aſide all thoughts of favouring the world with more of your works, it will be much diſappointed, and no one in it more than your very obliged humble ſervant,

"ANSON."

Robins was alſo preparing an enlarged edition of his New Principles of Gunnery: but, having provided himſelf with a complete ſet of aſtronomical and other inſtruments, for making obſervations and experiments in the Indies, he departed hence at Chriſtmas in 1749; and after a voyage, in which the ſhip was near being caſt away, he arrived at India in July following. There he immediately ſet about his proper buſineſs with the greateſt diligence, and formed complete plans for Fort St. David and Madras: but he did not live to put them into execution. For the great difference of the climate from that of England being beyond his conſtitution to ſupport, he was attacked by a fever in September the ſame year; and though he recovered out of this, yet about eight months after he fell into a languiſhing condition, in which he continued till his death, which happened the 29th of July 1751, at only 44 years of age.

By his laſt will, Mr. Robins left the publiſhing of his Mathematical Works to his honoured and intimate friend Martin Folkes, Eſq. preſident of the Royal Society, and to Dr. James Wilſon; but the former of theſe gentlemen

gentlemen being incapacitated by a paralytic diſorder, for ſome time before his death, they were afterwards publiſhed by the latter, in 2 volumes 8vo, 1761. To this collection, which contains his mathematical and philoſophical pieces only, Dr. Wilſon has prefixed an account of Mr. Robins, from which this memoir is chiefly extracted. He added alſo a large appendix at the end of the ſecond volume, containing a great many curious and critical matters in various intereſting parts of the mathematics. As to Mr. Robins's own papers in theſe two volumes, they are as follow: viz, in vol. I,

1. New Principles of Gunnery. Firſt printed in 1742.

2. An Account of that book. Read before the Royal Society, April the 14th and 21ſt 1743.

3. Of the Reſiſtance of the Air. Read the 12th of June 1746.

4. Of the Reſiſtance of the Air; together with the Method of computing the Motions of Bodies projected in that Medium. Read June 19, 1746.

5. Account of Experiments relating to the Reſiſtance of the Air. Read the 4th of June 1747.

6. Of the Force of Gunpowder, with the Computation of the Velocities thereby communicated to military projectiles. Read the 25th of June 1747.

7. A Compariſon of the Experimental Ranges of Cannon and Mortars, with the Theory contained in the preceding papers. Read the 27th of June 1751.

8. Practical Maxims relating to the Effects and Management of Artillery, and the Flight of Shells and Shot.

9. A Propoſal for increaſing the Strength of the Britiſh Navy. Read the 2d of April 1747.

10. A Letter to Martin Folkes, Eſq. Preſident of the Royal Society. Read the 7th of January 1748.

11. A Letter to Lord Anſon. Read the 26th of October 1749.

12. On Pointing, or Directing of Cannon to ſtrike diſtant objects.

13. Obſervations on the Height to which Rockets aſcend. Read the 4th of May 1749.

14. An Account of ſome Experiments on Rockets, by Mr. Ellicott.

15. Of the Nature and Advantage of Rifled Barrel Pieces, by Mr. Robins. Read the 2d of July 1747.

In volume II are,

16. A Diſcourſe concerning the Nature and Certainty of Sir Iſaac Newton's Methods of Fluxions, and of Prime and Ultimate Ratios.

17. An Account of the preceding Diſcourſe.

18. A Review of ſome of the principal Objections, that have been made to the Doctrine of Fluxions and Ultimate Proportions, with ſome Remarks on the different Methods, that have been taken to obviate them.

19. A Diſſertation ſhewing, that the Account of the Doctrines of Fluxions and of Prime and Ultimate Ratios, delivered in Mr. Robins's Diſcourſe, is agreeable to the real Meaning of their great Inventor.

20. A Demonſtration of the Eleventh Propoſition of Sir Iſaac Newton's Treatiſe of Quadratures.

21. Remarks on Bernoulli's Diſcourſe upon the Laws of the Communication of Motion.

22. An Examination of a Note concerning the Sun's Parallax, publiſhed at the end of Baxter's Matho.

23. Remarks on Euler's Treatiſe of Motion; Dr. Smith's Syſtem of Optics; and Dr. Jurin's Eſſay on Diſtinct and Indiſtinct Viſion.

24. Appendix by the Publiſher.

It is but juſtice to ſay, that Mr. Robins was one of the moſt accurate and elegant mathematical writers that our language can boaſt of; and that he made more real improvements in Artillery, the flight and the reſiſtance of projectiles, than all the preceding writers on that ſubject. His New Principles of Gunnery were tranſlated into ſeveral other languages, and commented upon by ſeveral eminent writers. The celebrated Euler tranſlated the work into the German language, accompanied with a large and critical commentary; and this work of Euler's was again tranſlated into Engliſh in 1714, by Mr. Hugh Brown, with Notes, in one volume 4to.

ROBINS, or ROBYNS (JOHN), an Engliſh mathematician, was born in Staffordſhire about the cloſe of the 15th century, as he was entered a ſtudent at Oxford in 1516, where he was educated for the church. But the bent of his genius lay to the ſciences, and he ſoon made ſuch a progreſs, ſays Wood, in "the pleaſant ſtudies of mathematics and aſtrology, that he became the ableſt perſon in his time for thoſe ſtudies, not excepted his friend Record, whoſe learning was more general. At length, taking the degree of bachelor of divinity in 1531, he was the year following made by king Henry the VIIIth (to whom he was chaplain) one of the canons of his college in Oxon, and in December 1543 canon of Windſor, and in fine chaplain to Queen Mary, who had him in great veneration for his learning. Among ſeveral things that he hath written relating to aſtrology (or aſtronomy) I find theſe following:

"*De Culminatione Fixarum Stellarum, &c.*
De Ortu & Occaſu Stellarum Fixarum, &c.
Annotationes Aſtrologicæ, &c. lib. 3.
Annotationes Edwardo VI.
Tractatus de Prognoſticatione per Eclipſin.

"All which books, that are in MS, were ſome time in the choice library of Mr. Thomas Allen of Gloceſter Hall. After his death, coming into the hands of Sir Kenelm Digby, they were by him given to the Bodleian library, where they yet remain. It is alſo ſaid, that he the ſaid Robyns hath written a book intitled, *De Portentoſis Cometis*, but ſuch a thing I have not yet ſeen, nor do I know any thing elſe of the author, only that paying his laſt debt to nature the 25th of Auguſt 1558, he was buried in the chappel of St. George at Windſore."

ROCKET, in Pyrotechny, an artificial firework, uſually conſiſting of a cylindrical caſe of paper, filled with a compoſition of certain combuſtible ingredients; which being tied to a rod, mounts into the air to a conſiderable height, and there burſts. Theſe are called *Sky Rockets*. Beſide which, there are others called *Water Rockets*, from their acting in water.

The

The compoſition with which Rockets are filled, conſiſts of the three following ingredients, viz, ſaltpetre, charcoal, and ſulphur, all well ground; and in the ſmaller ſizes, gunpowder duſt is alſo added. But the proportions of all the ingredients vary with the weight of the Rocket, as in the following Table.

Compoſitions for Rockets of Various Sizes.

The General Compoſition for Rockets is,

Saltpetre	4 lb.
Sulphur	1 lb.
Charcoal	1 lb.

But for large Rockets,

Saltpetre	4 lb.
Sulphur	1 lb.
Mealpowder	1 lb.

For Rockets of a Middle Size,

Saltpetre	3 lb.
Sulphur	2 lb.
Mealpowder	1 lb.
Charcoal	1 lb.

When Rockets are intended to mount upwards, they have a long ſlender rod fixed to the lower end, to direct their motion.

Theory of the Flight of Rockets.—Mariotte takes the riſe of Rockets to be owing to the impulſe or reſiſtance of the air againſt the flame. Deſaguliers accounts for it thus.

Conceive the Rocket to have no vent at the choke, and to be ſet on fire in the conical bore; the conſequence would be, either that the Rocket would burſt in the weakeſt place, or that, if all parts were equally ſtrong, and able to ſuſtain the impulſe of the flame, the Rocket would burn out immoveable. Now, as the force of the flame is equable, ſuppoſe its action downwards, or that upwards, ſufficient to lift 40 pounds; as theſe forces are equal, but their directions contrary, they will deſtroy each other's action.

Imagine then the Rocket opened at the choke; by this means the action of the flame downwards is taken away, and there remains a force equal to 40 pounds acting upwards, to carry up the Rocket, and the ſtick or rod it is tied to. Accordingly we find that if the compoſition of the Rocket be very weak, ſo as not to give an impulſe greater than the weight of the Rocket and ſtick, it does not riſe at all; or if the compoſition be ſlow, ſo that a ſmall part of it only kindles at firſt, the Rocket will not riſe.

The ſtick ſerves to keep it perpendicular; for if the Rocket ſhould begin to tumble, moving round a point in the choke, as being the common centre of gravity of Rocket and ſtick, there would be ſo much friction againſt the air, by the ſtick between the centre and the point, and the point would beat againſt the air with ſo much velocity, that the reaction of the medium would reſtore it to its perpendicularity. When the compoſition is burnt out, and the impulſe upwards has ceaſed, the common centre of gravity is brought lower towards the middle of the ſtick; by which means the velocity of the point of the ſtick is decreaſed, and that of the point of the Rocket is increaſed; ſo that the whole will tumble down, with the Rocket end foremoſt.

All the while the Rocket burns, the common centre of gravity is ſhifting and getting downwards, and ſtill the faſter and the lower as the ſtick is lighter; ſo that it ſometimes begins to tumble before it is quite burnt out: but when the ſtick is too heavy, the common centre of gravity will not get ſo low, but that the Rocket will riſe ſtraight, though not ſo faſt.

From the experiments of Mr. Robins, and other gentlemen, it appears that the Rockets of 2, 3, or 4 inches diameter, riſe the higheſt; and they found them riſe to all heights in the air, from 400 to 1254 yards, which is about three quarters of a mile. See Robins's Tracts, vol. 2, pa. 317, and the Philoſ. Tranſ. vol. 46, pa. 578.

ROD, or *Pole*, is a long meaſure, of 16½ feet, or 5½ yards, or the 4th part of a Gunter's chain, for land-meaſuring.

ROEMER (Olaus), a noted Daniſh aſtronomer and mathematician, was born at Arhuſen in Jutland, 1644; and at 18 years of age was ſent to the univerſity of Copenhagen. He applied aſſiduouſly to the ſtudy of the mathematics and aſtronomy, and became ſo expert in thoſe ſciences, that when Picard was ſent by Lewis the XIVth in 1671, to make obſervations in the north, he was greatly ſurpriſed and pleaſed with him. He engaged him to return with him to France, and had him preſented to the king, who honoured him with the dauphin as a pupil in mathematics, and ſettled a penſion upon him. He was joined with Picard and Caſſini, in making aſtronomical obſervations; and in 1672 he was admitted a member of the academy of ſciences.

During the ten years he reſided at Paris, he gained great reputation by his diſcoveries; yet it is ſaid he complained afterwards, that his coadjutors ran away with the honour of many things which belonged to him. Here it was that Roemer, firſt of any one, found out the velocity with which light moves, by means of the eclipſes of Jupiter's ſatellites. He had obſerved for many years that, when Jupiter was at his greateſt diſtance from the earth, where he could be obſerved, the emerſions of his firſt ſatellite happened conſtantly 15 or 16 minutes later than the calculation gave them. Hence he concluded that the light reflected by Jupiter took up this time in running over the exceſs of diſtance, and conſequently that it took up 16 or 18 minutes in running over the diameter of the earth's orbit, and 8 or 9 in coming from the ſun to us, provided its velocity was nearly uniform. This diſcovery had at firſt many oppoſers; but it was afterwards confirmed by Dr. Bradley in the moſt ingenious and beautiful manner.

In 1681 Roemer was recalled back to his own country by Chriſtian the Vth, king of Denmark, who made him profeſſor of aſtronomy at Copenhagen. The king employed him alſo in reforming the coin and the architecture, in regulating the weights and meaſures, and in meaſuring and laying out the high roads throughout the kingdom; offices which he diſcharged with the greateſt credit and ſatisfaction. In conſequence he was honoured by the king with the appointment of chancellor of the exchequer and other dignities. Finally he became counſellor of ſtate and burgomaſter of Copenhagen,

hagen, under Frederic the IVth, the ſucceſſor of Chriſtian. Roemer was preparing to publiſh the reſult of his obſervations, when he died the 19th of September 1710, at 66 years of age: but this loſs was ſupplied by Horrebow, his diſciple, then profeſſor of aſtronomy at Copenhagen, who publiſhed, in 4to, 1753, various obſervations of Roemer, with his method of obſerving, under the title of *Baſis Aſtronomiæ*.—He had alſo printed various aſtronomical obſervations and pieces, in ſeveral volumes of the Memoirs of the Royal Academy of Sciences at Paris, of the inſtitution of 1666, particularly vol. 1 and 10 of that collection.

ROHAULT (James), a French philoſopher, was the ſon of a rich merchant at Amiens, where he was born in 1620. He cultivated the languages and belles lettres in his own country, and then was ſent to Paris to ſtudy philoſophy. He ſeems to have been a great lover of truth, at leaſt what he thought ſo, and to have ſought it with much impartiality. He read the ancient and modern philoſophers; but Des Cartes was the author who moſt engaged his notice. Accordingly he became a zealous follower of that great man, and drew up an abridgment and explanation of his philoſophy with great clearneſs and method. In the preface to his *Phyſics*, for ſo his work is called, he makes no ſcruple to ſay, that "the abilities and accompliſhments of this philoſopher muſt oblige the whole world to confeſs, that France is at leaſt as capable of producing and raiſing men verſed in all arts and branches of knowledge, as ancient Greece." Clerſelier, well known for his tranſlation of many pieces of Des Cartes, conceived ſuch an affection for Rohault, on account of his attachment to this philoſopher, that he gave him his daughter in marriage againſt all the remonſtrances of his family.

Rohault's Phyſics were written in French, but have been tranſlated into Latin by Dr. Samuel Clarke, with notes, in which the Carteſian errors are corrected upon the Newtonian ſyſtem. The fourth and beſt edition of *Rohault's Phyſica*, by Clarke, is that of 1718, in 8vo. He wrote alſo,

Elemens de Mathematiques,
Traité de Mechanique, and
Entretiens ſur la Philoſophie.

But theſe dialogues are founded and carried on upon the principles of the Carteſian philoſophy, which has now little other merit, than that of having corrected the errors of the Ancients. Rohault died in 1675, and left behind him the character of an amiable, as well as a learned and philoſophic man.

His poſthumous works were collected and printed in two neat little volumes, firſt at Paris, and then at the Hague in 1690. The contents of them are, 1. The firſt 6 books of Euclid. 2. Trigonometry. 3. Practical Geometry. 4. Fortification. 5. Mechanics. 6. Perſpective. 7. Spherical Trigonometry. 8. Arithmetic.

ROLLE (Michel), a French mathematician, was born at Ambert, a ſmall town in Auvergne, the 21ſt of April 1652. His firſt ſtudies and employments were under notaries and attorneys; occupations but little ſuited to his genius. He went to Paris in 1675, with the only reſource of fine penmanſhip, and ſubſiſted by giving leſſons in writing. But as his inclination for the mathematics had drawn him to that city, he attended the maſters in this ſcience, and ſoon became one himſelf. Ozanam propoſed a queſtion in arithmetic to him, to which Rolle gave ſo clear and good a ſolution, that the miniſter Colbert made him a handſome gratuity, which at laſt grew into a fixed penſion. He then abandoned penmanſhip, and gave himſelf up entirely to algebra and other branches of the mathematics. His conduct in life gained him many friends; in which his ſcientific merit, his peaceable and regular behaviour, with an exact and ſcrupulous probity of manners, were his only ſolicitors.

Rolle was choſen a member of the Ancient Academy of Sciences in 1685, and named ſecond geometrical-penſionary on its renewal in 1699; which he enjoyed till his death, which happened the 5th of July 1719, at 67 years of age.

The works publiſhed by Rolle, were,

I. A Treatiſe of Algebra; in 4to, 1690.

II. A method of reſolving Indeterminate Queſtions in Algebra; in 1699. Beſides a great many curious pieces inſerted in the Memoirs of the Academy of Sciences, as follow:

1. A Rule for the Approximation of Irrational Cubes: an. 1666, vol. 10.

2. A Method of Reſolving Equations of all Degrees which are expreſſed in General Terms: an. 1666, vol. 10.

3. Remarks upon Geometric Lines: 1702 and 1703.

4. On the New Syſtem of Infinity: 1703, pa. 312.

5. On the Inverſe Method of Tangents: 1705, pa. 25, 171, 222.

6. Method of finding the Foci of Geometric Lines of all kinds: 1706, pa. 284.

7. On Curves, both Geometrical and Mechanical, with their Radii of Curvature: 1707, pa. 370.

8. On the Conſtruction of Equations: 1708, and 1709.

9. On the Extermination of the Unknown Quantities in the Geometrical Analyſis: 1709, pa. 419.

ROLLING, or *Rotation*, in Mechanics, a kind of circular motion, by which the moveable body turns round its own axis, or centre, and continually applies new parts of its ſurface to the body it moves upon. Such is that of a wheel, a ſphere, a garden roller, or the like.

The motion of Rolling is oppoſed to that of ſliding; in which latter motion the ſame ſurface is continually applied to the plane it moves along.

In a wheel, it is only the circumference that properly and ſimply rolls; the reſt of the wheel proceeds in a compound angular kind of motion, and partly rolls,

rolls, partly ſlides. The want of diſtinguiſhing between which two motions, occaſioned the difficulty of that celebrated problem of Ariſtotle's Wheel.

The friction of a body in rolling, is much leſs than the friction in ſliding. And hence ariſes the great uſe of wheels, rolls, &c, in machines; as much of the action as poſſible being laid upon it, to make the reſiſtance the leſs.

ROMAN *Order*, in Architecture, is the ſame as the compoſite. It was invented by the Romans, in the time of Auguſtus; and it is made up of the Ionic and Corinthian orders, being more ornamental than either.

RONDEL, in Fortification, a round tower, ſometimes erected at the foot of a baſtion.

ROOD, a ſquare meaſure, being a quantity of land juſt equal to the 4th part of an acre, or equal to 40 perches or ſquare poles.

ROOF, in Architecture, the uppermoſt part of a building; being that which forms the covering of the whole. In this ſenſe, the Roof compriſes the timber work, together with its furniture, of ſlate, or tile, or lead, or whatever elſe ſerves for a covering: though the carpenters uſually reſtrain Roof to the timber-work only.

The form of a Roof is various: viz, 1. *Pointed*, when the ridge, or angle formed by the two ſides, is an acute angle.—2. *Square*, when the pitch or angle of the ridge is a right angle, called the true pitch.—3. *Flat* or pediment Roof, being only pediment pitch, or the angle very obtuſe. There are alſo various other forms, as hip Roofs, valley Roofs, hopper Roofs, double ridges, platforms, round, &c.—In the true pitch, when the ſides form a ſquare or right angle, the girt over both ſides of the Roof, is accounted equal to the breadth of the building and the half of the ſame.

ROOKE (LAWRENCE), an Engliſh aſtronomer and geometrician, was born at Deptford in Kent, 1623, and educated at Eton ſchool. From hence he removed to King's College, Cambridge, in 1639. After taking the degree of maſter of arts in 1647, he retired into the country. But in the year 1650 he went to Oxford, and ſettled in Wadham College, that he might have the company of, and receive improvement from Dr. Wilkins, and Mr. Seth Ward the Aſtronomy Profeſſor; and that he might alſo accompany Mr. Boyle in his chemical operations.

After the death of Mr. Foſter, he was choſen Aſtronomy Profeſſor in Greſham College, London, in the year 1652. He made ſome obſervations upon the comet at Oxford, which appeared in the month of December that year; which were printed by Mr. Seth Ward the year following. And, in 1655, Dr. Wallis publiſhing his treatiſe on Conic Sections, he dedicated that work to thoſe two gentlemen.

In 1657, Mr. Rooke was permitted to exchange the aſtronomy profeſſorſhip for that of geometry. This ſtep might ſeem ſtrange, as aſtronomy ſtill continued to be his favourite ſtudy; but it was thought to have been from the convenience of the lodgings, which opened behind the reading hall, and therefore were proper for the reception of thoſe gentlemen after the lectures, who in the year 1660 formed the Royal Society there.

Mr. Rooke having thus ſucceſſively enjoyed thoſe two places ſome years before the reſtoration in 1658, moſt of thoſe gentlemen who had been accuſtomed to aſſemble with him at Oxford, coming to London, joined with other philoſophical gentlemen, and uſually met at Greſham College to hear Mr. Rooke's lectures, and afterwards withdrew into his apartment; till their meetings were interrupted by the quartering of ſoldiers in the college that year. And after the Royal Society came to be formed and ſettled into a regular body, Mr. Rooke was very zealous and ſerviceable in promoting that great and uſeful inſtitution; though he did not live till it received its eſtabliſhment by the Royal charter.

The Marquis of Dorcheſter, who was not only a patron of learning, but learned himſelf, uſed to entertain Mr. Rooke at his ſeat at Highgate after the reſtoration, and bring him every Wedneſday in his coach to the Royal Society, which then met on that day of the week at Greſham College. But the laſt time Mr. Rooke was at Highgate, he walked from thence; and it being in the ſummer, he overheated himſelf, and taking cold after it, he was thrown into a fever, which coſt him his life. He died at his apartments at Greſham College the 27th of June 1662, in the 40th year of his age.

One other very unfortunate circumſtance attended his death, which was, that it happened the very night that he had for ſome years expected to finiſh his accurate obſervations on the ſatellites of Jupiter. When he found his illneſs prevented him from making that obſervation, Dr. Pope ſays, he ſent to the Society his requeſt, that ſome other perſon, properly qualified, might be appointed for that purpoſe; ſo intent was he to the laſt on making thoſe curious and uſeful diſcoveries, in which he had been ſo long engaged.

Mr. Rooke made a nuncupatory will, leaving what he had to Dr. Ward, then lately made biſhop of Exeter: whom he permitted to receive what was due upon bond, if the debtors offered payment willingly, otherwiſe he would not have the bonds put in ſuit: "for, ſaid he, as I never was in law, nor had any contention with any man, in my life-time; neither would I be ſo after my death."

Few perſons have left behind them a more agreeable character than Mr. Rooke, from every perſon that was acquainted with him, or with his qualifications; and in nothing more than for his veracity: for what he aſſerted poſitively, might be fully relied on: but if his opinion was aſked concerning any thing that was dubious, his uſual anſwer was, "I have no opinion." Mr. Hook has given this copious, though conciſe character of him: "I never was acquainted with any perſon who knew more, and ſpoke leſs, being indeed eminent for the knowledge and improvement of aſtronomy." Dr. Wren and Dr. Seth Ward deſcribe him, as a man of profound judgment, a vaſt comprehenſion, prodigious memory, and ſolid experience. His ſkill in the mathematics was reverenced by all the lovers of thoſe ſtudies, and his perfection in many other ſorts of learning deſerves no leſs admiration; but above all, as another writer characterizes him, his extenſive know-

ledge had a right influence on the temper of his mind, which had all the humility, goodneſs, calmneſs, ſtrength, and ſincerity, of a ſound and unaffected philoſopher. Theſe accounts give us his picture only in miniature; but his ſucceſſor, Dr. Iſaac Barrow, has drawn it in full proportion, in his oration at Greſham College; which is too long to be inſerted in this place.

His writings were chiefly;

1. *Obſervations on the Comet* of Dec. 1652. This was printed by Dr. Seth Ward, in his Lectures on Comets, 4to, 1653.

2. *Directions for Seamen going to the Eaſt and Weſt Indies.* Publiſhed in the Philoſophical Tranſactions for Jan. 1665.

3. *A Method of Obſerving the Eclipſes of the Moon &c.* In the Philoſ. Tranſ. for Feb. 1666.

4. *A Diſcourſe concerning the Obſervations of the Eclipſes of the Satellites of Jupiter.* In the Hiſtory of the Royal Society, pa. 183.

5. *An Account of an Experiment made with Oil in a long Tube.* Read to the Royal Soc. April 23, 1662 — By this experiment it was found, that the oil ſunk when the ſun ſhone out, and roſe when he was clouded; the proportions of which are ſet down in the account.

ROOT, in Arithmetic and Algebra, denotes a quantity which being multiplied by itſelf produces ſome higher power; or a quantity conſidered as the baſis or foundation of a higher power, out of which this ariſes and grows, like as a plant from its Root.

In the involution of powers, from a given Root, the Root is alſo called the firſt power; when this is once multiplied by itſelf, it produces the ſquare or ſecond power; this multiplied by the Root again, makes the cube or 3d power; and ſo on. And hence the Roots alſo come to be denominated the ſquare-Root, or cube-Root, or 2d Root, or 3d Root, &c, according as the given power or quantity is conſidered as the ſquare, or cube, or 2d power, or 3d power, &c. Thus, 2 is the ſquare-Root or 2d Root of 4, and the cube-Root or 3d Root of 8, and the 4th Root of 16, &c.

Hence, the ſquare-Root is the mean proportional between 1 and the ſquare or given power; and the cube-Root is the firſt of two mean proportionals between 1 and the given cube; and ſo on.

To Extract the Root of a given number or power. This is the ſame thing as to find a number or quantity, which being multiplied the proper number of times, will produce the given number or power. So, to find the cube Root of 8, is finding the number 2, which multiplied twice by itſelf produces the given number 8.

For the uſual methods of extracting the Roots of Numbers, ſee the common treatiſes on Arithmetic.

A Root, of any power, that conſiſts of two parts, is called a binomial Root; as 12 or 10 + 2. If it conſiſt of three parts, it is a trinomial Root; as 126 or 100 + 20 + 6. And ſo on.

The extraction of the Roots of algebraic quantities, is alſo performed after the ſame manner as that of numbers; as may be ſeen in any treatiſe on algebra. See alſo the article EXTRACTION of Roots.

A general method for all Roots, is alſo by Newton's binomial theorem. See BINOMIAL *Theorem.*

Finite approximating rules for the extraction of Roots have alſo been given by ſeveral authors, as Raphſon, De Lagney, Halley, &c. See the articles APPROXIMATION and EXTRACTION. See alſo Newton's Univerſal Arith. the Appendix; Philoſ. Tranſ. numb. 210, or Abridg. vol. 1, pa. 81; Maclaurin's Alg. pa. 242; Simpſon's Alg. pa. 155; or his Eſſays, pa. 82, or his Diſſertations, pa. 102, or his Select Exerc. pa. 215: where various general theorems for approximating to the Roots of pure powers are given. See alſo EQUATION and REDUCTION of Equations, APPROXIMATION, and CONVERGING.

But the moſt commodious and general rule of any, for ſuch approximations, I believe, is that which has been invented by myſelf, and explained in my Tracts, vol. 1, pa. 49: which theorem is this;

$\frac{n+1.N+n-1.a^n}{n-1.N+n+1.a^n}a = \sqrt[n]{N}$. That is, having to extract the nth Root of the given number N; take a^n the neareſt rational power to that given quantity N, whether greater or leſs, its Root of the ſame kind being a; then the required Root, or $\sqrt[n]{N}$, will be as is expreſſed in this formula above; or the ſame expreſſed in a proportion will be thus:

$\overline{n-1}.N+\overline{n+1}.a^n : \overline{n+1}.N+\overline{n-1}.a^n :: a : \sqrt[n]{N}$ the Root ſought very nearly. Which rule includes all the particular rational formulas of De Lagney, and Halley, which were ſeparately inveſtigated by them; and yet this general formula is perfectly ſimple and eaſy to apply, and more eaſily kept in mind than any one of the ſaid particular formulas.

Ex. Suppoſe it be required to double the cube, or to extract the cube Root of the number 2.

Here $N = 2$, $n = 3$, the neareſt Root $a = 1$, alſo $a^3 = 1$; hence, for the cube Root the formula becomes $\frac{4N + 2a^3}{2N + 4a^3}a$ or $\frac{2N + a^3}{N + 2a^3}a = \sqrt[3]{N}$.

But $N + 2a^3 = 4$, and $2N + a^3 = 5$; therefore as $4 : 5 :: 1 : \frac{5}{4} = 1{\cdot}25$ = the Root nearly by a firſt approximation.

Again, for a ſecond approximation, take $a = \frac{5}{4}$,

and conſequently $a^3 = \frac{125}{64}$;

hence $2N + a^3 = 4 + \frac{125}{64} = \frac{381}{64}$,

and $N + 2a^3 = 2 + \frac{250}{64} = \frac{378}{64}$;

therefore as $378 : 381$, or as $126 : 127 :: \frac{5}{4} : \frac{635}{504} =$ 1·259921 &c, for the required cube Root of 2, which is true even in the laſt place of decimals.

ROOT *of an Equation*, denotes the value of the unknown quantity in an equation; which is ſuch a quantity,

quantity, as being ſubſtituted inſtead of that unknown letter, into the equation, ſhall make all the terms to vaniſh, or both ſides equal to each other. Thus, of the equation $3x + 5 = 14$, the Root or value of x is 3, becauſe ſubſtituting 3 for x, makes it become $9 + 5 = 14$. And the Root of the equation $2x^2 = 32$ is 4, becauſe $2 \times 4^2 = 32$. Alſo the Root of the equation $x^2 = a^2 + c^2$ is $x = \sqrt{a^2 + c^2}$.

For the Nature of Roots, and for extracting the ſeveral Roots of equations, ſee EQUATION.

Every equation has as many Roots, or values of the unknown quantity, as are the dimenſions or higheſt power in it. As a ſimple equation one Root, a quadratic two, a cubic three, and ſo on.

Roots are poſitive or negative, real or imaginary, rational or radical, &c. See EQUATION.

Cubic ROOT. This is threefold, even for a ſimple cubic. So the cube Root of a^3, is either

$$a, \text{ or } \frac{-1+\sqrt{-3}}{2}a, \text{ or } \frac{-1-\sqrt{-3}}{2}a.$$

And even the cube Root of 1 itſelf is either

$$1, \text{ or } \frac{-1+\sqrt{-3}}{2}, \text{ or } \frac{-1-\sqrt{-3}}{2}.$$

Real and Imaginary ROOTS. The odd Roots, as the 3d, 5th, 7th, &c Roots, of all real quantities, whether poſitive or negative, are real, and are reſpectively poſitive or negative. So the cube Root of a^3 is a, and of $-a^3$ is $-a$.

But the even Roots, as the 2d, 4th, 6th, &c, are only real when the quantity is poſitive; being imaginary or impoſſible when the quantity is negative. So the ſquare Root of a^2 is a, which is real; but the ſquare Root of $-a^2$, that is, $\sqrt{-a^2}$, is imaginary or impoſſible; becauſe there is no quantity, neither $+a$ nor $-a$, which by ſquaring will make the given negative ſquare $-a^2$.

TABLE *of* ROOTS, &c.

THE following Table of Roots, Squares, and Cubes, is very uſeful in many calculations, and will ſerve to find ſquare-Roots and cube Roots, as well as ſquare and cubic powers. The Table conſiſts of three columns: in the firſt column are the ſeries of common numbers, or Roots, 1, 2, 3, 4, 5, 6, &c; in the ſecond column are the ſquares, and in the third column the cubes of the ſame. For example, to find the ſquare or the cube of the number or Root 49. Finding this number 49 in the firſt column; upon the ſame line with it, ſtands its ſquare 2401 in the ſecond column, and its cube 117649 in the third column.

Again, to find the ſquare Root of the number 700. Near the beginning of the Table, it appears that the next leſs and greater tabular ſquares are 676 and 729, whoſe Roots are 26 and 27, and therefore the ſquare Root of 700 is between 26 and 27. But a little further on, viz, among the hundreds, it appears that the required Root lies between 26·4 and 26·5, the tabular ſquares of theſe being 696·96 and 702·25, cutting off the proper part of the figures for decimals. Take the difference between the leſs ſquare 696·96 and the given number 700, which gives 3·04, and divide the half of it, viz 1·52, by the leſs given tabular Root, viz 26·4, and the quotient 575 gives as many more figures of the Root, to be joined to the firſt three, and thus making the Root equal to 26·4575, which is true in all its places.

Alſo to find the cube Root of the number 7000; near the beginning of the Table, among the tens, it appears that the cube Root of this number is between 19 and 20; but farther on, among the hundreds, it appears that it lies between 19·1 and 19·2, allowing for the proper number of integers. But if more figures are required; from the given number 7000 take the next leſs tabular one, or the cube of 19·1, viz 6967871, and there remains 32·129, the 3d part of which, or 10·730, divide by the ſquare of 19·1, viz 364·81, found on the ſame line, and the quotient 293 is the next three figures of the Root, and therefore the whole cubic Root is 19·1293, which is true in all its figures.—The Table follows.

TABLE *of Square and Cubic* ROOTS.

Root.	Square.	Cube.	Root.	Square.	Cube.	Root.	Square.	Cube.	Root.	Square.	Cube.

The following is another Table of the Square Roots of the first 1000 Numbers to 10 places of decimal figures beside the integers, which needs no farther explanation, as Numbers ſtand always in the firſt column, and their Square Roots in the next.

Table of Square Roots to Ten Decimal Places.

No.	Square Root.	No.	Square Root.	No.	Square Root.	No.	Square Root.

ROTA, in Mechanics. See WHEEL.

ROTA *Ariſtotelica*, or *Ariſtotle's Wheel*, denotes a celebrated problem in mechanics, concerning the motion or rotation of a wheel about its axis; ſo called because firſt noticed by Ariſtotle.

The difficulty is this. While a circle makes a revolution on its centre, advancing at the ſame time in a right line along a plane, it deſcribes, on that plane, a right line which is equal to its circumference. Now if this circle, which may be called the deferent, carry with it another ſmaller circle, concentric with it, like the nave of a coach wheel; then this little circle, or nave, will deſcribe a line in the time of the revolution, which ſhall be equal to that of the large wheel or circumference itſelf; becauſe its centre advances in a right line as faſt as that of the wheel does, being in reality the ſame with it.

The ſolution given by Ariſtotle, is no more than a good explication of the difficulty.

Galileo, who next attempted it, has recourſe to an infinite number of infinitely little vacuities in the right line deſcribed by the two circles; and imagines that the little circle never applies its circumference to thoſe vacuities; but in reality only applies it to a line equal to its own circumference; though it appears to have applied it to a much larger. But all this is nothing to the purpoſe.

Tacquet will have it, that the little circle, making its rotation more ſlowly than the great one, does on that account deſcribe a line longer than its own circumference; yet without applying any point of its circumference to more than one point of its baſe. But this is no more ſatisfactory than the former.

After the fruitleſs attempts of ſo many great men, M. Dortous de Meyran, a French gentleman, had the good fortune to hit upon a ſolution, which he ſent to the Academy of Sciences; where being examined by Meſſ. de Louville and Soulmon, appointed for that purpoſe, they made their report that it was ſatisfactory. The ſolution is to this effect:

The wheel of a coach is only acted on, or drawn in a right line; its rotation or circular motion ariſes purely from the reſiſtance of the ground upon which it is applied. Now this reſiſtance is equal to the force which draws the wheel in the right line, inaſmuch as it defeats that direction; of conſequence the cauſes of the two motions, the one right and the other circular, are equal. And hence the wheel deſcribes a right line on the ground equal to its circumference.

As for the nave of the wheel, the caſe is otherwiſe. It is drawn in a right line by the ſame force as the wheel; but it only turns round becauſe the wheel does ſo, and can only turn in the ſame time with it. Hence it follows, that its circular velocity is leſs than that of the wheel, in the ratio of the two circumferences; and therefore its circular motion is leſs than the rectilinear one. Since then it neceſſarily deſcribes a right line equal to that of the wheel, it can only do it partly by ſliding, and partly by revolving, the ſliding part being more or leſs as the nave itſelf is ſmaller or larger. See CYCLOID.

ROTATION, *Rolling*, in Mechanics. See ROLLING.

ROTATION, in Geometry, the circumvolution of a ſurface round an immoveable line, called the axis of Rotation. By ſuch Rotation of plane figures certain regular ſolids are formed or generated. Such as, a cylinder by the Rotation of a rectangle, a cone by the Rotation of a triangle, a ſphere or globe by the Rotation of a ſemicircle, &c.

The method of cubing ſolids that are generated by Rotation, is laid down by [illegible] doctrine [illegible] of the circle [illegible] ſolid is ny^2x; the [illegible] of which will be the content of the ſolid.

Such ſolid may alſo be expreſſed in terms of the generating plane and its centre of gravity; for it is always equal to the product arising from the [illegible] plane multiplied by the path of its centre of gravity, or by the line deſcribed by that centre in the Rotation of the plane. And this theorem is general, by whatever kind of motion the plane is moved, in deſcribing a ſolid.

ROTATION, *Revolution*, in Aſtronomy. See REVOLUTION.

Diurnal ROTATION. See DIURNAL, and EARTH.

ROTONDO, or ROTUNDO, in Architecture, a popular term for any building that is round both within and without-ſide, whether it be a church, hall, a ſaloon, a veſtibule, or the like.

ROUND, ROUNDNESS, ROTUNDITY, the property of a circle and ſphere or globe &c.

ROWNING (JOHN), an ingenious Engliſh mathematician and philoſopher, was fellow of Magdalen College, Cambridge, and afterwards Rector of Anderby in Lincolnſhire, in the gift of that ſociety. He was a conſtant attendant at the meetings of the Spalding Society, and was a man of a great philoſophical habit and turn of mind, though of a cheerful and companionable diſpoſition. He had a good genius for mechanical contrivances in particular. In 1738 he printed at Cambridge, in 8vo, *A Compendious Syſtem of Natural Philoſophy*, in 2 vols 8vo; a very ingenious work, which has gone through ſeveral editions. He had alſo two pieces inſerted in the Philoſophical Tranſactions, viz, 1. *A Deſcription of a Barometer wherein the Scale of Variation may be increaſed at pleaſure*; vol. 38, pa. 39. And 2. *Direction for making a Machine for finding the Roots of Equations univerſally, and the Manner of uſing it*; vol. 60, pa. 240.—Mr. Rowning died at his lodgings in Carey-ſtreet near Lincoln's Inn Fields, the latter end of November 1771, aged 72 years of age.

Though a very ingenious and pleaſant man, he had but an unpromiſing and forbidding appearance. He was tall, ſtooping in the ſhoulders, and of a ſallow down-looking countenance.

ROYAL *Oak*, *Robur Carolinum*, in Aſtronomy, one of the new ſouthern conſtellations, the ſtars of which,

which, according to Sharp's catalogue, annexed to the Britannic, are 12.

ROYAL *Society of England*, is an academy or body of perſons, ſuppoſed to be eminent for their learning, inſtituted by king Charles the IId, for promoting natural knowledge.

This once illuſtrious body originated from an aſſembly of ingenious men, reſiding in London, who, being inquiſitive into natural knowledge, and the new and experimental philoſophy, agreed, about the year 1645, to meet weekly on a certain day, to diſcourſe upon ſuch ſubjects. Theſe meetings, it is ſaid, were ſuggeſted by Mr. Theodore Haak, a native of the Palatinate in Germany; and they were held ſometimes at Dr. Goddard's lodgings in Wood-ſtreet, ſometimes at a convenient place in Cheapſide, and ſometimes in or near Greſham College. This aſſembly ſeems to be that mentioned under the title of the *Inviſible, or Philoſophical College*, by Mr. Boyle, in ſome letters written in 1646 and 1647. About the years 1648 and 1649, the company which formed theſe meetings, began to be divided, ſome of the gentlemen removing to Oxford, as Dr. Wallis, and Dr. Goddard, where, in conjunction with other gentlemen, they held meetings alſo, and brought the ſtudy of natural and experimental philoſophy into faſhion there; meeting firſt in Dr. Petty's lodgings, afterwards at Dr. Wilkins's apartments in Wadham College, and, upon his removal, in the lodgings of Mr. Robert Boyle; while thoſe gentlemen who remained in London continued their meetings as before. The greater part of the Oxford Society coming to London about the year 1659, they met once or twice a week in Term-time at Greſham College, till they were diſperſed by the public diſtractions of that year, and the place of their meeting was made a quarter for ſoldiers. Upon the reſtoration, in 1660, their meetings were revived, and attended by many gentlemen, eminent for their character and learning.

They were at length noticed by the government, and the king granted them a charter, firſt the 15th of July 1662, then a more ample one the 22d of April 1663, and thirdly the 8th of April 1669; by which they were erected into a corporation, *conſiſting of a preſident, council, and fellows, for promoting natural knowledge*, and endued with various privileges and authorities.

Their manner of electing members is by ballotting; and two-thirds of the members preſent are neceſſary to carry the election in favour of the candidate. The council conſiſts of 21 members, including the preſident, vice-preſident, treaſurer, and two ſecretaries; ten of which go out annually, and ten new members are elected inſtead of them, all choſen on St. Andrew's day. They had formerly alſo two curators, whoſe buſineſs it was to perform experiments before the ſociety.

Each member, at his admiſſion, ſubſcribes an engagement, that he will endeavour to promote the good of the ſociety; from which he may be freed at any time, by ſignifying to the preſident that he deſires to withdraw.

The charges are five guineas paid to the treaſurer at admiſſion; and one ſhilling per week, or 52s. per year, as long as the perſon continues a member; or, in lieu of the annual ſubſcription, a compoſition of 25 guineas in one payment.

The ordinary meetings of the ſociety, are once a week, from November till the end of Trinity term the next ſummer. At firſt, the meeting was from 3 o'clock till 6 afternoon. Afterwards, their meeting was from 6 till 7 in the evening, to allow more time for dinner, which continued for a long ſeries of years, till the hour of meeting was removed, by the preſent preſident, to between 8 and 9 at night, that gentlemen of faſhion, as was alleged, might have the opportunity of coming to attend the meetings after dinner.

Their deſign is to "make faithful records of all the "works of nature or art, which come within their "reach; ſo that the preſent, as well as after ages, "may be enabled to put a mark on errors which have "been ſtrengthened by long preſcription; to reſtore "truths that have been long neglected; to puſh thoſe "already known to more various uſes; to make the "way more paſſable to what remains unrevealed, "&c."

To this purpoſe they have made a great number of experiments and obſervations on moſt of the works of nature; as eclipſes, comets, planets, meteors, mines, plants, earthquakes, inundations, ſprings, damps, fires, tides, currents, the magnet, &c: their motto being *Nullius in Verba*. They have regiſtered experiments, hiſtories, relations, obſervations, &c, and reduced them into one common ſtock. They have, from time to time, publiſhed ſome of the moſt uſeful of theſe, under the title of Philoſophical Tranſactions, &c. uſually one volume each year, which were, till lately, very reſpectable, both for the extent or magnitude of them, and for the excellent quality of their contents. The reſt, that are not printed, they lay up in their regiſters.

They have a good library of books, which has been formed, and continually augmenting, by numerous donations. They had alſo a muſeum of curioſities in nature, kept in one of the rooms of their own houſe in Crane Court Fleet-ſtreet, where they held their meetings, with the greateſt reputation, for many years, keeping regiſters of the weather, and making other experiments; for all which purpoſes thoſe apartments were well adapted. But, diſpoſing of theſe apartments, in order to remove into thoſe allotted them in Somerſet Place, where having neither room nor convenience for ſuch purpoſes, the muſeum was obliged to be diſpoſed of, and their uſeful meteorological regiſters diſcontinued for many years.

Sir Godfrey Copley, bart. left 5 guineas to be given annually to the perſon who ſhould write the beſt paper in the year, under the head of experimental philoſophy: this reward, which is now changed to a gold medal, is the higheſt honour the ſociety can beſtow; and it is conferred on St. Andrew's day: but the communications of late years have been thought of ſo little importance, that the prize medal remains ſometimes for years undiſpoſed of.

Indeed this once very reſpectable ſociety, now conſiſting of a great proportion of honorary members, who do not uſually communicate papers; and many ſcientific members being diſcouraged from making their

uſual

uſual communications, by what is deemed the prefe[nt] arbitrary government of the ſociety; the annual v[o]lumes have in conſequence become of much le[ſs] portance, both in reſpect of their bulk and the qualit[y] of their contents.

ROYAL *Society of Scotland*. See SOCIETY.

RUDOLPHINE *Tables*, a ſet of aſtronomic[al] bles that were publiſhed by the celebrated Kepler, a[nd] ſo called from the emperor Rudolph or Rudolphus.

RULE, *The Carpenters*, a folding ruler gener[ally] uſed by carpenters and other artificers; and is other[wiſe] called the ſliding Rule.

This inſtrument conſiſts of two equal pieces of [box] wood, each one foot in length, connected togethe[r by] a folding joint. One ſide or face, of the Rule, [is] divided into inches, and half-quarters, or eighths. [On] the ſame face alſo are ſeveral plane ſcales, divided [into] 12th parts by diagonal lines; which are uſed in p[lan]ning dimenſions that are taken in feet and inches. The edge of the Rule is commonly divided decimally, or into 10ths; viz, each foot into 10 equal parts, and each of theſe into 10 parts again, or 100dth parts of the foot: ſo that by means of this laſt ſcale, dimenſions are taken in feet and tenths and hundreds, and multiplied together as common decimal numbers, which is the beſt way.

On the one part of the other face are four lines, marked A, B, C, D, the two middle ones B and C being on a ſlider, which runs in a groove made in the ſtock. The ſame numbers ſerve for both theſe two middle lines, the one line being above the numbers, and the other below them.

Theſe four lines are logarithmic ones, and the three A, B, C, which are all equal to one another, are double lines, as they proceed twice over from 1 to 10. The loweſt line D is a ſingle one, proceeding from 4 to 40. It is alſo called the girt line, from its uſe in caſting up the contents of trees and timber: and upon it are marked WG at 17·15, and AG at 18·95, the wine and ale gauge points, to make this inſtrument ſerve the purpoſe of a gauging rule.

Upon the other part of this face is a table of the value of a load, or 50 cubic feet, of timber, at all prices, from 6 pence to 2s. a foot.

When 1 at the beginning of any line is accounted only 1, then the 1 in the middle is 10, and the 10 at the end 100; and when the 1 at the beginning is accounted 10, then 1 in the middle is 100, and the 10 at the end 1000; and ſo on. All the ſmaller diviſions being alſo altered proportionally.

By means of this Rule all the uſual operations of arithmetic may be eaſily and quickly performed, as multiplication, diviſion, involution, evolution, finding mean proportionals, 3d and 4th proportionals, or the Rule-of-three, &c. For all which, ſee my Menſuration, part 5, ſect. 3, 2d edition.

RULES *of Philoſophizing*. See PHILOSOPHIZING.

RULE, in Arithmetic, denotes a certain mode of operation with figures to find ſums or numbers unknown, and to facilitate computations.

Each Rule in arithmetic has its particular name, according to the uſe for which it is intended. The firſt four, which ſerve as a foundation of the whole art, are called *addition*, *ſubtraction*, *multiplication*, and *diviſion*.

From theſe ariſe numerous other Rules, which are indeed only applications of theſe to particular purpoſes and occaſions; as the Rule-of-three, or Golden Rule, or Rule of Proportion; alſo the Rules of Fellowſhip, Intereſt, Exchanges, Poſition, Progreſſions, &c. For which, ſee each article ſeverally.

[illegible] Rule-of-Three, or Rule of Proportion, commonly [illegible] Rule from its great uſefulness [illegible] that [illegible] with proportional numbers, or three [illegible] of the equation contain 360 miles [illegible] 360 degrees, or the [illegible] tion, ſtate them proportionally, thus

		deg.	miles.	deg. miles.
as	3	: 208	::	360 : 24960
		360		
		12480		
		624		
	3	)74880		
		24960		

Then multiply the 2d and 3d terms together, and divide the product by the 1ſt term, ſo ſhall the quotient be the 4th term in proportion, or the anſwer to the queſtion, which in this example is 24960 or nearly 25 thouſand miles, for the circumference of the earth.

This rule is often conſidered as of two kinds, viz. *Direct*, and *Inverſe*.

Rule-of-Three Direct, is that in which more requires more, or leſs requires leſs. As in this; if 3 men mow 21 yards of graſs in a certain time, how much will 6 men mow in the ſame time? Here more requires more, that is, 6 men, which are more than 3 men, will alſo perform more work, in the ſame time. Or if it were thus; if 6 men mow 42 yards, how much will 3 men mow in the ſame time? here then leſs requires leſs, or 3 men will perform proportionally leſs work, in the ſame time. In both theſe caſes then, the Rule, or the proportion, is direct; and the ſtating muſt be

thus, as 3 : 21 :: 6 : 42,
or thus, as 6 : 42 :: 3 : 21.

Rule-of-Three Inverſe, is when more requires leſs or leſs requires more. As in this; if 3 men mow a certain quantity of graſs in 14 hours, in how many hours will 6 men mow the like quantity? Here it is evident that 6 men, being more than 3, will perform the ſame work in leſs time, or fewer hours; hence then more requires leſs, and the Rule or queſtion is inverſe, and muſt be ſtated by making the number of men change places, thus, as 6 : 14 :: 3 : 7 hours, the time in which 6 men will perform the work; ſtill multiplying the 2d and 3d terms together, and dividing by the 1ſt.

For various abbreviations, and other particulars relating

lating to theſe Rules, ſee any of the common books of arithmetic.

RULE-*of-Five*, or *Compound Rule-of-Three*, is where two Rules-of-three are required to be wrought, or to be combined together, to find out the number ſought.

This Rule may be performed, either by working the two ſtatings or proportions ſeparately, making the reſult or 4th term of the 1ſt operation to be the 2d term of the laſt proportion; or elſe by reducing the two ſtatings into one, by multiplying the two firſt terms together, and the two third terms together, and uſing the products as the 1ſt and 3d terms of the compound ſtating. As, if the queſtion be this: If 100l. in 2 years yield 9l. intereſt, how much will 500l. yield in 6 years. Here, the two ſtatings are,

$$\left.\begin{matrix}100\\2\end{matrix}\right\} : 9 :: \left\{\begin{matrix}500\\6\end{matrix}\right.$$

Then, to work the two ſtatings ſeparately,

as 100 : 9 :: 500 : 45l.
and 2 : 45 :: 6 : 135l.

ſo that 135l. is the intereſt or anſwer ſought. But to work by one ſtating, it will be thus,

100	500	
2	6	
200	3000	: 135l. the anſwer.

2·00) 270.00 (135l.

See the books of arithmetic for more particulars.

Central RULE. See CENTRAL *Rule*.

Parallel RULER. See PARALLEL *Ruler*.

RUMB, or RUM. See RHUMB.

RUMB-*Line*, or *Loxodromic*. See RHUMB-*Line*.

RUSTIC, in Architecture, denotes a manner of building in imitation of ſimple or rude nature, rather than according to the rules of art.

RUSTIC *Quoins*. See QUOIN.

RUSTIC *Work* is where the ſtones in the face &c of a building, inſtead of being ſmooth, are hatched or picked with the point of an inſtrument.

Regular RUSTICS, are thoſe in which the ſtones are chamfered off at the edges, and form angular or ſquare receſſes of about an inch deep at their jointings, or beds, and ends.

RUSTIC *Order*, is an order decorated with ruſtic quoins, or ruſtic work, &c.

RUTHERFORD (THOMAS, D. D.), an ingenious Engliſh philoſopher, was the ſon of the Rev. Thomas Rutherford, rector of Papworth Everard in the county of Cambridge, who had made large collections for the hiſtory of that county.

Our author was born the 13th of October 1712. He ſtudied at Cambridge, and became fellow of St. John's college, and regius profeſſor of divinity, in that univerſity; afterwards rector of Shenfield in Eſſex, and of Barley in Hertfordſhire, and archdeacon of Eſſex. He died the 5th of October 1771, at 59 years of age.

Dr. Rutherford, beſides a number of theological writings, publiſhed, at Cambridge,

1. *Ordo Inſtitutionum Phyſicarum*, 1743, in 4to.

2. *A Syſtem of Natural Philoſophy*, in 2 vols, 4to, 1748. A work which has been much eſteemed.

3. He communicated alſo to the Gentleman's Society at Spalding, a curious correction of Plutarch's deſcription of the inſtrument uſed to renew the Veſtal fire, as relating to the triangle with which the inſtrument was formed. It was nothing elſe, it ſeems, but a concave ſpeculum, whoſe principal focus, which collected the rays, is not in the centre of concavity, but at the diſtance of half a diameter from its ſurface. But ſome of the Ancients thought otherwiſe, as appears from prop. 31 of Euclid's Catoptrics.

The writer of his epitaph ſays, "He was eminent no leſs for his piety and integrity, than his extenſive learning; and filled every public ſtation in which he was placed with general approbation. In private life, his behaviour was truly amiable. He was eſteemed, beloved, and honoured by his family and friends; and his death was ſincerely lamented by all who had ever heard of his well deſerved character."

S.

SAI

S, IN books of Navigation, &c, denotes ſouth. So alſo S. E. is ſouth-eaſt; S. W. ſouth-weſt; and S. S. E. ſouth-ſouth-eaſt, &c. See COMPASS.

SAGITTA, in Aſtronomy, the *Arrow* or *Dart*, a conſtellation of the northern hemiſphere near the eagle, and one of the 48 old aſteriſms. The Greeks ſay that this conſtellation owes its origin to one of the arrows of Hercules, with which he killed the eagle or vulture that gnawed the liver of Prometheus.

The ſtars in this conſtellation, in the catalogues of Ptolomy, Tycho, and Hevelius, are only 5, but in Flamſteed's they are extended to 18.

SAGITTA, in Geometry, is a term uſed by ſome writers for the abſciſs of a curve.

SAGITTA, in Trigonometry &c, is the ſame as the verſed ſine of an arch; being ſo called becauſe it is like a dart or arrow, ſtanding on the chord of the arch.

SAGITTARIUS, SAGITTARY, the *Archer*, one of the ſigns of the zodiac, being the 9th in order, and marked with the character ♐ of a dart or arrow. This conſtellation is drawn in the figure of a Centaur, or an animal half man and half horſe, in the act of ſhooting an arrow from a bow. This figure the Greeks feign to be Crotus, the ſon of Eupheme, the nurſe of the muſes. Among more ancient nations the figure was probably meant for a hunter, to denote the hunting ſeaſon, when the ſun enters this ſign.

The ſtars in this conſtellation are, in Ptolomy's catalogue 31, in Tycho's 14, in Hevelius's 22, and in the Britannic catalogue 69.

SAILING, in a general ſenſe, denotes the movement by which a veſſel is wafted along the ſurface of the water, by the action of the wind upon her ſails.

Sailing is alſo uſed for the art or act of navigating; or of determining all the caſes of a ſhip's motion, by means of ſea charts &c. Theſe charts are conſtructed either on the ſuppoſition that the earth is a large extended flat ſurface, whence we obtain thoſe that are called plane charts; or on the ſuppoſition that the earth is a ſphere, whence are derived globular charts. Accordingly, Sailing may be diſtinguiſhed into two general kinds, viz, *plane Sailing*, and *globular Sailing*. Sometimes indeed a third ſort is added, viz, *ſpheroidical Sailing*, which proceeds upon the ſuppoſition of the ſpheroidical figure of the earth.

Plane SAILING is that which is performed by means of a plane chart; in which caſe the meridians are conſidered as parallel lines, the parallels of latitude are at right angles to the meridians, the lengths of the degrees on the meridians, equator, and parallels of latitude, are every where equal.

SAI

In Plane Sailing, the principal terms and circumſtances made uſe of, are, courſe, diſtance, departure, difference of latitude, rhumb, &c; for as to longitude, that has no place in plane Sailing, but belongs properly to globular or ſpherical ſailing. For the explanation of all which terms, ſee the reſpective articles.

If a ſhip ſails either due north or ſouth, ſhe ſails on a meridian, her diſtance and difference of latitude are the ſame, and ſhe makes no departure; but where the ſhip ſails either due eaſt or weſt, ſhe runs on a parallel of latitude, making no difference of latitude, and her departure and diſtance are the ſame. It may farther be obſerved, that the departure and difference of latitude always make the legs of a right-angled triangle, whoſe hypotenuſe is the diſtance the ſhip has ſailed; and the angles are the courſe, its complement, and the right angle; therefore among theſe four things, courſe, diſtance, difference of latitude, and departure, any two of them being given, the reſt may be found by plane trigonometry.

Thus, in the annexed figure, ſuppoſe the circle FHFH to repreſent the horizon of the place A, from whence a ſhip ſails; AC the rhumb ſhe ſails upon, and C the place arrived at: then HH repreſents the parallel of latitude ſhe ſailed from, and CC the parallel of the latitude arrived in: ſo that

AD becomes the difference of latitude.
DC the departure,
AC the diſtance ſailed,
∠DAC is the courſe, and
∠DCA the comp. of the courſe.

And all theſe particulars will be alike repreſented, whether the ſhip ſails in the NE, or NW, or SE, or SW quarter of the horizon.

From the ſame figure, in which
AE or AF or AH repreſents the rad. of the tables,
EB the ſine of the courſe,
AB the coſine of the courſe,

we may eaſily deduce all the proportions or canons, as they are uſually called by mariners, that can ariſe in Plane Sailing; becauſe the triangles ADC and ABE and AFG are evidently ſimilar. Theſe proportions are exhibited in the following Table, which conſiſts of 6 caſes, according to the varieties of the two parts that can be given.

Caſe

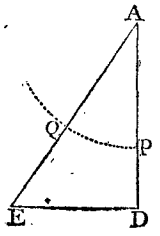
Caſe.	Given.	Required.	Solutions.
1	∠A and AC, i. e. courſe and diſtance.	AD and DC, i. e. difference of latitude and departure.	AE : AB :: AC : AD, i. e. rad. : ſ. courſe : : diſt. : dif. lat. AE : EB :: AC : DC, i. e. rad. : cof. courſe :: diſt. : depart.
2	∠A and AD, i. e. courſe and difference of latitude.	AC and DC, i. e. diſtance and departure.	AB : AE :: AD : AC, i. e. cof. cour. : rad. : : dif. lat. : diſt. AB : BE :: AD : DC, i. e. cof. cour. : ſ. cour. :: dif. lat. : dep.
3	∠A and DC, i. e. courſe and departure.	AC and AD, i. e. diſtance and difference of latitude.	BE : AE :: DC : AC, i. e. ſ. cour. : rad. : : depart. : diſt. BE : AB :: DC : AD, i. e. ſ. cour. : cof. cour. :: dep. : dif. lat.
4	AC and AD, i. e. diſtance and difference of latitude.	∠A and DC, i. e. courſe and departure.	AC : AD :: AE : AB, i. e. diſt. : dif. lat. :: rad. : cof. courſe. AE : EB :: AC : DC, i. e. rad. : ſ. courſe : : diſt. : depart.
5	AC and DC, i. e. diſtance and departure.	∠A and AD, i. e. courſe and difference of latitude.	AC : DC : : AE : EB, i. e. diſt. : dep. : : rad. : ſ. courſe. AE : AB : : AC : AD, i. e. rad. : cof. cour. : : diſt. : dif. lat.
6	AD and DC, i. e. difference of latitude and departure.	∠A and AC, i. e. courſe and diſtance.	AD : DC : : AF : FG, i. e. dif. lat. : dep. : : rad. : tang. courſe. BE : AE :: DC : AC, i. e. ſ. cour. : rad. : : dep. : diſt.

For the ready working of any ſingle courſe, there is a table, called a *Traverſe Table*, uſually annexed to treatiſes of navigation; which is ſo contrived, that by finding the given courſe in it, and a diſtance not exceeding 100 or 120 miles, the uſual extent of the table; then the difference of latitude and the departure are had by inſpection. And the ſame table will ſerve for greater diſtances, by doubling, or trebling, or quadrupling, &c; or taking proportional parts. See TRAVERSE *Table*.

An ex. to the firſt caſe may ſuffice to ſhew the method. Thus, A ſhip from the latitude 47° 30′ N, has ſailed SW by S 98 miles; required the departure made, and the latitude arrived in.

1. *By the Traverſe Table.* In the column of the courſe, viz 3 points, againſt the diſtance 98, ſtands the number 54·45 miles for the departure, and 81·5 miles for the diff. of lat.; which is 1° 21′½; and this being taken from the given lat. 47° 30′, leaves 46° 8′½ for the lat. come to.

2. *By Conſtruction.* Draw the meridian AD; and drawing an arc, with the chord of 60, make PQ or angle A equal to 3 points; through Q draw the diſtance AQE = 98 miles, and through E the departure ED perp. to AD. Then, by meaſuring, the diff. of lat. AD meaſures about 81½ miles, and the departure DE about 54½ miles.



3. *By Computation.*

Firſt, as radius - - - - - - -	10·00000
to ſin. courſe 33° 45′ - - -	9·74474
ſo diſt. 98 - - - - - - - -	1·99123
to depart. 54·45 - - - -	1·73597
Again, as radius - - - - - -	10·00000
to cof. courſe - - - - - -	9·91985
ſo diſt. 98 - - - - - - - -	1·99123
to diff. of lat. 81·48 - - -	1·91108

4. *By Gunter's Scale.* The extent from radius, or 8 points, to 3 points, on the line of fine rhumbs, applied to the line of numbers, will reach from 98 to 54½ the departure. And the extent from 8 points to 5 points, of the rhumbs, reaches from 98 to 81½ on the line of numbers, for the difference of latitude.

And in like manner for other caſes.

Traverſe SAILING, or *Compound Courſes*, is the uniting of ſeveral caſes of plane ſailing together into one; as when a ſhip ſails in a zigzag manner, certain diſtances upon ſeveral different courſes, to find the whole difference of latitude and departure made good on all of them. This is done by working all the caſes ſeparately, by means of the traverſe table, and conſtructing the figure as in this example.

Ex. A ship sailing from a place in latitude 24° 32′ N, has run five different courses and distances, as set down in the 1st and 2d columns of the following traverse table; required her present latitude, with the departure, and the direct course and distance, between the place sailed from, and the place come to.

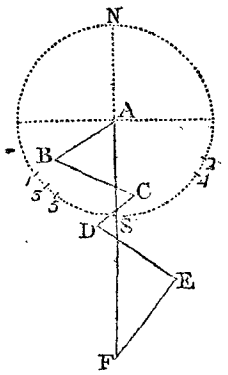
Traverse Table.

Courses.	Dist.	N	S	E	W
SW b S	45		25·0		37·4
ESE	50		19·1	46·2	
SW	30		21·2		21·2
SE b E	60		33·3	49·9	
SW b S ¼ W	63		50·6		37·5
			149·2	96·1	96·1

Here, by finding, in the general traverse table, the difference of latitude and departure answering to each course and distance, they are set down on the same lines with each course, and in their proper columns of northing, southing, casting, or westing, according to the quarter of the compass the ship sails in, at each course. As here, there is no northing, the differences of latitude are all southward, also two departures are eastward, and three are westward. Then, adding up the numbers in each column, the sum of the eastings appears to be exactly equal to the sum of the westings, consequently the ship is arrived in the same meridian, without making any departure; and the southings, or difference of latitude being 149·2 miles or minutes, that is - - - - - - - - - 2° 29′,
which taken from - - 24 32, the latitude dep. from,

leaves - - - - - - - - 22 3 N, the latitude come to.

To Construct this Traverse. With the chord of 60 degrees describe the circle N 135 S &c, and quarter it by the two perpendicular diameters; then from S set upon it the several courses, to the points marked 1, 2, 3, 4, 5, through which points draw lines from the centre A, or conceive them to be drawn; lastly, upon the first line lay off the first distance 45 from A to B, also draw BC = 50 and parallel to A 2, and CD = 30 parallel to A 3, and DE = 60 parallel to A 4, and EF = 63, parallel to A 5; then it is found that the point F falls exactly upon the meridian NAF produced, thereby shewing that there is no departure; and by measuring AF, it gives 149 miles for the difference of latitude.

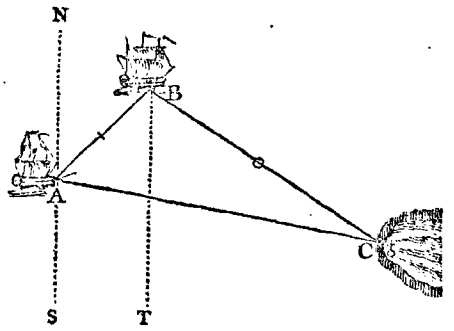


Oblique SAILING, is the resolution of certain cases and problems in Sailing by oblique triangles, or in which oblique triangles are concerned.

In this kind of Sailing, it may be observed, that *to set an object*, means to observe what rhumb or point of the nautical compass is directed to it. And the *bearing* of an object is the rhumb on which it is seen; also the bearing of one place from another, is reckoned by the name of the rhumb passing through those two places.

In every figure relating to any case of plane Sailing, the bearing of a line, not running from the centre of the circle or horizon, is found by drawing a line parallel to it, from the centre, and towards the same quarter.

Ex. A ship sailing at sea, observed a point of land to bear E by S; and then after sailing NE 12 miles, its bearing was found to be SE by E. Required the place of that point, and its distance from the ship at the last observation.



Construction. Draw the meridian line NAS, and, assuming A for the first place of the ship, draw AC the E by S rhumb, and AB the NE one, upon which lay off 12 miles from A to B; then draw the meridian BT parallel to NS, from which set off the SE by E point BC, and the point C will be the place of the land required; then the distance BC measures 26 miles.

By Computation. Here are given the side AB, and the two angles A and B, viz, the ∠A = 5 points or 56° 15′, and the ∠B = 9 points or 101° 15′; consequently the ∠C = 2 points or 22° 30′. Then, by plane trigonometry,

As sin. ∠C	22° 30′	9·58284
To sin. ∠B	56 15	9·91985
So is AB	12 miles	1·07918
To BC	26·073 miles	1·41619

SAILING *to Windward*, is working the ship towards that quarter of the compass from whence the wind blows.

For rightly understanding this part of navigation, it will be necessary to explain the terms that occur in it, though most of them may be seen in their proper places in this work.

When the wind is directly, or partly, against a ship's direct course for the place she is bound to, she reaches her port by a kind of zigzag or z like course; which is made by sailing with the wind first on one side of the ship, and then on the other side.

In a ship, when you look towards the head, *Starboard* denotes the right hand side.

Larboard

Larboard the left hand ſide.

Forwards, or *afore*, is towards the head.

Aft, or *abaft*, is towards the ſtern.

The *beam* ſignifies athwart or acroſs the middle of the ſhip.

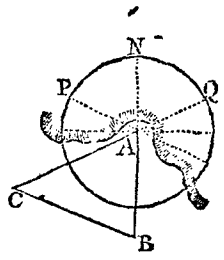
When a ſhip ſails the ſame way that the wind blows, ſhe is ſaid to ſail or run before the wind; and the wind is ſaid to be *right aft*, or *right aſtern*; and her courſe is then 16 points, or the fartheſt poſſible, from the wind, that is from the point the wind blows from.—When the ſhip ſails with the wind blowing directly acroſs her, ſhe is ſaid to have the *wind on the beam*; and her courſe is 8 points from the wind.—When the wind blows obliquely acroſs the ſhip, the wind is ſaid to be *abaft the beam* when it purſues her, or blows more on the hinder part, but *before the beam* when it meets or oppoſes her courſe, her courſe being more than 8 points from the wind in the former caſe, but leſs than 8 points in the latter caſe.—When a ſhip endeavours to ſail towards that point of the compaſs from which the wind blows, ſhe is ſaid to *ſail on a wind*, or to *ply to windward*.—And a veſſel ſailing as near as ſhe can to the point from which the wind blows, ſhe is ſaid to be *cloſe hauled*. Moſt ſhips will lie within about 6 points of the wind; but ſloops, and ſome other veſſels, will lie much nearer. To know how near the wind a ſhip will lie; obſerve the courſe ſhe goes on each tack, when ſhe is cloſe hauled; then half the number of points between the two courſes, will ſhew how near the wind the ſhip will lie.

The *windward*, or *weather ſide*, is that ſide of the ſhip on which the wind blows; and the other ſide is called the *leeward*, or *lee ſide*.—*Tacks* and *ſheets* are large ropes faſtened to the lower corners of the fore and main ſails; by which either of theſe corners is hauled fore or aft.—When a ſhip ſails on a wind, the windward tacks are always hauled forwards, and the leeward ſheets aft.—The *ſtarboard tacks are aboard*, when the ſtarboard ſide is to windward, and the larboard ſide to leeward. And the *larboard tacks are aboard*, when the larboard ſide is to windward, and the ſtarboard to leeward.

The moſt common caſes in turning to windward may be conſtructed by the following precepts. Having drawn a circle with the chord of 60°, for the compaſs, or the horizon of the place, quarter it by drawing the meridian and parallel of latitude perpendicular to each other, and both through the centre; mark the place of the wind in the circumference; draw the rhumb paſſing through the place bound to, and lay on it, from the centre, the diſtance of that place. On each ſide of the wind lay off, in the circumference, the points or degrees ſhewing how near the wind the ſhip can lie; and draw theſe rhumbs.—Now the firſt courſe will be on one of theſe rhumbs, according to the tack the ſhip leads with. Draw a line through the place bound to, parallel to the other rhumb, and meeting the firſt; and this will ſhew the courſe and diſtance on the other tack.

Ex. The wind being at north, and a ſhip bound to a port 25 miles directly to windward; beginning with the ſtarboard tacks, what muſt be the courſe and diſtance on each of two tacks to reach the port?

Conſtruction. Having drawn the circle &c, as above deſcribed, where A is the port, AP and AQ the two rhumbs, each within 6 points of AN; in NA produced take AB = 25 miles, then B is the place of the ſhip; draw BC parallel to AP, and meeting QA produced in C; ſo ſhall BC and CA be the diſtances on the two tacks; the former being WNW, and the latter ENE.



Computation.

Here ∠B = NAP = 6 points,
and ∠A = NAQ = 6 points,
therefore ∠C = 4 points.

So that all the angles are given, and the ſide AB, to find the other two ſides AC and BC, which are equal to each other, becauſe their oppoſite angles A and B are equal. Hence

as ſin. C : AB : : ſin. A : BC,
i. e. s. 45° : 25 : : s. 67° 30′ : 32$\frac{2}{3}$ = BC or AC, the diſtance to be run on each tack.

SAILING *in Currents*, is the method of determining the true courſe and diſtance of a ſhip when her own motion is affected and combined with that of a current.

A *current* or *tide* is a progreſſive motion of the water, cauſing all floating bodies to move that way towards which the ſtream is directed.—The *ſetting* of a tide, or current, is that point of the compaſs towards which the waters run; and the *drift* of the current is the rate at which it runs per hour.

The drift and ſetting of the moſt remarkable tides and currents, are pretty well known; but for unknown currents, the uſual way to find the drift and ſetting, is thus: Let three or four men take a boat a little way from the ſhip; and by a rope, faſtened to the boat's ſtem, let down a heavy iron pot, or loaded kettle, into the ſea, to the depth of 80 or 100 fathoms, when it can be done: by which means the boat will ride almoſt as ſteady as at anchor. Then heave the log, and the number of knots run out in half a minute will give the current's rate, or the miles which it runs per hour; and the bearing of the log ſhews the ſetting of the current.

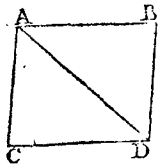
A body moving in a current, may be conſidered in three caſes: viz,

1. Moving with the current, or the ſame way it ſets.
2. Moving againſt it, or the contrary way it ſets.
3. Moving obliquely to the current's motion.

In the 1ſt caſe, or when a ſhip ſails with a current, its velocity will be equal to the ſum of its proper motion, and the current's drift. But in the 2d caſe, or when a ſhip ſails againſt a current, its velocity will be equal to the difference of her own motion and the drift of the current: ſo that if the current drives ſtronger than the wind, the ſhip will drive aſtern, or loſe way. In the 3d caſe, when the current ſets oblique to the courſe of the ſhip, her real courſe, or that made good, will be ſomewhere between that in which the ſhip endeavours to go, and the track in which the current tries to drive her; and indeed it will always be along the diagonal of a parallelogram, of which one ſide repreſents the ſhip's courſe ſet, and the other adjoining ſide is the current's drift.

Thus,

Thus, if ABDC be a parallelogram. Now if the wind alone would drive the ſhip from A to B in the ſame time as the current alone would drive her from A to C: then, as the wind neither helps nor hinders the ſhip from coming towards the line CD, the current will bring her there in the ſame time as if the wind did not act. And as the current neither helps nor hinders the ſhip from coming towards the line BD, the wind will bring her there in the ſame time as if the current did not act. Therefore the ſhip muſt, at the end of that time, be found in both thoſe lines, that is, in their meeting D. Conſequently the ſhip muſt have paſſed from A to D in the diagonal AD.



Hence, drawing the rhumbs for the proper courſe of the ſhip and of the current, and ſetting the diſtances off upon them, according to the quantity run by each in the given time; then forming a parallelogram of theſe two, and drawing its diagonal, this will be the real courſe and diſtance made good by the ſhip.

Ex. 1. A ſhip ſails E. 5 miles an hour, in a tide ſetting the ſame way 4 miles an hour: required the ſhip's courſe, and the diſtance made good.

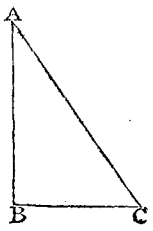
The ſhip's motion is	5m. E.
The current's motion is	4m. E.
Theref. the ſhip's run is	9m. E.

Ex. 2. A ſhip ſails SSW. with a briſk gale, at the rate of 9 miles an hour, in a current ſetting NNE. 2 miles an hour: required the ſhip's courſe, and the diſtance made good.

The ſhip's motion is	SSW. 9m.
The current's motion is	NNE. 2m.
Theref. ſhip's true run is	SSW. 7m.

Ex. 3. A ſhip running ſouth at the rate of 5 miles an hour, in 10 hours croſſes a current, which all that time was ſetting eaſt at the rate of 3 miles an hour: required the ſhip's true courſe and diſtance ſailed.

Here the ſhip is firſt ſuppoſed to be at A, her imaginary courſe is along the line AB, which is drawn ſouth, and equal to 50 miles, the run in 10 hours; then draw BC eaſt, and equal to 30 miles, the run of the current in 10 hours. Then the ſhip is found at C, and her true path is in the line AC = 58·31 her diſtance, and her courſe is the angle at A = 30° 58′ from the ſouth towards the eaſt.



Globular SAILING is the eſtimating the ſhip's motion and run upon principles derived from the globular figure of the earth, viz, her courſe, diſtance, and difference of latitude and longitude.

The principles of this method are explained under the articles RHUMB-*line*, *Mercator's* CHART, and MERIDIONAL *Parts*; which ſee.

Globular Sailing, in the extenſive ſenſe here applied to the term, comprehends *Parallel Sailing*, *Middle-latitude Sailing*, and *Mercator's Sailing*; to which may be added *Circular Sailing*, or *Great-circle Sailing*. Of each of which it may be proper here to give a brief account.

Parallel SAILING is the art of finding what diſtance a ſhip ſhould run due eaſt or weſt, in ſailing from the meridian of one place to that of another place, in any parallel of latitude.

The computations in parallel ſailing depend on the following rule:

As radius,
To coſine of the lat. of any parallel;
So are the miles of long. between any two meridians,
To the diſt. of theſe meridians in that parallel.

Alſo, for any two latitudes,
As the coſine of one latitude,
Is to the coſine of another latitude;
So is a given meridional diſt. in the 1ſt parallel,
To the like meridional diſt. in the 2d parallel.

Hence, counting 60 nautical miles to each degree of longitude, or on the equator; then, by the firſt rule the number of miles in each degree on the other parallels, will come out as in the following table.

Table of Meridional Diſtances.

Lat.	Miles.	Lat.	Miles.	Lat.	Miles.
1	59·99	31	51·43	61	29·09
2	59·96	32	50·88	62	28·17
3	59·92	33	50·32	63	27·24
4	59·85	34	49·74	64	26·30
5	59·77	35	49·15	65	25·36
6	59·67	36	48·54	66	24·41
7	59·56	37	47·92	67	23·44
8	59·42	38	47·28	68	22·48
9	59·26	39	46·63	69	21·50
10	59·09	40	45·96	70	20·52
11	58·89	41	45·28	71	19·53
12	58·69	42	44·59	72	18·54
13	58·46	43	43·88	73	17·54
14	58·22	44	43·16	74	16·54
15	57·95	45	42·43	75	15·53
16	57·67	46	41·68	76	14·51
17	57·38	47	40·92	77	13·50
18	57·06	48	40·15	78	12·48
19	56·73	49	39·36	79	11·45
20	56·38	50	38·57	80	10·42
21	56·01	51	37·76	81	9·38
22	55·63	52	36·94	82	8·35
23	55·23	53	36·11	83	7·32
24	54·81	54	35·27	84	6·28
25	54·38	55	34·41	85	5·23
26	53·93	56	33·55	86	4·18
27	53·46	57	32·68	87	3·14
28	52·97	58	31·79	88	2·09
29	52·47	59	30·90	89	1·05
30	51·96	60	30·00	90	0·00

See another table of this kind, allowing $69\frac{1}{15}$ Engliſh miles to one degree, under the article DEGREE.

To find the meridional diſtance to any number of minutes between any of the whole degrees in the table, as for inſtance in the parallel of 48° 26′; take out the tabular diſtances for the two whole degrees between which the parallel or the odd minutes lie, as for 48° and 49°; ſubtract the one from the other, and take the proportional part of the remainder for the odd minutes, by multiplying it by thoſe minutes, and dividing by 60; and laſtly, ſubtract this proportional part from the greater tabular number. Thus,

Lat. 48° - -	40·15	
Lat. 49. - -	39·36	
As 60′ : 26′ : :	0·79 rem. : 0·34	
	26	
	474	
	158	
60)	20·54	
	0·34	pro. part
Taken from -	40·15	for lat. 48°
Leaves merid. diſt.	39·81	for lat. 48° 26′

And, in like manner, by the counter operation, to find what latitude anſwers to a given meridional diſtance. As, for ex. in what latitude 46·08 miles anſwer to a degree of longitude.

From 46·63 for 39°	from 46·63 for 39°
Take 45·96 for 40°	take 46·08 given number.
Then as 0·67 : 60′ : :	0·55 : 49′
	60
	67) 3300
	49′ pro. part.

Therefore the latitude ſought is 39° 49′.

Ex. 3. Given the latitude and meridional diſtance; to find the correſponding difference of longitude. As, if a ſhip, in latitude 53° 36′, and longitude 10° 18 eaſt, ſail due weſt 236 miles; required her preſent longitude.

Here, by the firſt rule,

As coſ. lat.	53° 36′ comp.	0·22664
To radius -	90 00 - -	10·00000
So merid. diſt.	236 m. -	2·37291
To diff. long.	397·7 - -	2·59955

Its 60th gives 6° 38′ W. diff. long.
Taken from 10 18 E. long. from

Leaves - - 3 40 E. long. come to.

By the table; the length of a degree on the parallel of 53° 36′ is 35·6.

Then as 35·6 : 60 : : 236 : 397·7, the diff. of long. the ſame as before.

Middle-latitude SAILING, is a method of reſolving the caſes of globular Sailing by means of the middle latitude between the latitude departed from, and that come to. This method is not quite accurate, being only an approximation to the truth, and it makes uſe of the principles of plane Sailing and parallel Sailing conjointly.

The method is founded on the ſuppoſition that the departure is reckoned as a meridional diſtance in that latitude which is a middle parallel between the latitude ſailed from, and the latitude come to. And the method is not quite accurate, becauſe the arithmetical mean, or half ſum of the coſines of two diſtant latitudes, is not exactly the coſine of the middle latitude, or half the ſum of thoſe latitudes; nor is the departure between two places, on an oblique rhumb, equal to the meridional diſtance in the middle latitude; as is preſumed in this method. Yet when the parallels are near the equator, or near to each other, in any latitude, the error is not conſiderable.

This method ſeems to have been invented on account of the eaſy manner in which the ſeveral caſes may be reſolved by the traverſe table, and when a table of meridional parts is wanting. The computations depend on the following rules:

1. Take half the ſum, or the arithmetical mean, of the two given latitudes, for the middle latitude. Then,

2. As coſine of middle latitude,
Is to the radius;
So is the departure,
To the diff. of longitude. And,

3. As coſine of middle latitude,
Is to the tangent of the courſe;
So is the difference of latitude,
To the difference of longitude.

Mercator's SAILING, is the art of reſolving the ſeveral caſes of globular Sailing, by plane trigonometry, with the aſſiſtance of a table of meridional parts, or of logarithmic tangents. And the computations are performed by the following rules:

1. As meridional diff. lat.
To diff. of longitude;
So is the radius,
To tangent of the courſe.

2. As the proper diff lat.
To the departure;
So is merid. diff. lat.
To diff. of longitude.

3. As diff. log. tang. half colatitudes,
To tang. of 51° 38′ 09″;
So is a given diff. longitude,
To tangent of the courſe.

The manner of working with the meridional parts and logarithmic tangents, will appear from the two following caſes.

1. Given the latitudes of two places; to find their meridional difference of latitude.

By the Merid. Parts. When the places are both on the

the same side of the equator, take the difference of the meridional parts answering to each latitude; but when the places are on opposite sides of the equator, take the sum of the same parts, for the meridional difference of latitude sought.

By the Log. Tangents. In the former case, take the difference of the long. tangents of the half colatitudes; but in the latter case, take the sum of the same; then the said difference or sum divided by 12·63, will give the meridional difference of latitude sought.

2. Given the latitude of one place, and the meridional difference of latitude between that and another place; to find the latitude of this latter place.

By the Merid. Parts. When the places have like names, take the sum of the merid. parts of the given lat. and the given diff.; but take the difference between the same when they have unlike names; then the result, being found in the table of meridional parts, will give the latitude sought.

By the Log. Tangents. Multiply the given meridional diff. of lat. by 12·63; then in the former case subtract the product from the log. tangent of the given half colatitude, but in the latter case add them; then seek the degrees and minutes answering to the result among the log. tangents, and these degrees, &c. doubled will be the colatitude sought.

Circular SAILING, or *Great-circle* SAILING, is the art of finding what places a ship must go through, and what courses to steer, that her track may be in the arc of a great circle on the globe, or nearly so, passing through the place sailed from and the place bound to.

This method of Sailing has been proposed, because the shortest distance between two places on the sphere, is an arc of a great circle intercepted between them, and not the spiral rhumb passing through them, unless when that rhumb coincides with a great circle, which can only be on a meridian, or on the equator.

As the solutions of the cases in Mercator's Sailing are performed by plane triangles, in this method of Sailing they are resolved by means of spherical triangles. A great variety of cases might be here proposed, but those that are the most useful, and most commonly occur, pertain to the following problem.

Problem I. Given the latitudes and longitudes of two places on the earth; to find their nearest distance on the surface, together with the angles of position from either place to the other.

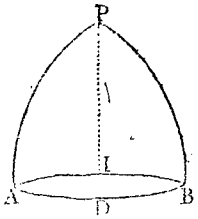
This problem comprehends 6 cases.

Case 1. When the two places lie under the same meridian; then their difference of latitude will give their distance, and the position of one from the other will be directly north and south.

Case 2. When the two places lie under the equator; their distance is equal to their difference of longitude, and the angle of position is a right angle, or the course from one to the other is due east or west.

Case 3. When both places are in the same parallel of latitude. Ex. gr. The places both in 37° north, but the longitude of the one 25° west, and of the other 76° 23′ west.

Let P denote the north pole, and A and B the two places on the same parallel BDA, also BIA their distance asunder, or the arc of a great circle passing through them. Then is the angle A or B that of position, and the angle BPA = 51° 23′ the difference of longitude, and the side PA or PB = 53° the colatitude.

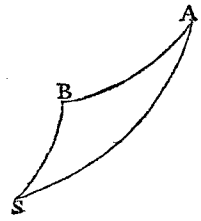


Draw PI perp. to AB, or bisecting the angle at P. Then in the triangle API, right-angled at I, are given the hypotenuse AP = 53°, and the angle API = 25° 41′ 30″; to find the angle of position A or B = 73° 51′; and the half distance AI = 20° 15′½; this doubled gives 40° 31′ for the whole distance AB, or 2431 nautical miles, which is 31 miles less than the distance along ADB, or by parallel Sailing.

Case 4. When one place has latitude, and the other has none, or is under the equator. For example, suppose the Island of St. Thomas, lat. 0°, and long. 1° 0′ east, and Port St. Julian, in lat. 48° 51′ south, and long. 65° 10′ west.

Port St. Julian, lat. 48° 51′ S.	-	long. 65° 10′ W.	
Isle St. Thomas - 0 00	- - - -	1 00 E	
Julian's colat.	41 09	Diff. long.	66 10

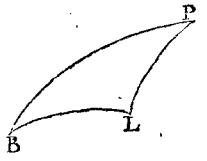
Hence, if S denote the south pole, A the Isle St. Thomas at the equator, and B St. Julian; then in the triangle are given SA a quadrant or 90°, BS = 41° 9′ the colat. of St. Julian, and the ∠S = 66° 10′ the dif. of longitude; to find AB = 74° 35′ = 4475 miles, which is less by 57 miles than the distance found by Mercator's Sailing; also the angle of position at A = 51°22′, and the angle of position B = 108° 24′.



Case 5. When the two given places are both on the same side of the equator; for example the Lizard, and the island of Bermudas.

The Lizard, lat. 49° 57′ N.	-	long. 5° 21′ W.	
Bermudas, 32 35 N.	-	63 32 W.	
		58 11	

Here, if P be the north pole, L the Lizard, and B Bermudas; there are given, PL = 40° 03′ colat. of the Lizard, PB = 57 25 colat. of Bermudas, ∠P = 58 11 diff. of longitude; to find BL = 45° 44 = 2744 miles the distance, and ∠ of position B = 49° 27′, also ∠ of position L = 90° 31′.

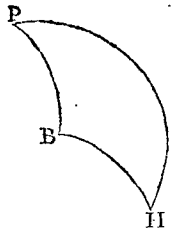


Case 6. When the given places lie on different sides of the equator; as suppose St. Helena and Bermudas. Here

PB = 57° 25′ polar dist. Bermudas,

PH = 105 55 polar dist. St. Helena,

∠P = 57 43 diff. long.



To find BH = 73° 26′ = 4406 miles, the distance, also the angle of position H = 48° 0′, and the angle of position B = 121° 59′.

From the solutions of the foregoing cases it appears, that to sail on the arc of a great circle, the ship must continually alter her course; but as this is a difficulty too great to be admitted into the practice of navigation, it has been thought sufficiently exact to effect this business by a kind of approximation, that is, by a method which nearly approaches to the sailing on a great circle: namely, upon this principle, that in small arcs, the difference between the arc and its chord or tangent is so small, that they may be taken for one another in any nautical operations: and accordingly it is supposed that the great circles on the earth are made up of short right lines, each of which is a segment of a rhumb line. On this supposition the solution of the following problem is deduced.

Problem II. Having given the latitudes and longitudes of the places sailed from and bound to; to find the successive latitudes on the arc of a great circle in those places where the alteration in longitude shall be a given quantity; together with the courses and distances between those places.

1. Find the angle of position at each place, and their distance, by one of the preceding cases.

2. Find the greatest latitude the great circle runs through, i. e. find the perpendicular from the pole to that circle; and also find the several angles at the pole, made by the given alterations of longitude between this perpendicular and the successive meridians come to.

3. With this perpendicular and the polar angles severally, find as many corresponding latitudes, by saying, as radius : tang. greatest lat. : : cos. 1st polar angle : tang. 1st lat. : : cos. 2d polar angle : tang. of 2d lat. &c.

4. Having now the several latitudes passed through, and the difference of longitude between each, then by Mercator's Sailing find the courses and distances between those latitudes. And these are the several courses and distances the ship must run, to keep nearly on the arc of a great circle.

The smaller the alterations in longitude are taken, the nearer will this method approach to the truth; but it is sufficient to compute to every 5 degrees of difference of longitude; as the length of an arc of 5 degrees differs from its chord, or tangent, only by 0·002.

The track of a ship, when thus directed nearly in the arc of a great circle, may be delineated on the Mercator's chart, by marking on it, by help of the latitudes and longitudes, the successive places where the ship is to alter her course; then those places or points, being joined by right lines, will shew the path along which the ship is to sail, under the proposed circumstances.

On the subject of these articles, see Robertson's Elements of Navigation, vol. 2.

Spheroidical SAILING, is computing the cases of navigation on the supposition or principles of the spheroidical figure of the earth. See Robertson's Navigation, vol. 2, b. 8. sect. 8.

SAILING, *in a more confined sense*, is the art of conducting a ship from place to place, by the working or handling of her sails and rudder.

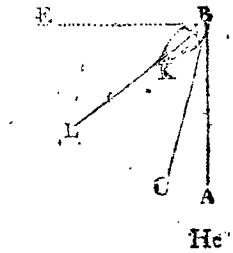
To bring Sailing to certain rules, M. Renau computes the force of the water, against the ship's rudder, stem, and side; and the force of the wind against her sails. In order to this, he first considers all fluid bodies, as the air, water, &c, as composed of little particles, which when they act upon, or move against any surface, do all move parallel to one another, or strike against the surface after the same manner. Secondly, that the motion of any body, with regard to the surface it strikes, must be either perpendicular, parallel, or oblique.

From these principles he computes, that the force of the air or water, striking perpendicularly upon a sail or rudder, is to the force of the same striking obliquely, in the duplicate ratio of radius to the sine of the angle of incidence: and consequently that all oblique forces of the wind against the sails, or of the water against the rudder, will be to one another in the duplicate ratio of the sines of the angles of incidence.

Such are the conclusions from theory; but it is very different in real practice, or experiments, as appears from the tables of experiments inserted at the article RESISTANCE.

Farther, when the different degrees of velocity are considered, it is also found that the forces are as the squares of the velocities of the moving air or water nearly; that is, a wind that blows twice as swift, as another, will have 4 times the force upon the sail; and when 3 times as swift, 9 times the force, &c. And it being also indifferent, whether we consider the motion of a solid in a fluid at rest, or of the fluid against the solid at rest; the reciprocal impressions being always the same; if a solid be moved with different velocities in the same fluid matter, as water, the different resistances which it will receive from that water, will be in the same proportion as the squares of the velocities of the moving body.

He then applies these principles to the motions of a ship, both forwards and sideways, through the water, when the wind, with certain velocities, strikes the sails in various positions. After this, the author proceeds to demonstrate, that the best position or situation of a ship, so as she may make the least lee-way, or side motion, but go to windward as much as possible, is this: that, let the sail have what situation it will, the ship be always in a line bisecting the complement of the wind's angle of incidence upon the sail. That is, supposing the sail in the position BC, and the wind blowing from A to B, and consequently the angle of the wind's incidence on the sail is ABC, the complement of which is CBE: then must the ship be put in the position BK, or move in the line BL, bisecting the ∠ CBE.



He ſhews farther, that the angle which the ſail ought to make with the wind, i. e. the angle ABC, ought to be but 24 degrees; that being the moſt advantageous ſituation to go to windward the moſt poſſible.

To this might be added many curious particulars from Borelli de Vi Percuſſionis, concerning the different directions given to a veſſel by the rudder, when ſailing with a wind, or floating without ſails in a current: in the former caſe, the head of the ſhip always coming to the rudder, and in the latter always flying off from it; as alſo from Euler, Bouguer, and Juan, who have all written learnedly on this ſubject.

SALIANT, in Fortification, is ſaid of an angle that projects its point outwards; in oppoſition to a re-entering angle, which has its point turned inwards. Inſtances of both kinds of theſe we have in tenailles and ſtar-works.

SALON, or SALOON, in Architecture, a grand, lofty, ſpacious ſort of hall, vaulted at top, and uſually comprehending two ſtories, with two ranges of windows. It is ſometimes built ſquare, ſometimes round or oval, ſometimes octagonal, as at Marly, and ſometimes in other forms.

SAP, or SAPP, in Building, as to ſap a wall, &c, is to dig out the ground from beneath it, ſo as to bring it down all at once for want of ſupport.

SAP, in the Military Art, denotes a work carried on under cover of gabions and faſcines on the flank, and mantlets or ſtuffed gabions on the front, to gain the deſcent of a ditch, or the like.

It is performed by digging a deep trench, deſcending by ſteps from top to bottom, under a corridor, carrying it as far as the bottom of the ditch, when that is dry; or as far as the ſurface of the water, when wet.

SAROS, in Chronology, a period of 223 lunar months. The etymology of the word is ſaid to be Chaldean, ſignifying reſtitution, or return of eclipſes; that is, conjunctions of the ſun and moon in nearly the ſame place of the ecliptic. The Saros was a cycle like to that of Meto.

SARRASIN, or SARRAZIN, in Fortification, a kind of port-cullis, otherwiſe called a herſe, which is hung with ropes over the gate of a town or fortreſs, to be let fall in caſe of a ſurpriſe.

SATELLITES, in Aſtronomy, are certain ſecondary planets, moving round the other planets, as the moon does round the earth. They are ſo called becauſe always found attending them, from riſing to ſetting, and making the tour about the ſun together with them.

The words moon and Satellite are ſometimes uſed indifferently: thus we ſay, either Jupiter's moons, or Jupiter's Satellites; but uſually we diſtinguiſh, reſtraining the term moon to the earth's attendant, and applying the term Satellite to the little moons more recently diſcovered about Jupiter, Saturn, and the Georgian planet, by the aſſiſtance of the teleſcope, which is neceſſary to render them viſible.

The Satellites move round their primary planets, as their centres, by the ſame laws as thoſe primary ones do round their centre the ſun; viz, in ſuch manner that, in the Satellites of the ſame planet, the ſquares of the periodic times are proportional to the cubes of their diſtances from the primary planet. For the phyſical cauſe of their motions, ſee GRAVITY. See alſo PLANETS.

We know not of any Satellites beſide thoſe above mentioned; what other diſcoveries may be made by farther improvements in teleſcopes, time only can bring to light.

SATELLITES *of Jupiter*. There are are four little moons, or ſecondary planets now known performing their evolutions about Jupiter, as that planet does about the Sun.

Simon Marius, mathematician of the elector of Brandenburg, about the end of November 1609, obſerved three little ſtars moving round Jupiter's body, and proceeding along with him; and in January 1610, he found a 4th. In January 1610 Galileo alſo obſerved the ſame in Italy, and in the ſame year publiſhed his obſervations. Theſe Satellites were alſo obſerved in the ſame month of January 1710, by Thomas Harriot, the celebrated author of a work upon algebra, and who made conſtant obſervations of theſe Satellites, from that time till the 26th of February 1612; as appears by his curious aſtronomical papers, lately diſcovered by Dr. Zach, at the ſeat of the earl of Egremont, at Petworth in Suſſex.

One Antony Maria Schyrlæus di Reita, a capuchin of Cologne, imagined that, beſides the four known Satellites of Jupiter, he had diſcovered five more, on December 29, 1642. But the obſervation being communicated to Gaſſendus, who had obſerved Jupiter on the ſame day, he ſoon perceived that the monk had miſtaken five fixed ſtars, in the effuſion of the water of Aquarius, marked in Tycho's catalogue 24, 25, 26, 27, 28, for Satellites of Jupiter.

When Jupiter comes into a line between any of his Satellites and the ſun, the Satellite diſappears, being then *eclipſed*, or involved in his ſhadow.—When the Satellite goes behind the body of Jupiter, with reſpect to an obſerver on the earth, it is then ſaid to be *occulted*, being hid from our ſight by his body, whether in his ſhadow or not.—And when the Satellite comes into a poſition between Jupiter and the Sun, it caſts a ſhadow upon the face of that planet, which we ſee as an obſcure round ſpot.—And laſtly, when the Satellite comes into a line between Jupiter and us, it is ſaid to *tranſit* the diſc of the planet, upon which it appears as a round black ſpot.

The periods or revolutions of Jupiter's Satellites, are found out from their conjunctions with that planet; after the ſame manner, as thoſe of the primary planets are diſcovered from their oppoſitions to the ſun. And their diſtances from the body of Jupiter, are meaſured by a micrometer, and eſtimated in ſemidiameters of that planet, and thence in miles.

By the lateſt and moſt exact obſervations, the periodical times and diſtances of theſe Satellites, and the angles under which their orbits are ſeen from the earth, at its mean diſtance from Jupiter, are as below:

SATEL-

SATELLITES *of* JUPITER.

Satellites.	Periodic Times.	Distances in Semidiameters.	Distances in Miles.	Angles of Orbit.
1	1d 18h 27′ 34″	5⅔	266,000	3′ 55″
2	3 13 13 42	9 1/9	423,000	6 14
3	7 3 42 36	14 5/9	676,000	9 58
4	16 16 32 9	25 5/9	1,189,000	17 30

The eclipses of the Satellites, especially of those of Jupiter, are of very great use in astronomy. First, in determining pretty exactly the distance of Jupiter from the earth. A second advantage still more considerable, which is drawn from these eclipses, is the proof which they give of the progressive motion of light. It is demonstrated by these eclipses, that light does not come to us in an instant, as the Cartesians pretended, although its motion is extremely rapid. For if the motion of light were infinite, or came to us in an instant, it is evident that we should see the commencement of an eclipse of a Satellite at the same moment, at whatever distance we might be from it; but, on the contrary, if light move progressively, then it is as evident, that the farther we are from a planet, the later we shall be in seeing the moment of its eclipse, because the light will take up a longer time in arriving at us; and so it is found in fact to happen, the eclipses of these Satellites appearing always later and later than the true computed times, as the earth removes farther and farther from the planet. When Jupiter and the earth are at their nearest distance, being in conjunction both on the same side of the sun, then the eclipses are seen to happen the soonest; and when the sun is directly between Jupiter and the earth, they are at their greatest distance asunder, the distance being more than before by the whole diameter of the earth's annual orbit, or by double the earth's distance from the sun, then the eclipses are seen to happen the latest of any, and later than before by about a quarter of an hour. Hence therefore it follows, that light takes up a quarter of an hour in travelling across the orbit of the earth, or near 8 minutes in passing from the sun to the earth; which gives us about 12 millions of miles per minute, or 200,000 miles per second, for the velocity of light. A discovery that was first made by M. Roemer.

The third and greatest advantage derived from the eclipses of the Satellites, is the knowledge of the longitudes of places on the earth. Suppose two observers of an eclipse, the one, for example, at London, the other at the Canaries; it is certain that the eclipse will appear at the same moment to both observers; but as they are situated under different meridians, they count different hours, being perhaps 9 o'clock to the one, when it is only 8 to the other; by which observations of the true time of the eclipse, on communication, they find the difference of their longitudes to be one hour in time, which answers to 15 degrees of longitude.

SATELLITES *of Saturn*, are 7 little secondary planets revolving about him.

One of them, which till lately was reckoned the 4th in order from Saturn, was discovered by Huygens, the 25th of March 1655, by means of a telescope 12 feet long; and the 1st, 2d, 3d, and 5th, at different times, by Cassini; viz, the 5th in October 1671, by a telescope of 17 feet; the 3d in December 1672, by a telescope of Campani's, 35 feet long; and the first and second in March 1684, by help of Campani's glasses, of 100 and 136 feet. Finally, the 6th and 7th Satellites have lately been discovered by Dr. Herschel, with his 40 feet reflecting telescope, viz, the 6th on the 19th of August 1787, and the 7th on the 17th of September 1788. These two he has called the 6th and 7th Satellites, though they are nearer to the planet Saturn than any of the former five, that the names or numbers of these might not be mistaken or confounded, with regard to former observations of them.

Moreover, the great distance between the 4th and 5th Satellite, gave occasion to Huygens to suspect that there might be some intermediate one, or else that the 5th might have some other Satellite moving round it, as its centre. Dr. Halley, in the Philos. Trans. (numb. 145, or Abr. vol. 1. pa. 371) gives a correction of the theory of the motions of the 4th or Huygenian Satellite. Its true period he makes 11d 22h 41′ 6″.

The periodical revolutions, and distances of these Satellites from the body of Saturn, expressed in semidiameters of that planet, and in miles, are as follow.

SATELLITES *of* SATURN.

Satellites.	Periods.	Distances in Semidiameters.	Distances in Miles.	Diam. of Orbit.
1	1d 21h 18′ 27″	4 3/6	170,000	1′ 27″
2	2 17 41 22	5½	217,000	1 52
3	4 12 25 12	8	303,000	2 36
4	15 22 41 13	18	704,000	6 18
5	79 7 48 0	54	2,050,000	17 4
6	1 8 53 9	3 5/9	135,000	1 14
7	0 22 40 46	2 5/9	107,000	0 57

The four first describe ellipses like to those of the ring, and are in the same plane. Their inclination to the ecliptic is from 30 to 31 degrees. The 5th describes an orbit inclined from 17 to 18 degrees with the orbit of Saturn; his plane lying between the ecliptic and those of the other Satellites, &c. Dr. Herschel observes that the 5th Satellite turns once round its axis exactly in the time in which it revolves about the planet Saturn; in which respect it resembles our moon, which does the same thing. And he makes the angle of its distance from Saturn, at his mean distance, 17′ 2″. Philos. Trans. 1792, pa. 22. See a long account of observations of these Satellites, with tables of their mean motions, by Dr. Herschel, Philos. Trans. 1790, pa. 427 &c.

SATELLITES *of the Georgian Planet*, or *Herschel*, are two little moons that revolve about him, like those of

Jupiter and Saturn. Theſe Satellites were diſcovered by Dr. Herſchel, in the month of January 1787, who gave an account of them in the Philoſ. Tranſ. of that year, pa. 125 &c; and a ſtill farther account of them in the vol. for 1788, pa. 364 &c; from which it appears that their ſynodical periods, and angular diſtances from their primary, are as follow:

Satellite.	Periods.	Diſt.
1	8d 17h 1′ 19″	0′ 33″
2	13 11 5 1½	0 44⅔

The orbits of theſe Satellites are nearly perpendicular to the ecliptic; and in magnitude they are probably not leſs than thoſe of Jupiter.

SATELLITE *of Venus*. Caſſini thought he ſaw one, and Mr. Short and other aſtronomers have ſuſpected the ſame thing. (Hiſt. de l'Acad. 1741, Philoſ. Tranſ. numb. 459). But the many fruitleſs ſearches that have been ſince made to diſcover it, leave room to ſuſpect that it has been only an optical illuſion, formed by the glaſſes of teleſcopes; as appears to be the opinion of F. Hell, at the end of his Ephemeris for 1766, and Boſcovich, in his 5th Optical Diſſertation.

Neither has it been diſcovered that either of the other planets Mars and Mercury have any Satellites revolving about them.

SATURDAY, the 7th or laſt day of the week, ſo called, as ſome have ſuppoſed, from the idol Seater, worſhipped on this day by the ancient Saxons, and thought to be the ſame as the Saturn of the Latins. In aſtronomy, every day of the week is denoted by ſome one of the planets, and this day is marked with the planet ♄ Saturn. Saturday anſwers to the Jewiſh ſabbath.

SATURN, one of the primary planets, being the 6th in order of diſtance from the ſun, and the outermoſt of all, except the Georgian planet, or Herſchel, lately diſcovered; and is marked with the character ♄, denoting an old man ſupporting himſelf with a ſtaff, repreſenting the ancient god Saturn.

Saturn ſhines with but a feeble light, partly on account of his great diſtance, and partly from its dull red colour. This planet is perhaps one of the moſt engaging objects that aſtronomy offers to our view; it is ſurrounded with a double ring, one without the other, and beyond theſe by 7 Satellites, all in the plane of the rings; the rings and planets being all dark and denſe bodies, like Saturn himſelf, theſe bodies caſting their ſhadows mutually one upon another; though the reflected light of the rings is uſually brighter than that of the planet itſelf.

Saturn has alſo certain obſcure zones, or belts, appearing at times acroſs his diſc, like thoſe of Jupiter, which are changeable, and are probably obſcurations in his atmoſphere. Dr. Herſchel, Philoſ. Tranſ. 1790, ſhews that Saturn has a denſe atmoſphere; that he revolves about an axis, which is perpendicular to the plane of the rings; that his figure is, like the other planets, the oblate ſpheroid, being flatted at the poles, the polar diameter being to the equatorial one as 10 to 11; that his ring has a motion of rotation in its own plane, its axis of motion being the ſame as that of Saturn himſelf, and its periodical time 10h 32′ 15″·4. See alſo RING, and SATELLITE.

Concerning the diſcovery of the ring and figure of Saturn; we find that Galileo firſt perceived that his figure is not round: but Huygens ſhewed, in his Syſtema Saturniana 1659, that this was owing to the poſitions of his ring; for his ſpheroidical form could only be ſeen by Herſchel's teleſcope; though indeed Caſſini, in an obſervation made June 19, 1692, ſaw the oval figure of Saturn's ſhadow upon his ring.

Mr. Bugge determines (Philoſ. Tranſ. 1787, pa. 42) the heliocentric longitude of Saturn's deſcending node to be 9s 21° 5′ 8″½; and that the planet was in that node Auguſt 21, 1784, at 18h 20′ 10″, time at Copenhagen.

The annual period of Saturn about the ſun, is 10759 days 7 hours, or almoſt 30 years; and his diameter is about 67000 miles, or near 8½ times the diameter of the earth; alſo his diſtance is about 9½ times that of the earth. Hence ſome have concluded that his light and heat are entirely unfit for rational inhabitants. But that their light is not ſo weak as we imagine, is evident from their brightneſs in the night time. Beſides, allowing the ſun's light to be 45000 times as ſtrong, with reſpect to us, as the light of the moon when full, the ſun will afford 500 times as much light to Saturn as the full moon does to us, and 1600 times as much to Jupiter. So that theſe two planets, even without any moon, would be much more enlightened than we at firſt imagine; and by having ſo many, they may be very comfortable places of reſidence. Their heat, ſo far as it depends on the force of the ſun's rays, is certainly much leſs than ours; to which no doubt the bodies of their inhabitants are as well adapted as ours are to the ſeaſons we enjoy. And if it be conſidered that Jupiter never has any winter, even at his poles, which probably is alſo the caſe with Saturn, the cold cannot be ſo intenſe on theſe two planets as is generally imagined. To this may be added, that there may be ſomething in the nature of their mould warmer than in that of our earth; and we find that all our heat does not depend on the rays of the ſun; for if it did, we ſhould always have the ſame months equally hot or cold at their annual return, which is very far from being the caſe.

See the articles PLANET, PERIOD, RING, SATELLITE.

SAUCISSE, in Artillery, a long train of powder incloſed in a roll or pipe of pitched cloth, and ſometimes of leather, about 2 inches in diameter; ſerving to ſet fire to mines or caiſſons. It is uſually placed in a wooden pipe, called an auget, to prevent its growing damp.

SAUCISSON, in Fortification, a kind of faggot, made of thick branches of trees, or of the trunks of ſhrubs, bound together; for the purpoſe of covering the men, and to ſerve as epaulements; and alſo to repair breaches, ſtop paſſages, make traverſes over a wet ditch, &c.

The Sauciſſon differs from the faſcine, which is only made of ſmall branches; and by its being bound at both ends, and in the middle.

SAVILLE (Sir HENRY), a very learned Engliſh-

man,

man, the second son of Henry Saville, Esq. was born at Bradley, near Halifax, in Yorkshire, November the 30th, 1549. He was entered of Merton-college, Oxford, in 1561, where he took the degrees in arts, and was chosen fellow. When he proceeded master of arts in 1570, he read for that degree on the Almagest of Ptolomy, which procured him the reputation of a man eminently skilled in mathematics and the Greek language; in the former of which he voluntarily read a public lecture in the university for some time.

In 1578 he travelled into France and other countries; where, diligently improving himself in all useful learning, in languages, and the knowledge of the world, he became a most accomplished gentleman. At his return, he was made tutor in the Greek tongue to queen Elizabeth, who had a great esteem and liking for him.

In 1585 he was made warden of Merton-college, which he governed six-and-thirty years with great honour, and improved it by all the means in his power.—In 1596 he was chosen provost of Eton-college; which he filled with many learned men.—James the First, upon his accession to the crown of England, expressed a great regard for him, and would have preferred him either in church or state; but Saville declined it, and only accepted the ceremony of knighthood from the king at Windsor in 1604. His only son Henry dying about that time, he thenceforth devoted his fortune to the promoting of learning. Among other things, in 1619, he founded, in the university of Oxford, two lectures, or professorships, one in geometry, the other in astronomy; which he endowed with a salary of 160l. a year each, besides a legacy of 600l. to purchase more lands for the same use. He also furnished a library with mathematical books near the mathematical school, for the use of his professors; and gave 100l. to the mathematical chest of his own appointing: adding afterwards a legacy of 40l. a year to the same chest, to the university, and to his professors jointly. He likewise gave 120l. towards the new-building of the schools, beside several rare manuscripts and printed books to the Bodleian library; and a good quantity of Greek types to the printing-press at Oxford.

After a life thus spent in the encouragement and promotion of science and literature in general, he died at Eton-college the 19th of February 1622, in the 73d year of his age, and was buried in the chapel there. On this occasion, the university of Oxford paid him the greatest honours, by having a public speech and verses made in his praise, which were published soon after in 4to, under the title of *Ultima Linea Savilii*.

As to the character of Saville, the highest encomiums are bestowed on him by all the learned of his time: by Casaubon, Mercerus, Meibomius, Joseph Scaliger, and especially the learned bishop Montague; who, in his *Diatribæ* upon Selden's History of Tythes, styles him, "that magazine of learning, whose memory shall be honourable amongst not only the learned, but the righteous for ever."

Several noble instances of his munificence to the republic of letters have already been mentioned: in the account of his publications many more, and even greater, will appear. These are,

1. *Four Books of the Histories of Cornelius Tacitus, and the Life of Agricola*; with Notes upon them, in folio, dedicated to Queen Elizabeth, 1581.

2. *A View of certain Military Matters*, or Commentaries concerning Roman Warfare, 1598.

3. *Rerum Anglicarum Scriptores post Bedam*, &c. 1596. This is a collection of the best writers of our English history; to which he added chronological tables at the end, from Julius Cæsar to William the Conqueror.

4. *The Works of St. Chrysostom*, in Greek, in 8 vols. folio, 1613. This is a very fine edition, and composed with great cost and labour. In the preface he says, "that having himself visited, about 12 years before, all the public and private libraries in Britain, and copied out thence whatever he thought useful to this design, he then sent some learned men into France, Germany, Italy, and the East, to transcribe such parts as he had not already, and to collate the others with the best manuscripts." At the same time, he makes his acknowledgments to several eminent men for their assistance; as Thuanus, Velserus, Schottus, Casaubon, Ducæus, Gruter, Hoeschelius, &c. In the 8th volume are inserted Sir Henry Saville's own notes, with those of other learned men. The whole charge of this edition, including the several sums paid to learned men, at home and abroad, employed in finding out, transcribing, and collating the best manuscripts, is said to have amounted to no less than 8000l. Several editions of this work were afterwards published at Paris.

5. In 1618 he published a Latin work, written by Thomas Bradwardin, abp. of Canterbury, against Pelagius, intitled, *De Causa Dei contra Pelagium, et de virtute causarum*; to which he prefixed the life of Bradwardin.

6. In 1621 he published a collection of his own Mathematical Lectures on Euclid's Elements; in 4to.

7. *Oratio coram Elizabetha Regina Oxoniæ habita*, anno 1592. Printed at Oxford in 1658, in 4to.

8. He translated into Latin king James's *Apology for the Oath of Allegiance*. He also left several manuscripts behind him, written by order of king James; all which are in the Bodleian library. He wrote notes likewise upon the margin of many books in his library, particularly Eusebius's *Ecclesiastical History*; which were afterwards used by Valesius, in his edition of that work in 1659.—Four of his letters to Camden are published by Smith, among *Camden's Letters*, 1691, 4to.

Sir Henry Saville had a younger brother, *Thomas* SAVILLE, who was admitted probationer fellow of Merton-college, Oxford, in 1580. He afterwards travelled abroad into several countries. Upon his return he was chosen fellow of Eton-college; but he died at London in 1593. Thomas Saville was also a man of great learning, and an intimate friend of Camden; among whose letters, just mentioned, there are 15 of Mr. Saville's to him.

SAUNDERSON (Dr. NICHOLAS), an illustrious professor of mathematics in the university of Cambridge, and a fellow of the Royal Society, was born at Thurlston in Yorkshire in 1682. When he was but twelve months old, he lost not only his eye-sight, but his very eye-balls, by the small-pox; so that he could retain no more ideas of vision than if he had been born blind. At an early age, however, being of very promising

miſing parts, he was ſent to the free-ſchool at Penniſton, and there laid the foundation of that knowledge of the Greek and Latin languages, which he afterwards improved ſo far, by his own application to the claſſic authors, as to hear the works of Euclid, Archimedes, and Diophantus read in their original Greek.

Having acquired a grammatical education, his father, who was in the exciſe, inſtructed him in the common rules of arithmetic. And here it was that his excellent mathematical genius firſt appeared: for he very ſoon became able to work the common queſtions, to make very long calculations by the ſtrength of his memory, and to form new rules to himſelf for the better reſolving of ſuch queſtions as are often propoſed to learners as trials of ſkill.

At the age of 18, our author was introduced to the acquaintance of Richard Weſt, of Underbank, Eſq. a lover of mathematics, who, obſerving Mr. Saunderſon's uncommon capacity, took the pains to inſtruct him in the principles of algebra and geometry, and gave him every encouragement in his power to the proſecution of theſe ſtudies. Soon after this he became acquainted alſo with Dr. Nettleton, who took the ſame pains with him. And it was to theſe two gentlemen that Mr. Saunderſon owed his firſt inſtitution in the mathematical ſciences: they furniſhed him with books, and often read and expounded them to him. But he ſoon ſurpaſſed his maſters, and became fitter to teach, than to learn any thing from them.

His father, otherwiſe burdened with a numerous family, finding a difficulty in ſupporting him, his friends began to think of providing both for his education and maintenance. His own inclination led him ſtrongly to Cambridge, and it was at length determined he ſhould try his fortune there, not as a ſcholar, but as a maſter: or, if this deſign ſhould not ſucceed, they promiſed themſelves ſucceſs in opening a ſchool for him at London. Accordingly he went to Cambridge in 1707, being then 25 years of age, and his fame in a ſhort time filled the univerſity. Newton's Principia, Optics, and Univerſal Arithmetic, were the foundations of his lectures, and afforded him a noble field for the diſplaying of his genius; and great numbers came to hear a blind man give lectures on optics, diſcourſe on the nature of light and colours, explain the theory of viſion, the effect of glaſſes, the phenomenon of the rainbow, and other objects of ſight.

As he inſtructed youth in the principles of the Newtonian philoſophy, he ſoon became acquainted with its incomparable author, though he had ſeveral years before left the univerſity; and frequently converſed with him on the moſt difficult parts of his works: he alſo held a friendly communication with the other eminent mathematicians of the age, as Halley, Cotes, Demoivre, &c.

Mr. Whiſton was all this time in the mathematical profeſſor's chair, and read lectures in the manner propoſed by Mr. Saunderſon on his ſettling at Cambridge; ſo that an attempt of this kind looked like an encroachment on the privilege of his office; but, as a good-natured man, and an encourager of learning, he readily conſented to the application of friends made in behalf of ſo uncommon a perſon.

Upon the removal of Mr. Whiſton from his profeſſorſhip, Mr. Saunderſon's merit was thought ſo much ſuperior to that of any other competitor, that an extraordinary ſtep was taken in his favour, to qualify him with a degree, which the ſtatute requires: in conſequence he was choſen in 1711, Mr. Whiſton's ſucceſſor, for in the Lucaſian profeſſorſhip of mathematics, but Iſaac Newton intereſting himſelf greatly in his favour. His firſt performance, after he was ſeated in the chair, was an inaugural ſpeech made in very elegant Latin, and a ſtyle truly Ciceronian; for he was well verſed in the writings of Tully, who was his favourite author, as Virgil and Horace were in verſe. From this time he applied himſelf cloſely to the reading of lectures, and gave up his whole time to his pupils. He continued to reſide among the gentlemen of Chriſt-college till the year 1723, when he took a houſe in Cambridge, and ſoon after married a daughter of Mr. Dickens, rector of Boxworth in Cambridgeſhire, by whom he had a ſon and a daughter.

In the year 1728, when king George viſited the univerſity, he expreſſed a deſire of ſeeing ſo remarkable a perſon; and accordingly our profeſſor attended the king in the ſenate, and by his favour was there created doctor of laws.

Dr. Saunderſon was naturally of a ſtrong healthy conſtitution; but being too ſedentary, and conſtantly confining himſelf to the houſe, he became a valetudinarian: and in the ſpring of the year 1739 he complained of a numbneſs in his limbs, which ended in a mortification in his foot, of which he died the 19th of April that year, in the 57th year of his age.

There was ſcarcely any part of the mathematics on which Dr. Saunderſon had not compoſed ſomething for the uſe of his pupils. But he diſcovered no intention of publiſhing any thing till, by the perſuaſion of his friends, he prepared his Elements of Algebra for the preſs, which after his death were publiſhed by ſubſcription in 2 vols 4to, 1740.

He left many other writings, though none perhaps prepared for the preſs. Among theſe were ſome valuable comments on Newton's Principia, which not only explain the more difficult parts, but often improve upon the doctrines. Theſe are publiſhed in Latin at the end of his poſthumous Treatiſe on Fluxions, a valuable work, publiſhed in 8vo, 1756.—His manuſcript lectures too, on moſt parts of natural philoſophy, which I have ſeen, might make a conſiderable volume, and prove an acceptable preſent to the public if printed.

Dr. Saunderſon, as to his character, was a man of much wit and vivacity in converſation, and eſteemed an excellent companion. He was endued with a great regard to truth; and was ſuch an enemy to diſguiſe, that he thought it his duty to ſpeak his thoughts at all times with unreſtrained freedom. Hence his ſentiments on men and opinions, his friendſhip or diſregard, were expreſſed without reſerve; a ſincerity which raiſed him many enemies.

A blind man, moving in the ſphere of a mathematician, ſeems a phenomenon difficult to be accounted for, and has excited the admiration of every age in which it has appeared. Tully mentions it as a thing ſcarce credible in his own maſter in philoſophy, Diodotus; that he exerciſed himſelf in it with more aſſi-

dity after he became blind; and, what he thought next to impoſſible to be done without ſight, that he profeſſed geometry, deſcribing his diagrams ſo exactly to his ſcholars, that they could draw every line in its proper direction. St. Jerome relates a ſtill more remarkable inſtance in Didymus of Alexandria, who, though blind from his infancy, and therefore ignorant of the very letters, not only learned logic, but geometry alſo to very great perfection, which ſeems moſt of all to require ſight. But, if we conſider that the ideas of extended quantity, which are the chief objects of mathematics, may as well be acquired by the ſenſe of feeling as that of ſight, that a fixed and ſteady attention is the principal qualification for this ſtudy, and that the blind are by neceſſity more abſtracted than others (for which reaſon it is ſaid that Democritus put out his eyes, that he might think more intenſely), we ſhall perhaps find reaſon to ſuppoſe that there is no branch of ſcience ſo much adapted to their circumſtances.

At firſt, Dr. Saunderſon acquired moſt of his ideas by the ſenſe of feeling; and this, as is commonly the caſe with the blind, he enjoyed in great perfection. Yet he could not, as ſome are ſaid to have done, diſtinguiſh colours by that ſenſe; for, after having made repeated trials, he uſed to ſay, it was pretending to impoſſibilities. But he could with great nicety and exactneſs obſerve the ſmalleſt degree of roughneſs or defect of poliſh in a ſurface. Thus, in a ſet of Roman medals, he diſtinguiſhed the genuine from the falſe, though they had been counterfeited with ſuch exactneſs as to deceive a connoiſſeur who had judged by the eye. By the ſenſe of feeling alſo, he diſtinguiſhed the leaſt variation; and he has been ſeen in a garden, when obſervations have been making on the ſun, to take notice of every cloud that interrupted the obſervation almoſt as juſtly as they who could ſee it. He could alſo tell when any thing was held near his face, or when he paſſed by a tree at no great diſtance, merely by the different impulſe of the air on his face.

His ear was alſo equally exact. He could readily diſtinguiſh the 5th part of a note. By the quickneſs of this ſenſe he could judge of the ſize of a room, and of his diſtance from the wall. And if ever he walked over a pavement, in courts or piazzas which reflected a ſound, and was afterwards conducted thither again, he could tell in what part of the walk he ſtood, merely by the note it ſounded.

Dr. Saunderſon had a peculiar method of performing arithmetical calculations, by an ingenious machine and method which has been called his Palpable Arithmetic, and is particularly deſcribed in a piece prefixed to the firſt volume of his Algebra. That he was able to make long and intricate calculations, both arithmetical and algebraical, is a thing as certain as it is wonderful. He had contrived for his own uſe, a commodious notation for any large numbers, which he could expreſs on his abacus, or calculating table, and with which he could readily perform any arithmetical operations, by the ſenſe of feeling only, for which reaſon it was called his Palpable Arithmetic.

His calculating table was a ſmooth thin board, a little more than a foot ſquare, raiſed upon a ſmall frame ſo as to lie hollow; which board was divided into a great number of little ſquares, by lines interſecting one another perpendicularly, and parallel to the ſides of the table, and the parallel ones only one-tenth of an inch from each other; ſo that every ſquare inch of the table was thus divided into 100 little ſquares. At every point of interſection the board was perforated by ſmall holes, capable of receiving a pin; for it was by the help of pins, ſtuck up to the head through theſe holes, that he expreſſed his numbers. He uſed two ſorts of pins, a larger and a ſmaller ſort; at leaſt their heads were different, and might eaſily be diſtinguiſhed by feeling. Of theſe pins he had a large quantity in two boxes, with their points cut off, which always ſtood ready before him when he calculated. The writer of that account deſcribes particularly the whole proceſs of uſing the machine, and concludes, "He could place and diſplace his pins with incredible nimbleneſs and facility, much to the pleaſure and ſurprize of all the beholders. He could even break off in the middle of a calculation, and reſume it when he pleaſed, and could preſently know the condition of it, by only drawing his fingers gently over the table."

SAURIN (Joseph), an ingenious French mathematician, was born in 1659, at Courtaiſon, in the principality of Orange. His father, miniſter at Grenoble, was a man of a very ſtudious diſpoſition, and was the firſt preceptor or inſtructor to our author; who made a rapid progreſs in his ſtudies, and at a very early age was admitted a miniſter at Eure in Dauphiny. But preaching an offenſive ſermon, he was obliged to quit France in 1683. On this occaſion he retired to Geneva; from whence he went into the State of Berne, and was appointed to a living at Yverdun. He was no ſooner eſtabliſhed in this his poſt, than certain theologians raiſed a ſtorm againſt him. Saurin, diſguſted with the controverſy, and ſtill more with the Swiſs, where his talents were buried, paſſed into Holland, and from thence into France, where he put himſelf under the protection of the celebrated Boſſu, to whom he made his abjuration in 1690, as it is ſuſpected, that he might find protection, and have an opportunity of cultivating the ſciences at Paris. And he was not diſappointed: he met with many flattering encouragements; was even much noticed by the king, had a penſion from the court, and was admitted of the Academy of Sciences in 1707, in the quality of geometrician. This ſcience was now his chief ſtudy and delight; with many writings upon which he enriched the volumes of the Journal des Savans, and the Memoirs of the Academy of Sciences. Theſe were the only works of this kind that he publiſhed: he was author of ſeveral other pieces of a controverſial nature, againſt the celebrated Rouſſeau, and other antagoniſts, over whom with the aſſiſtance of government he was enabled to triumph. The latter part of his life was ſpent in more peace, and in cultivating the mathematical ſciences; and he died the 29th of December 1737, of a lethargic fever, at 78 years of age.

The character of Saurin was lively and impetuous, endued with a conſiderable degree of that noble independence and loftineſs of manner, which is apt to be miſtaken for haughtineſs or inſolence; in conſequence of which, his memory was attacked after his death, as his reputation had been during his life; and it was even

ſaid

ſaid he had been guilty of crimes, by his own confeſſion, that ought to have been puniſhed with death.

Saurin's mathematical and philoſophical papers, printed in the Memoirs of the Academy of Sciences, which are pretty numerous, are to be found in the volumes for the years following; viz, 1709, 1710, 1713, 1716, 1718, 1720, 1722, 1723, 1725, 1727.

SAUVEUR (Joseph), an eminent French mathematician, was born at La Fleche the 24th of March 1653. He was abſolutely dumb till he was ſeven years of age; and then the organs of ſpeech did not diſengage ſo effectually, but that he was ever after obliged to ſpeak very ſlowly and with difficulty. He very early diſcovered a great turn for mechanics, and was always inventing and conſtructing ſomething or other in that way.

He was ſent to the college of the Jeſuits to learn polite literature, but made very little progreſs in poetry and eloquence. Virgil and Cicero had no charms for him; but he read with greedineſs books of arithmetic and geometry. However, he was prevailed on to go to Paris in 1670, and, being intended for the church, there he applied himſelf for a time to the ſtudy of philoſophy and theology; but ſtill ſucceeded no better. In ſhort, mathematics was the only ſtudy he had any paſſion or reliſh for, and this he cultivated with extraordinary ſucceſs; for during his courſe of philoſophy, he learned the firſt ſix books of Euclid in the ſpace of a month, without the help of a maſter.

As he had an impediment in his voice, though otherwiſe endued with extraordinary abilities, he was adviſed by M. Boſſuet, to give up all deſigns upon the church, and to apply himſelf to the ſtudy of phyſic: but this being utterly againſt the inclination of his uncle, from whom he drew his principal reſources, Sauveur determined to devote himſelf to his favourite ſtudy, and to perfect himſelf in it, ſo as to teach it for his ſupport; and in effect he ſoon became the faſhionable preceptor in mathematics, ſo that at 23 years of age he had prince Eugene for his ſcholar.—He had not yet read the geometry of Des Cartes; but a foreigner of the firſt quality deſiring to be taught it, he made himſelf maſter of it in an inconceivably ſmall ſpace of time. —Baſſet being a faſhionable game at that time, the marquis of Dangeau aſked him for ſome calculations relating to it, which gave ſuch ſatisfaction, that Sauveur had the honour to explain them to the king and queen.

In 1681 he was ſent with M. Mariotte to Chantilli, to make ſome experiments upon the waters there, which he did with much applauſe. The frequent viſits he made to this place inſpired him with the deſign of writing a treatiſe on fortification; and, in order to join practice with theory, he went to the ſiege of Mons in 1691, where he continued all the while in the trenches. With the ſame view alſo he viſited all the towns of Flanders; and on his return he became the mathematician in ordinary at the court, with a penſion for life.—In 1680 he had been choſen to teach mathematics to the pages of the Dauphineſs. In 1686 he was appointed mathematical profeſſor in the Royal College. And in 1696 admitted a member of the Academy of Sciences, where he was in high eſteem with the members of that ſociety.—He became alſo particularly acquainted with the prince of Condé, from whom he received many marks of favour and affection. Finally, M. Vauban having been made marſhal of France, in 1703, he propoſed Sauveur to the king as his ſucceſſor in the office of examiner of the engineers; to which the king agreed, and honoured him with a penſion, which our author enjoyed till his death, which happened the 9th of July 1716, in the 64th year of his age.

Sauveur, in his character, was of a kind obliging diſpoſition, of a ſweet, uniform, and unaffected temper; and although his fame was pretty generally ſpread abroad, it did not alter his humble deportment, and the ſimplicity of his manners. He uſed to ſay, that what one man could accompliſh in mathematics, another might do alſo, if he choſe it.

He was twice married. The firſt time he took a very ſingular precaution; for he would not meet the lady till he had been with a notary to have the conditions, he intended to inſiſt on, reduced into a written form; for fear the ſight of her ſhould not leave him enough maſter of himſelf. This was acting very wiſely, and like a true mathematician; who always proceeds by rule and line, and makes his calculations when his head is cool.—He had children by both his wives; and by the latter a ſon who, like himſelf, was dumb for the firſt ſeven years of his life.

An extraordinary part of Sauveur's character is, that though he had neither a muſical voice nor ear, yet he ſtudied no ſcience more than muſic, of which he compoſed an entire new ſyſtem. And though he was obliged to borrow other people's voice and ears, yet he amply repaid them with ſuch demonſtrations as were unknown to former muſicians. He alſo introduced a new diction in muſic, more appropriate and extenſive. He invented a new doctrine of ſounds. And he was the firſt that diſcovered, by theory and experiment, the velocity of muſical ſtrings, and the ſpaces they deſcribe in their vibrations, under all circumſtances of tenſion and dimenſions. It was he alſo who firſt invented for this purpoſe the monochord and the echometer. In ſhort, he purſued his reſearches even to the muſic of the ancient Greeks and Romans, to the Arabs, and to the very Turks and Perſians themſelves; ſo jealous was he, leſt any thing ſhould eſcape him in the ſcience of ſounds.

Sauveur's writings, which conſiſt of pieces rather than of ſet works, are all inſerted in the volumes of the Memoirs of the Academy of Sciences, from the year 1700 to the year 1716, on various geometrical, mathematical, philoſophical, and muſical ſubjects.

SCALE, a mathematical inſtrument, conſiſting of certain lines drawn on wood, metal, or other matter, divided into various parts, either equal or unequal. It is of great uſe in laying down diſtances in proportion, or in meaſuring diſtances already laid down.

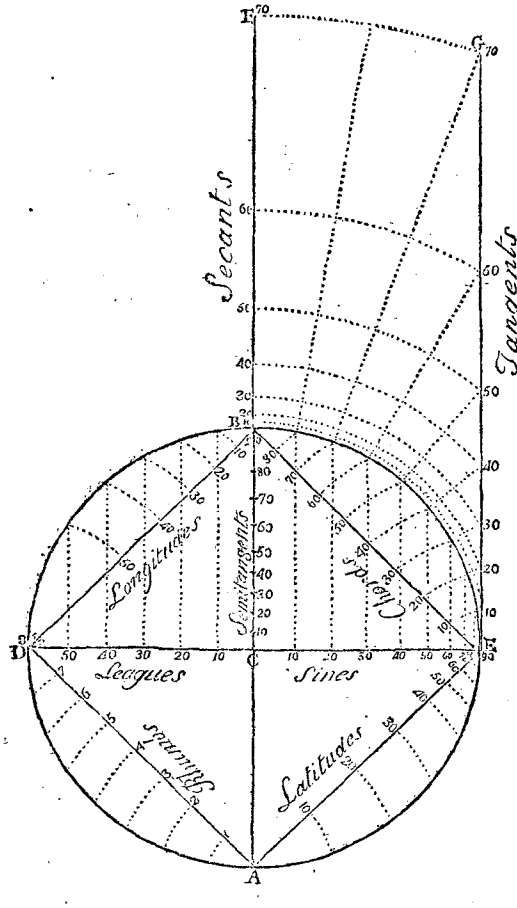
There are Scales of various kinds, accommodated to the ſeveral uſes: the principal are the *plane Scale*, the *diagonal Scale*, *Gunter's Scale*, and the *plotting Scale*.

Plane or Plain Scale, a mathematical inſtrument of very extenſive uſe and application; which is commonly made of 2 feet in length; and the lines uſually drawn upon it are the following, viz,

1. Lines

1	Lines of	Equal parts, and marked	E. P.
2	- -	Chords - - - -	Cho.
3	- -	Rhumbs - - -	Ru.
4	- -	Sines - - -	Sin.
5	- -	Tangents - -	Tan.
6	- -	Secants - -	Sec.
7	- -	Semitangents - -	S. T.
8	- -	Longitude - -	Long.
9	- -	Latitude - -	Lat.

1. The lines of equal parts are of two kinds, viz, simply divided, and diagonally divided. The firſt of theſe are formed by drawing three lines parallel to one another, and dividing them into any equal parts by ſhort lines drawn acroſs them, and in like manner ſubdividing the firſt diviſion or part into 10 other equal ſmall parts; by which numbers or dimenſions of two figures may be taken off. Upon ſome rulers, ſeveral of theſe ſcales of equal parts are ranged parallel to each other, with figures ſet to them to ſhew into how many equal parts they divide the inch; as 20, 25, 30, 35, 40, 45, &c. The 2d or diagonal diviſions are formed by drawing eleven long parallel and equidiſtant lines, which are divided into equal parts, and croſſed



by other ſhort lines, as the former; then the firſt of the equal parts have the two outermoſt of the eleven parallels divided into 10 equal parts, and the points of diviſion being connected by lines drawn diagonally, the whole ſcale is thus divided into dimenſions or numbers of three places of figures.

The other lines upon the ſcales are ſuch as are commonly uſed in trigonometry, navigation, aſtronomy, dialling, projection of the ſphere, &c, &c; and their conſtructions are moſtly taken from the diviſions of a circle, as follow:

Deſcribe a circle with any convenient radius, and quarter it by drawing the diameters AB and DE at right angles to each other; continue the diameter AB out towards F, and draw the tangent line EG parallel to it; alſo draw the chords AD, DB, BE, EA. Then,

2. For the line of chords, divide a quadrant BE into 90 equal parts; on E as a centre, with the compaſſes transfer theſe diviſions to the chord line EB, which mark with the correſponding numbers, and it will become a line of chords, to be transferred to the ruler.

3. For the line of rhumbs, divide the quadrant AD into 8 equal parts; then with the centre A tranſfer the diviſions to the chord AD, for the line of rhumbs.

4. For the line of ſines, through each of the diviſions of the arc BE, draw right lines parallel to the radius BC, which will divide the radius CE into the ſines, or verſed ſines, numbering it from C to E for the ſines, and from E to C for the verſed ſines.

5. For the line of tangents, lay a ruler on C, and the ſeveral diviſions of the arc BE, and it will interſect the line EG, which will become a line of tangents, and numbered from E to G with 10, 20, 30, 40, &c.

6. For the line of ſecants, tranſfer the diſtances between the centre C and the diviſions on the line of tangents to the line BF, from the centre C, and theſe will give the diviſions of the line of ſecants, which muſt be numbered from B towards F, with 10, 20, 30, &c.

7. For the line of ſemitangents, lay a ruler on D and the ſeveral diviſions of the arc EB, which will interſect the radius CB in the diviſions of the ſemitangents, which are to be marked with the correſponding figures of the arc EB.

The chief uſes of the ſines, tangents, ſecants, and ſemitangents, are to find the poles and centres of the ſeveral circles repreſented in the projections of the ſphere.

8. For the line of longitude, divide the radius CD into 60 equal parts; through each of theſe, parallels to the radius BC will interſect the arc BD in as many points: from D as a centre the diviſions of the arc BD being tranſferred to the chord BD, will give the diviſions of the line of longitude.

If this line be laid upon the ſcale cloſe to the line of chords, both inverted, ſo that 60° in the ſcale of longitude be againſt 0° in the chords, &c; and any degree of latitude be counted on the chords, there will ſtand oppoſite to it, in the line of longitude, the miles contained in one degree of longitude, in that latitude; the meaſure of 1 degree under the equator being 60 geographical miles.

9. For the line of latitude, lay a ruler on B, and the ſeveral diviſions on the lines on CE, and it will interſect the arc AE in as many points; on A as a centre transfer the interſections of the arc AE to the chord AE, for the line of latitude.

See alſo Robertſon's Deſcription and uſe of Mathematical Inſtruments.

Decimal, or *Gunter's*, or *Plotting*, or *Proportional*, or *Reducing* SCALE. See the ſeveral articles.

SCALE, in Architecture and Geography, a line divided into equal parts, placed at the bottom of a map or draught, to ſerve as a common meaſure to all the parts of the building, or all the diſtances and places of the map.

In maps of large tracts, as kingdoms and provinces, &c, the Scale uſually conſiſts of miles; whence it is denominated a Scale of miles.—In more particular maps, as thoſe of manors, &c, the Scale is uſually of chains &c.—The Scales uſed in draughts of buildings moſtly conſiſt of modules, feet, inches, palms, fathoms, or the like.

To find the diſtance between two towns &c, in a map, the interval is taken in the compaſſes, and ſet off in the ſcale; and the number of diviſions it includes gives the diſtance. The ſame method ſerves to find the height of a ſtory, or other part in a deſign.

Front SCALE, in Perſpective, is a right line in the draught, parallel to the horizontal line; divided into equal parts, repreſenting feet, inches, &c.

Flying SCALE, is a right line in the draught, tending to the point of view, and divided into unequal parts, repreſenting feet, inches, &c.

Differential SCALE, is uſed for the ſcale of relation ſubtracted from unity. See SERIES.

SCALE *of Relation*, in Algebra, an expreſſion denoting the relation of the terms of recurring ſeries to each other. See SERIES.

Hour SCALE. See HOUR.

SCALE, in Muſic, is a denomination given to the arrangement of the ſix ſyllables, invented by Guido Aratino, *ut re mi fa ſol la*; called alſo gammut. It is called Scale, or ladder, becauſe it repreſents a kind of ladder, by means of which the voice riſes to acute, or ſinks to grave; each of the ſix ſyllables being as it were one ſtep of the ladder.

SCALE is alſo uſed for a ſeries of ſounds riſing or falling towards acuteneſs or gravity, from any given pitch of tune, to the greateſt diſtance that is fit or practicable, through ſuch intermediate degrees as to make the ſucceſſion moſt agreeable and perfect, and in which we have all the harmonical intervals moſt commodiouſly divided.

The ſcale is otherwiſe called an *univerſal ſyſtem*, as including all the particular ſyſtems belonging to muſic. See SYSTEM.

There were three different Scales in uſe among the Ancients, which had their denominations from the three ſeveral ſorts of muſic, viz, the *diatonic*, *chromatic*, and *inharmonic*. Which ſee.

SCALENE, or SCALENOUS *triangle*, is a triangle whoſe ſides and angles are all unequal.—A cylinder or cone, whoſe axis is oblique or inclined to its baſe, is alſo ſaid to be ſcalenous: though more frequently it is called oblique.

SCALIGER (JOSEPH JUSTUS), a celebrated French chronologer and critic, was the ſon of Julius Cæſar Scaliger, and born at Agen in France, in 1540. He ſtudied in the college of Bourdeaux; after which his father took him under his own care, and employed him in tranſcribing his poems; by which means he obtained ſuch a taſte for poetry, that before he was 15 years old, he wrote a tragedy upon the ſubject of Dionyſius, in which he introduced all the poetical ornaments of ſtyle and ſentiment.

His father dying in 1558, he went to Paris the year following, with a deſign to apply himſelf to the Greek tongue. For this purpoſe he for two months attended the lectures of Turnebus; but finding that in the uſual courſe he ſhould be a long time in gaining his point, he ſhut himſelf up in his cloſet, and by conſtant application for two years gained a perfect knowledge of the Greek language. After which he applied himſelf to the Hebrew, which he learned by himſelf with great facility. And in like manner he ran through many other languages, till he could ſpeak it is ſaid no leſs than 13 ancient and modern ones. He made no leſs progreſs in the ſciences; and his writings procured him the reputation of one of the greateſt men of that or any other age. He embraced the reformed religion at 22 years of age. In 1563, he attached himſelf to Lewis Caſteignier de la Roch Pazay, whom he attended in ſeveral journies. And, in 1593, the curators of the univerſity of Leyden invited him to an honorary profeſſorſhip in that univerſity, where he lived 16 years, and where he died of a dropſy in 1609, at 69 years of age.

Scaliger was a man of great temperance; was never married; and was ſo cloſe a ſtudent, that he often ſpent whole days in his ſtudy without eating: and though his circumſtances were always very narrow, he conſtantly refuſed the preſents that were offered him.

He was author of many ingenious works on various ſubjects. His elaborate work, *De Emendatione Temporum*; his exquiſite animadverſions on Euſebius; with his *Canon Iſagogicus Chronologiæ*; and his accurate comment upon Manilius's *Aſtronomicon*, ſufficiently evince his knowledge in the aſtronomy, and other branches of learning, among the Ancients, and who, according to the opinion of the celebrated Vieta, was far ſuperior to any of that age. And he had no leſs a character given him by the learned Caſaubon.—He wrote *Cyclometrica et Diatriba de Equinoctiorum Anticipatione*. He wrote alſo notes upon Seneca, Varro, and Auſonius's Poems. But that which above all things renders the name of Scaliger memorable to poſterity, is the invention of the Julian period, which conſiſts of 7980 years, being the continued product of the three cycles, of the ſun 28, the moon 19, and Roman indiction 15. This period had its beginning fixed to the 764th year before the creation, and is not yet completed, and comprehends all other cycles, periods, and epochas, with the times of all memorable actions and hiſtories.—The collections intitled *Scaligeriana*, were collected from his converſations by one of his friends; and being ranged in alphabetical order, were publiſhed by Iſaac Voſſius.

SCANTLING, a meaſure, ſize, or ſtandard, by which the dimenſions &c of things are to be determined.

The

The term is particularly applied to the dimenſions of any piece of timber, with regard to its breadth and thickneſs.

SCAPEMENT, in Clock-work, a general term for the manner of communicating the impulſe of the wheels to the pendulum. The ordinary Scapements conſiſt of the ſwing-wheel and pallets only; but modern improvements have added other levers or detents, chiefly for the purpoſes of diminiſhing friction, or for detaching the pendulum from the preſſure of the wheels during part of the time of its vibration. Notwithſtanding the very great importance of the Scapement to the performance of clocks, no material improvement was made in it from the firſt application of the pendulum to clocks to the days of Mr. George Graham; nothing more was attempted before his time, than to apply the impulſe of the ſwing-wheel in ſuch manner as was attended with the leaſt friction, and would give the greateſt motion to the pendulum. Dr. Halley diſcovered, by ſome experiments made at the Royal Obſervatory at Greenwich, that by adding more weight to the pendulum, it was made to vibrate larger arcs, and the clock went faſter; by diminiſhing the weight of the pendulum, the vibrations became ſhorter, and the clock went ſlower; the reſult of theſe experiments being diametrically oppoſite to what ought to be expected from the theory of the pendulum, probably firſt roufed the attention of Mr. Graham, and led him to ſuch farther trials as convinced him, that this ſeeming paradox was occaſioned by the retrograde motion, which was given to the ſwing-wheel by every conſtruction of Scapement that was at that time in uſe; and his great ſagacity ſoon produced a remedy for this defect, by conſtructing a Scapement which prevented all recoil of the wheels, and reſtored to the clock pendulum, wholly in theory, and nearly in practice, all its natural properties in its detached ſimple ſtate; this Scapement was named by its celebrated inventor the *dead beat*, and its great ſuperiority was ſo univerſally acknowledged, that it was ſoon introduced into general uſe, and ſtill continues in univerſal eſteem. The importance of the Scapement to the accurate going of clocks, was by this improvement rendered ſo unqueſtionable, that artiſts of the firſt rate all over Europe, were forward in producing each his particular conſtruction, as may be ſeen in the works of Thiout l'ainé, M. J. A. Lepante, M. le Roy, M. Ferdinand Bertoud, and Mr. Cummings' Elements of Clock and Watchwork, in which we have a minute deſcription of ſeveral new and ingenious conſtructions of Scapements, with an inveſtigation of the principles on which their claim to merit is founded; and a comparative view of the advantages or defects of the ſeveral conſtructions. Beſides the Scapements deſcribed in the above works, many curious conſtructions have been produced by eminent artiſts, who have not publiſhed any account of them, nor of the motives which have induced each to prefer his favourite conſtruction: Mr. Harriſon, Mr. Hindley of York, Mr. Ellicot, Mr. Mudge, Mr. Arnold, Mr. Whitehurſt, and many other ingenious artiſts of this country, have made Scapements of new and peculiar conſtructions, of which we are unable, for the above reaſon, to give any farther account than that thoſe of Mr. Harriſon and Mr. Hindley had ſcarce any friction, with a certain mode and quantity of recoil; thoſe of all the other gentlemen, we believe, have been on the principle of the dead beat, with ſuch other improvements as they ſeverally judged moſt conducive to a good performance.

Count Bruhl has juſt publiſhed (in 1794) a ſmall pamphlet, "On the Inveſtigation of Aſtronomical Circles," to which he has annexed, "a Deſcription of the Scapement in Mr. Mudge's firſt Timekeeper, drawn up in Auguſt 1771." Before entering upon the Deſcription, the Count premiſes a few obſervations, in one of which he recognizes a hint concerning the nature of Mr. Mudge's Scapement, thrown out by this artiſt in a ſmall tract printed by him in the year 1763, which is this: "The force derived from the mainſpring ſhould be made as equal as poſſible, by making the mainſpring wind up another ſmaller ſpring at a leſs diſtance from the balance, at ſhort intervals of time. *I think it would not be impracticable to make it wind up at every vibration, a ſmall ſpring ſimilar to the pendulum ſpring, that ſhould immediately act on the balance, by which the whole force acting on the balance would be reduced to the greateſt ſimplicity, with this advantage, that the force would increaſe in proportion to the arch.*" From this hint, Count Bruhl is ſurpriſed that no other artiſts have taken up Mr. Mudge's invention. He then gives the Deſcription of that invention as follows: "Mr. Mudge's Timekeeper has five wheels, with numbers high enough to admit pinions of twelve, and yet to go eight days. The Scapement conſiſts of a wheel almoſt like that of a common crown wheel, and acts on pallets, each of which has a ſeparate axis lying in the ſame line. To each pallet a ſpring is fixed in the ſhape of a pendulum ſpring; theſe ſprings are wound up alternately by the action of the laſt wheel upon the pallets, which is performed in the following manner:—Whenever one of the pallets (for inſtance the upper one) is ſet in motion by a tooth of the wheel ſliding upon it, and then reſting againſt a hook, or, rather a bearing at its end, the balance is entirely detached from it, being then employed in carrying the other pallet the contrary way. When the balance returns from that vibration (partly by the force of the pendulum ſpring, and partly by that of one of the two ſmall ſprings which it had bent by the motion of that pallet which it had carried along with itſelf) it lays hold of the upper pallet and carries it round in the ſame manner as it did before the lower one, and, of courſe, in the ſame direction which the upper pallet had received from the power of the mainſpring at the time that it was quite unconnected with the balance. The communication of motion from the balance to the pallets, and vice verſa, is effected by two pins fixed to a crank, which in following the balance, hit each its proper pallet alternately. By what has been ſaid, it is evident that whatever inequality there may be in the power derived from the mainſpring (provided the latter be ſufficient to wind up thoſe little pallet ſprings) it can never interfere with the regularity of the balance's motion, but at the inſtant of unlocking the pallets, which is ſo inſtantaneous an operation, and the reſiſtance ſo exceedingly ſmall, that it cannot poſſibly amount to any ſenſible error. The removal of this great obſtacle was certainly never ſo effectually done by any other contri-

vance, and deſerves the higheſt commendation, as a probable means to perfect a portable machine that will meaſure time correctly. But this is not the only, nor indeed the principal advantage which this timekeeper will poſſeſs over any other; for, as it is impoſſible to reduce friction to ſo ſmall a quantity as not to affect the motion of a balance, the conſequence of which is, that it deſcribes ſometimes greater and ſometimes ſmaller arcs, it became neceſſary to think of ſome method by which the balance might be brought to deſcribe thoſe different arcs in the ſame time. If a balance could be made to vibrate without friction or reſiſtance from the medium in which it moves, the mere expanding and contracting of the pendulum ſpring, would probably produce the ſo much wiſhed-for effect, as its force is ſuppoſed to be proportional to the arcs deſcribed; but as there is no machine void of friction, and as from that cauſe, the velocity of every balance decreaſes more rapidly than the ſpaces gone through decreaſe, this inequality could only be removed by a force acting on the balance, which aſſuming different ratios in its different ſtages, could counterbalance that inequality. This very material and important remedy, Mr. Mudge has effected by the conſtruction of his Scapement; for his pallet ſprings having a force capable of being increaſed almoſt at pleaſure, at the commencement of every vibration, the proportion in their different degrees of tenſion may be altered till it anſwers the intended purpoſe. This ſhews how effectually Mr. Mudge's Scapement removes the two greateſt difficulties that have hitherto baffled the attempts of every other artiſt, namely, the inequalities of the power derived from the main ſpring, and the irregularities ariſing from friction, and the variable reſiſtance of the medium in which the balance moves. Although at the time I am writing this account of his invention, the machine is not yet finiſhed; I am not the leſs confident that whenever it is, it will be found to be one of the moſt uſeful of any which has as yet appeared."

SCARP, in Fortification, the interior ſlope of the ditch of a place; that is, the ſlope of that ſide of a ditch which is next to the place, or on the outſide of the rampart at its foot, facing the champaign or open country. The ſlope on the outer ſide of the ditch is called the *counterſcarp*.

SCENOGRAPHY, in Perſpective, the perſpective repreſentation of a body on a plane; or a deſcription and view of it in all its parts and dimenſions, ſuch as it appears to the eye in any oblique view.

This differs eſſentially from the ichnography and the orthography. The ichnography of a building, &c, repreſents the plan or ground work of the building, or ſection parallel to it; and the orthography the elevation, or front, or one ſide, alſo in its natural dimenſions; but the Scenography exhibits the whole of the building that appears to the eye, front, ſides, height, and all, not in their real dimenſions or extent, but raiſed on the geometrical plan in perſpective.

In architecture and fortification, Scenography is the manner of delineating the ſeveral parts of a building or fortreſs, as they are repreſented in perſpective.

To exhibit the SCENOGRAPHY *of any body.* 1. Lay down the baſis, ground-plot, or plan, of the body, in the perſpective ichnography, that is, draw the perſpective appearance of the plan or baſement, by the proper rules of perſpective. 2. Upon the ſeveral points of the ſaid perſpective plan, raiſe the perſpective heights, and connect the tops of them by the proper ſlope or oblique lines. So will the Scenography of the body be completed when a proper ſhade is added. See PERSPECTIVE.

SCHEINER (CHRISTOPHER), a conſiderable German mathematician and aſtronomer, was born at Mundeilheim in Schwaben in 1575. He entered into the ſociety of the Jeſuits at 20 years of age; and afterwards taught the Hebrew tongue and the mathematics at Ingolſtadt, Friburg, Briſac, and Rome. At length he became confeſſor to the archduke Charles, and rector of the college of the Jeſuits at Neiſſe in Silesia, where he died in 1650, at 75 years of age.

Scheiner was chiefly remarkable for being one of the firſt who obſerved the ſpots in the ſun with a telescope, though not the very firſt; for his obſervations of thoſe ſpots were firſt made, at Ingolſtadt, in the latter part of the year 1611, whereas Galileo and Harriot both obſerved them in the latter part of the year before, or 1610. Scheiner continued his obſervations on the ſolar phenomena for many years afterwards at Rome, with great aſſiduity and accuracy, conſtantly making drawings of them on paper, deſcribing their places, figures, magnitude, revolutions and periods, ſo that Riccioli delivered it as his opinion that there was little reaſon to hope for any better obſervations of thoſe ſpots. Des Cartes and Hevelius alſo ſay, that in their judgment, nothing can be expected of that kind more ſatisfactory. Theſe obſervations were publiſhed in one volume folio, 1630, under the title of *Roſa Urſina*, &c; almoſt every page of which is adorned with an image of the ſun with the ſpots. He wrote alſo ſeveral ſmaller pieces relating to mathematics and philoſophy, the principal of which are,

2. *Oculus, ſive Fundamentum Opticum, &c;* which was reprinted at London, in 1652, in 4to.

3. *Sol Ecliptícus, Diſquiſitiones Mathematicæ.*

4. *De Controverſiis et Novitatibus Aſtronomicis.*

SCHEME, a draught or repreſentation of any geometrical or aſtronomical figure, or problem, by lines ſenſible to the eye; or of the celeſtial bodies in their proper places for any moment; otherwiſe called a diagram.

SCHEME *Arches.* See ARCH.

SCHOLIUM, a note, remark, or annotation, occaſionally made on ſome paſſage, propoſition, or the like.

The term is much uſed in geometry, and other parts of the mathematics; where, after demonſtrating a propoſition, it is uſed to point out how it might be done ſome other way; or to give ſome advice or precaution, in order to prevent miſtakes; or to add ſome particular uſe or application of it.

Wolfius has given abundance of curious and uſeful arts and methods, and a good part of the modern philoſophy, with the deſcription of mathematical inſtruments, &c; all by way of Scholia to the reſpective propoſitions in his Elementa Matheſeos.

SCHONER (JOHN), a noted German philoſopher and mathematician, was born at Caroloſtadt in the year 1477, and died in 1547, at 70 years of age.—His early propenſity to thoſe ſciences may be deemed a juſt prognoſtication of the great progreſs

which

which he afterwards made in them. So that from his uncommon acquirements, he was choſen mathematical profeſſor at Nuremburg when he was but a young man. He wrote a great many works, and was particularly famous for his aſtronomical tables, which he publiſhed after the manner of thoſe of Regiomontanus, and to which he gave the title of *Reſolutæ*, on account of their clearneſs. But notwithſtanding his great knowledge, he was, after the faſhion of the times, much addicted to judicial aſtrology, which he took great pains to improve. The liſt of his writings is chiefly as follows:

1. Three Books of Judicial Aſtrology.
2. The Aſtronomical Tables named *Reſolutæ*.
3. *De Uſu Globi Stelliferi; De Compoſitione Globi Cœleſtis; De Uſu Globi Terreſtris, et de Compoſitione ejuſdem.*
4. *Æquatorium Aſtronomicum.*
5. *Libellus de Diſtantiis Locorum per Inſtrumentum et Numeros Inveſtigandis.*
6. *De Compoſitione Torqueti.*
7. *In Conſtructionem et Uſum Rectanguli ſive Radii Aſtronomici Annotationes.*
8. *Horarii Cylindri Canones.*
9. *Planiſphærium, ſeu Meteoriſcopium.*
10. *Organum Uranicum.*
11. *Inſtrumentum Impedimentorum Lunæ.*

All printed at Nuremburg, in folio, 1551.

Of theſe, the large treatiſe of dialling rendered him more known in the learned world than all his other works beſides; in which he diſcovers a ſurpriſing genius and fund of learning of that kind.

SCHOOL, a place where the languages, humanities, or arts and ſciences, &c, are taught.

SCHOOL is alſo uſed for a whole faculty, univerſity, or ſect; as Plato's ſchool, the ſchool of Epicurus, the ſchool of Paris, &c.—The ſchool of Tiberias was famous among the ancient Jews; and it is to this we owe the Maſſora, and Maſſoretes.

SCHOOL *Philoſophy*, &c. the ſame with *ſcholaſtic*.

SCIAGRAPHY, or SCIOGRAPHY, the profile or vertical ſection of a building; uſed to ſhew the inſide of it.

SCIAGRAPHY, in Aſtronomy &c, is a term uſed by ſome authors for the art of finding the hour of the day or night, by the ſhadow of the ſun, moon, ſtars, &c. See DIAL.

SCIENCE, a clear and certain knowledge of any thing, founded on demonſtration, or on ſelf-evident principles.—In this ſenſe, *doubting* is oppoſed to ſcience; and *opinion* is the middle between the two.

SCIENCE is more particularly uſed for a formed ſyſtem of any branch of knowledge, comprehending the doctrine, reaſon, and theory of the thing, without any immediate application of it to any uſes or offices of life. And in this ſenſe, the word is uſed in oppoſition to *art*.

Science may be divided into theſe three ſorts: Firſt, the knowledge of things, their conſtitutions, properties, and operations, whether material or immaterial. And this, in a little more enlarged ſenſe of the word, may be called phyſics, or natural philoſophy. Secondly, the ſkill of rightly applying our own powers and actions for the attainment of good and uſeful things, as *Ethics*. Thirdly, the doctrine of ſigns; as words, logic, &c.

SCIENTIFIC, or SCIENTIFICAL, ſomething relating to the pure and ſublimer ſciences; or that abounds in ſcience, or knowledge.

A work, or method, &c, is ſaid to be ſcientifical, when it is founded on the pure reaſon of things, or conducted wholly on the principles of them. In which ſenſe the word ſtands oppoſed to narrative, arbitrary, opinionative, poſitive, tentative, &c.

SCIOPTIC, or SCIOPTRIC *Ball*, a ſphere or globe of wood, with a circular hole or perforation, where a lens is placed. It is ſo fitted that, like the eye of an animal, it may be turned round every way, to be uſed in making experiments of the darkened room.

SCIOPTRICS. See CAMERA OBSCURA.

SCIOTHERICUM *Teleſcopium*, is an horizontal dial, adapted with a teleſcope for obſerving the true time both by day and night, to regulate and adjuſt pendulum clocks, watches, and other time-keepers. It was invented by Mr. Molyneux, who publiſhed a book with this title, which contains an accurate deſcription of this inſtrument, with all its uſes and applications.

SCLEROTICA, one of the common membranes of the eye, on its hinder part. It is a large, thick, firm, hard, opaque membrane, extended from the external circumference of the cornea to the optic nerve, and forms much the greater part of the external globe of the eye. The Sclerotica and the cornea compoſe the caſe in which all the internal coats of the eye and its humours are contained.

SCONCES, ſmall forts, built for the defence of ſome paſs, river, or other place. Some Sconces are made regular, of four, five, or ſix baſtions; others are of ſmaller dimenſions, fit for paſſes, or rivers; and others for the field.

SCORE, in Muſic, denotes partition, or the original draught of the whole compoſition, in which the ſeveral parts, viz the treble, ſecond treble, baſs, &c. are diſtinctly ſcored, and marked.

SCORPIO, the *Scorpion*, the 8th ſign of the zodiac, denoted by the character ♏, being a rude deſign of the animal of that name.

The Greeks, who would be ſuppoſed the inventors of aſtronomy, and who have, with that intent, fathered ſome ſtory or other of their own upon every one of the conſtellations, give a very ſingular account of the origin of this one. They tell us that this is the creature which killed Orion. The ſtory goes, that the famous hunter of that name boaſted to Diana and Latona, that he would deſtroy every animal that was upon the earth; the earth, they ſay, enraged at this, ſent forth the poiſonous reptile the Scorpion, which inſignificant creature ſtung him, that he died. Jupiter, they ſay, raiſed the Scorpion to the heavens, giving him this place among the conſtellations; and that afterwards Diana requeſted of him to do the ſame honour to Orion, which he at laſt conſented to, but placed him in ſuch a ſituation, that when the Scorpion riſes, he ſets.

But the Egyptians, or whatever early nation it was that framed the zodiac, probably placed this poiſonous reptile in that part of the heavens to denote that when the ſun arrived at it, fevers and ſickneſſes, the maladies of autumn, would begin to rage. This they repreſented by an animal whoſe ſting was of power to occaſion ſome

of

of them; and it was thus they formed all the conſtellations.

The ancients allotted one of the twelve principal among their deities to be the guardian for each of the 12 ſigns of the zodiac. The Scorpion, as their hiſtory of it made it a fierce and fatal animal that had killed the great Orion, fell naturally to the protection of the god of war; Mars is therefore its tutelary deity; and to this ſingle circumſtance is owing all that jargon of the aſtrologers, who tell us that there is a great analogy between the planet Mars and the conſtellation Scorpio. To this alſo is owing the doctrine of the alchymiſts, that iron, which they call Mars, is alſo under the dominion of the ſame conſtellation, and that the tranſmutation of that metal into gold can only be performed when the ſun is in this ſign.

The ſtars in Scorpio, in Ptolomy's catalogue, are 24; in that of Tycho 10, in that of Hevelius 20, but in that of Flamſteed and Sharp 44.

SCORPION is alſo the name of an ancient military engine, uſed chiefly in the defence of walls, &c.

Marcellinus deſcribes the Scorpion, as conſiſting of two beams bound together by ropes. From the middle of the two, roſe a third beam, ſo diſpoſed, as to be pulled up and let down at pleaſure; and on the top of this were faſtened iron hooks, where a ſling was hung, either of iron or hemp; and under the third beam lay a piece of hair-cloth full of chaff, tied with cords. It had its name Scorpio, becauſe when the long beam or tiller was erected, it had a ſharp top in manner of a ſting.

To uſe the engine, a round ſtone was put into the ſling, and four perſons on each ſide, looſening the beams bound by the ropes, drew back the erect beam to the hook; then the engineer, ſtanding on an eminence, gave a ſtroke with a hammer on the chord to which the beam was faſtened with its hook, which ſet it at liberty; ſo that hitting againſt the ſoft hair-cloth, it ſtruck out the ſtone with a great force.

SCOTIA, in Architecture, a ſemicircular cavity or channel between the tores, in the baſes of columns; and ſometimes under the larmier or drip, in the cornice of the Doric order. The workmen often call it the Caſement, and it is alſo otherwiſe called the Trochilus.

SCREW, or SCRUE, one of the ſix mechanical powers; chiefly uſed in preſſing or ſqueezing bodies cloſe, though ſometimes alſo in raiſing weights.

The Screw is a ſpiral thread or groove cut round a cylinder, and everywhere making the ſame angle with the length of it. So that, if the ſurface of the cylinder, with this ſpiral thread upon it, were unfolded and ſtretched into a plane, the ſpiral thread would form a ſtraight inclined plane, whoſe length would be to its height, as the circumference of the cylinder is to the diſtance between two threads of the Screw; as is evident by conſidering, that in making one round, the ſpiral riſes along the cylinder the diſtance between the two threads.

Hence the threads of a Screw may be traced upon the ſmooth ſurface of a cylinder thus: Cut a ſheet of paper into the form of a right-angled triangle, having its baſe to its height in the above proportion, viz, as the circumference of the cylinder of the Screw is to the intended diſtance between two threads; then wrap this paper triangle about the cylinder, and the hypothenuſe of it will trace out the line of the ſpiral.

When the ſpiral thread is upon the outſide of the cylinder, the Screw is ſaid to be a *male* one. But if the thread be cut along the inner ſurface of a hollow cylinder, or a round perforation, it is ſaid to be a female; this latter is alſo ſometimes called the nut or box.

When motion is to be given to ſomething, the male and female Screw are neceſſarily conjoined: but whenever the ſcrew is to be uſed as a ſimple mechanical power. But when joined with the peritrochio, there is no occaſion for a female; but in that caſe it becomes part of a compound engine.

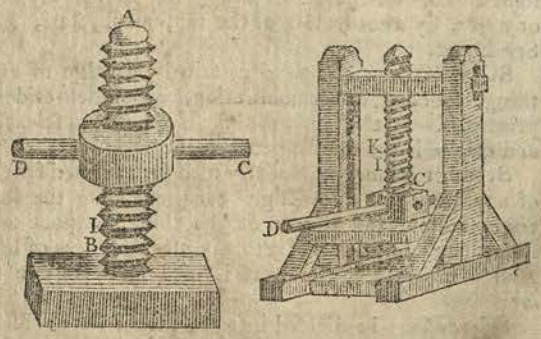
The Screw cannot properly be called a ſimple machine, becauſe it is never uſed without the application of a lever, or winch, to aſſiſt in turning it.

Of the Force and Power of the Screw.

1. The force of a power applied [illegible] round, is to the force with which it preſſes upwards or downwards, ſetting aſide the friction, as the diſtance between two threads is to the circumference where the power is applied.

For, the Screw being only an inclined plane, or half wedge, whoſe height is the diſtance between two threads, and its baſe the ſaid circumference; and the force in the horizontal direction being to that in the vertical one as the lines perpendicular to them, viz, as the height of the plane, or diſtance of the two threads, is to the baſe of the plane, or circumference at the place where the power is applied; therefore the power is to the preſſure, as the diſtance of two threads, is to that circumference.

2. Hence, when the Screw is put in motion; then the power is to the weight which would keep it in equilibrio, as the velocity of the latter is to that of the former. And hence their two momenta are equal, which are produced by multiplying each weight or power by its own velocity. Two different forms of Screw preſſes, are as below.



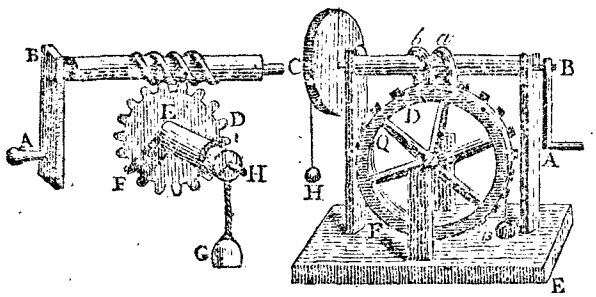
3. Hence we can eaſily compute the force of any machine turned by a Screw. Let the annexed figure repreſent a preſs driven by a Screw, whoſe threads are each a quarter of an inch aſunder; and let the Screw be turned by a handle of 4 feet long from C to D; then if the natural force of a man, by which he can lift, or pull,

pull, or draw, be 150 pounds; and it be required to determine with what force the Screw will preſs on the board, when the man turns the handle at C and D with his whole force. The diameter CD of the power being 4 feet, or 48 inches, its circumference is $48 \times 3{\cdot}1416$ or $150\frac{4}{5}$ nearly; and the diſtance of the threads being $\frac{4}{5}$ of an inch; therefore the power is to the preſſure, as $\frac{1}{4}$ to $150\frac{4}{5}$ or as 1 to $603\frac{1}{5}$: but the power is equal to 150lb; therefore as $1 : 603\frac{1}{5} :: 150 : 90{,}480$; and conſequently the preſſure at the bottom of the Screw, is equal to a weight of 90,480 pounds, independent of friction.

But the power has to overcome, not only the weight, or other reſiſtance, but alſo the friction of the Screw, which in this machine is very great, in ſome caſes equal to the weight itſelf, ſince it is ſometimes ſufficient to ſuſtain the weight, when the power is taken off.

Mr. Hunter has deſcribed a new method of applying the Screw with advantage in particular caſes, in the Philoſ. Tranſ. vol. 71, pa. 58 &c.

The Endleſs SCREW, or *Perpetual* SCREW, is one which works in, and turns, a dented wheel DF, without a concave or female Screw; being ſo called becauſe it may be turned for ever, without coming to an end. From the following ſchemes it is evident, that while the Screw turns once round, the wheel only advances the diſtance of one tooth.



1. If the power applied to the lever, or handle, of an endleſs Screw AB, be to the weight, in a ratio compounded of the periphery of the axis of the wheel EH, to the periphery deſcribed by the power in turning the handle, and of the revolutions of the wheel DF to the revolutions of the Screw CB, the power will balance the weight. Hence,

2. As the motion of the wheel is very ſlow, a ſmall power may raiſe a very great weight, by means of an endleſs Screw. And therefore the chief uſe of ſuch a Screw is, either where a great weight is to be raiſed through a little ſpace; or where only a ſlow gentle motion is wanted. For which reaſon it is very uſeful in clocks and watches.

3. Having given the number of teeth, the diſtance of the power from the centre of the Screw B, the radius of the axis HE, and the power; to find the weight it will raiſe. Multiply the diſtance of the power from the centre of the Screw AB, by the number of the teeth, and the product will be the ſpace paſſed through by the power, while the weight paſſes through a ſpace equal to the periphery of the axis: then ſay, as the radius of the axis is to the ſpace of the power juſt found, ſo is the power to a 4th proportional, which will be the weight the power is able to ſuſtain. Thus, if AB = 3, the radius of the axis HE = 1, the power 150 pounds, and the number of teeth of the wheel DF 48; then the weight will be found = 21,600 = 3 × 150 × 48. Whence it appears that the endleſs Screw exceeds all others in increaſing the force of a power.

4. A machine for ſhewing the power of the Screw may be contrived in the following manner. Let the wheel C (laſt fig.) have a Screw *a b* on its axis, working in the teeth of the wheel D, which ſuppoſe to be 48 in number. It is plain that for every revolution of the wheel C, and Screw *ab*, by the winch A, the wheel D will be moved one tooth by the Screw; and therefore in 48 revolutions of the winch, the wheel D will be turned once round. Then if the circumference of a circle, deſcribed by the handle of the winch, be equal to the circumference of a groove *e* round the wheel D, the velocity of the handle will be 48 times as great as the velocity of any given point in the groove. Conſequently when a line G goes round the groove *e*, and has a weight of 48lb hung to it below the pedeſtal EF, a power equal to one pound at the handle will balance and ſupport the weight.

Archimedes's SCREW, is a ſpiral pump, being a machine for raiſing water, firſt invented by Archimedes.

Its ſtructure and uſe will be underſtood by the following deſcription of it.

ABCD (Pl. xxiii, fig. 6) is a wheel, which is turned round, according to the order of thoſe letters, by the fall of water EF, which need not be more than 3 feet. The axis G of the wheel is raiſed ſo as to make an angle of about 44° with the horizon; and on the top of that axle is a wheel H, which turns ſuch another wheel I of the ſame number of teeth; the axle K of this laſt wheel being parallel to the axle G of the two former wheels. The axle G is cut into a double threaded Screw, as in the annexed figure (fig. 7), exactly reſembling the Screw on the axis of the fly of a common jack, which muſt be what is called a right-handed Screw, if the firſt wheel turns in the direction ABCD; but a left-handed Screw, if the ſtream turns the wheel the contrary way; and the Screw on the axle G muſt be cut in a contrary way to that on the axle K, becauſe theſe axles turn in contrary directions. Theſe Screws muſt be covered cloſe over with boards, like theſe of a cylindrical caſk; and then they will be ſpiral tubes. Or they may be made of tubes or pipes of lead, and wrapt round the axles in ſhallow grooves cut in it, like the figure 8. The lower end of the axle G turns conſtantly in the ſtream that turns the wheel, and the lower ends of the ſpiral tubes are open into the water. So that, as the wheel and axle are turned round, the water riſes in the ſpiral tubes, and runs out at L through the holes M, N, as they come about below the axle. Theſe holes, of which there may be any number, as 4 or 6, are in a broad cloſe ring on the top of the axle, into which ring the water is delivered from the upper open ends of the Screw tubes, and falls into the open box N. The lower end of the axle K turns on a gudgeon in the water in N; and the ſpiral tubes in that axle take up the water from N, and deliver it into another ſuch box under the top of K; on which there may be ſuch another

wheel

wheel as I, to turn a third axle by ſuch a wheel upon it. And in this manner may water be raiſed to any propoſed height, when there is a ſtream ſufficient for that purpoſe to act on the broad float-boards of the firſt wheel. Archimedes's Screw, or a ſtill ſimpler form of it, is alſo repreſented in fig. 9.

SCROLLS, or SCROWLS, or *Volutes*, a term in Architecture. See VOLUTES.

SCRUE. See SCREW.

SCRUPLE, the leaſt of the weights uſed by the ancients. Among the Romans it was the 24th part of an ounce, or the third part of a drachm.

SCRUPLE is ſtill a ſmall weight among us, equal to 20 grains, or the 3d part of a drachm. Among goldſmiths the ſcruple is 24 grains.

SCRUPLE, in Chronology, a ſmall portion of time much uſed by the Chaldeans, Jews, Arabs, and other eaſtern people, in computations of time. It is the 1080th part of an hour, and by the Hebrews called *helakin*.

SCRUPLES, in Aſtronomy. As

SCRUPLES *Eclipſed*, denote that part of the moon's diameter which enters the ſhadow, expreſſed in the ſame meaſure in which the apparent diameter of the moon is expreſſed. See DIGIT.

SCRUPLES *of Half Duration*, an arch of the moon's orbit, which the moon's centre deſcribes from the beginning of an eclipſe to its middle.

SCRUPLES *of Immerſion*, or *Incidence*, an arch of the moon's orbit, which her centre deſcribes from the beginning of the eclipſe, to the time when the centre falls into the ſhadow. See IMMERSION.

SCRUPLES *of Emerſion*, an arch of the moon's orbit, which her centre deſcribes in the time from the firſt emerſion of the moon's limb, to the end of the eclipſe.

SCYTALA, in Mechanics, a term which ſome writers uſe for a kind of radius, or ſpoke, ſtanding out from the axis of a machine, as a lever or handle, to turn it round, and work it by.

SEA, in Geography, is frequently uſed for that vaſt tract of water encompaſſing the whole earth, more properly called ocean. But

SEA is more properly uſed for a particular part or diviſion of the ocean, denominated from the countries it waſhes, or from other circumſtances. Thus we ſay, the Iriſh ſea, the Mediterranean ſea, the Baltic ſea, the Red ſea, &c.

SEA among ſailors is variouſly applied, to a ſingle wave, or to the agitation produced by a multitude of waves in a tempeſt, or to their particular progreſs and direction. Thus they ſay, a heavy ſea broke over our quarter, or we ſhipped a heavy ſea; there is a great ſea in the offing; the ſea ſets to the ſouthward. Hence a ſhip is ſaid to head the ſea, when her courſe is oppoſed to the ſetting or direction of the ſurges. A *Long Sea* implies a ſteady and uniform motion of long and extenſive waves. On the contrary, a *Short Sea* is when they run irregularly, broken, and interrupted, ſo as frequently to burſt over a veſſel's ſide or quarter.

Properties and Affections of the SEA.

1. *General Motion of the Sea.* M. Daſſie of Paris, in a work long ſince publiſhed, has been at great pains to prove that the Sea has a general motion, independent of winds and tides, and of more conſequence in navigation than is uſually ſuppoſed. He affirms that this motion is from eaſt to weſt, inclining toward the north when the ſun is on the north ſide of the equinoctial, but toward the ſouth when he is on the ſouth ſide of it. Philoſ. Tranſ. No. 135.

2. *Baſon or Bottom of the* SEA, or *Fundus Maris*, a term uſed to expreſs the bed or bottom of the ſea in general. Mr. Boyle has publiſhed a treatiſe on this ſubject, in which he has given an account of its irregularities and various depths founded on the obſervations communicated to him by mariners.

Count Marſigli has, ſince his time, given a much fuller account of this part of the globe. The materials which compoſe the bottom of the Sea, may reaſonably be ſuppoſed, in ſome degree, to influence the taſte of its waters; and this author has made many experiments to prove that foſſil coal, and other bituminous ſubſtances, which are found in plenty at the bottom of the Sea, may communicate in great part its bitterneſs to it.

It is a general rule among ſailors, and is found to hold true in many inſtances, that the more the ſhores of any place are ſteep and high, forming perpendicular cliffs, the deeper the Sea is below; and that on the contrary, level ſhores denote ſhallow Seas. Thus the deepeſt part of the Mediterranean is generally allowed to be under the height of Malta. And the obſervation of the ſtrata of earth and other foſſils, on and near the ſhores, may ſerve to form a good judgment as to the materials to be found in its bottom. For the veins of ſalt and of bitumen doubtleſs run on the ſame, and in the ſame order, as we ſee them at land; and the ſtrata of rocks that ſerve to ſupport the earth of hills and elevated places on ſhore, ſerve alſo, in the ſame continued chain, to ſupport the immenſe quantity of water in the baſon of the Sea.

The coral fiſheries have given occaſion to obſerve that there are many, and thoſe very large caverns or hollows in the bottom of the Sea, eſpecially where it is rocky; and that the like caverns are ſometimes found in the perpendicular rocks which form the ſteep ſides of thoſe fiſheries. Theſe caverns are often of great depth, as well as extent, and have ſometimes wide mouths, and ſometimes only narrow entrances into large and ſpacious hollows.

The bottom of the Sea is covered with a variety of matters, ſuch as could not be imagined by any but thoſe who have examined into it, eſpecially in deep water, where the ſurface only is diſturbed by tides and ſtorms, the lower part, and conſequently its bed at the bottom, remaining for ages perhaps undiſturbed. The ſoundings, when the plummet firſt touches the ground on approaching the ſhores, give ſome idea of this. The bottom of the plummet is hollowed, and in that hollow there is placed a lump of tallow; which being the part that firſt touches the ground, the ſoft nature of the fat receives into it ſome part of thoſe ſubſtances which it meets with at the bottom: this matter, thus brought up, is ſometimes pure ſand, ſometimes a kind of ſand made of the fragment of ſhells, beaten to a ſort of powder, ſometimes it is made of a like powder of the ſeveral ſorts of corals, and ſometimes it is compoſed

of fragments of rocks; but beſide theſe appearances, which are natural enough, and are what might well be expected, it brings up ſubſtances which are of the moſt beautiful colours. Marſigli Hiſt. Phyſ. de la Mer.

Dr. Donati, in an Italian work, containing an eſſay towards a natural hiſtory of the Adriatic Sea, printed at Venice in 1750, has related many curious obſervations on this ſubject, and which confirm the obſervations of Marſigli: having carefully examined the ſoil and productions of the various countries that ſurround the Adriatic Sea, and compared them with thoſe which he took up from the bottom of the Sea, he found that there is very little difference between the former and the latter. At the bottom of the water there are mountains, plains, vallies, and caverns, ſimilar to thoſe upon land. The ſoil conſiſts of different ſtrata placed one upon another; and moſtly parallel and correſpondent to thoſe of the rocks, iſlands, and neighbouring continents. They contain ſtones of different ſorts, minerals, metals, various putrefied bodies, pumice ſtones, and lavas formed by volcanos.

One of the objects which moſt excited his attention, was a cruſt, which he diſcovered under the water, compoſed of cruſtaceous and teſtaceous bodies, and beds of polypes of different kinds, confuſedly blended with earth, ſand, and gravel; the different marine bodies which form this cruſt, are found at the depth of a foot or more, entirely petrified and reduced into marble; theſe he ſuppoſes are naturally placed under the Sea when it covers them, and not by means of volcanos and earthquakes, as ſome have conjectured. On this account he imagines that the bottom of the Sea is conſtantly riſing higher and higher, with which other obvious cauſes of increaſe concur; and from this riſing of the bottom of the Sea, that of its level or ſurface naturally reſults; in proof of which this writer recites a great number of facts. Philoſ. Tranſ. vol. 49, pa. 585.

3. *Luminouſneſs of the* SEA. This is a phenomenon that has been noticed by many nautical and philoſophical writers. Mr. Boyle aſcribes it to ſome coſmical law or cuſtom of the terreſtrial globe, or at leaſt of the planetary vortex.

Father Bourzes, in his voyage to the Indies, in 1704, took particular notice of this phenomenon, and very minutely deſcribes it, without aſſigning the true cauſe.

The Abbé Nollet was long of opinion, that the light of the Sea proceeded from electricity; and others have had recourſe to the ſame principle, and ſhewn that the luminous points in the ſurface of the Sea are produced merely by friction.

There are however two other hypotheſes, which have more generally divided between them the ſolution of this phenomenon; the one of theſe aſcribes it to the ſhining of luminous inſects or animalcules, and the other to the light proceeding from the putrefaction of animal ſubſtances. The Abbé Nollet, who at firſt conſidered this luminouſneſs as an electrical phenomenon, having had an opportunity of obſerving the circumſtances of it, when he was at Venice in 1749, relinquiſhed his former opinion, and concluded that it was occaſioned either by the luminous aſpect, or by ſome liquor or effluvia of an inſect which he particularly deſcribes, though he does not altogether exclude other cauſes, and eſpecially the ſpawn or fry of fiſh.

The ſame hypotheſis had alſo occurred to M. Vianelli; and both he and Grizellini, a phyſician in Venice, have given drawings of the inſects from which they imagined this light to proceed.

A ſimilar conjecture is propoſed by a correſpondent of Dr. Franklin, in a letter read at the Royal Society in 1756; the writer of which apprehends, that this appearance may be cauſed by a great number of little animals, floating on the ſurface of the Sea. And Mr. Forſter, in his account of a voyage round the world with captain Cook, in the years 1772, 3, 4, and 5, deſcribes this phenomenon as a kind of blaze of the Sea; and, having attentively examined ſome of the ſhining water, expreſſes his conviction that the appearance was occaſioned by innumerable minute animals of a round ſhape, moving through the water in all directions, which ſhow ſeparately as ſo many luminous ſparks when taken up on the hand: he imagines that theſe ſmall gelatinous luminous ſpecks may be the young fry of certain ſpecies of ſome meduſæ, or blubber. And M. Dagelat and M. Rigaud obſerved ſeveral times, and in different parts of the ocean, ſuch luminous appearances by vaſt maſſes of different animalcules; and a few days after the Sea was covered, near the coaſts, with whole banks of ſmall fiſh in innumerable multitudes, which they ſuppoſed had proceeded from the ſhining animalcules.

But M. le Roi, after giving much attention to this phenomenon, concludes that it is not occaſioned by any ſhining inſects, eſpecially as, after carefully examining with a microſcope ſome of the luminous points, he found them to have no appearance of an animal; and he alſo found that the mixture of a little ſpirit of wine with water juſt drawn from the Sea, would give the appearance of a great number of little ſparks, which would continue viſible longer than thoſe in the ocean: the ſame effect was produced by all the acids, and various other liquors. M. le Roi is far from aſſerting that there are no luminous inſects in the Sea; for he allows that ſeveral gentlemen have found them; but he is ſatisfied that the Sea is luminous chiefly on ſome other account, though he does not ſo much as offer a conjecture with reſpect to the true cauſe.

Other authors, equally diſſatisfied with the hypotheſis of luminous inſects, for explaining the phenomenon which is the ſubject of this article, have aſcribed it to ſome ſubſtance of the phoſphoric kind, ariſing from putrefaction. The obſervations of F. Bourzes, above referred to, render it very probable, that the luminouſneſs of the Sea ariſes from ſlimy and other putreſcent matter, with which it abounds, though he does not mention the tendency to putrefaction, as a circumſtance of any conſequence to the appearance. But the experiments of Mr. Canton, which have the advantage of being eaſily made, ſeem to leave no room to doubt that the luminouſneſs of the Sea is chiefly owing to putrefaction. And his experiments confirm an obſervation of Sir John Pringle's, that the quantity of ſalt contained in Sea-water haſtens putrefaction; but ſince that preciſe quantity of ſalt which promotes putre-

faction the moſt, is leſs than that which is found in Sea-water, it is probable, Mr. Canton obſerves, that if the Sea were leſs ſalt, it would be more luminous. See Philoſ. Tranſ. vol. 59, pa. 446, and Franklin's Exper. and Obſerv. pa. 274.

Of the Depth of the Sea, its Surface, &c.

What proportion the ſuperficies of the Sea bears to that of the land, is not accurately known, though it is ſaid to be ſomewhat more than two to one. This proportion of the ſurface of the Sea to the land, has been found by experiment thus: taking the printed paper map or covering of a terreſtrial globe, with a pair of ſciſſors clip out the parts that are land, and thoſe that are water; then weighing theſe parcels ſeparately in a pair of fine ſcales, the land is found to be near $\frac{1}{3}$, and the water rather more than $\frac{2}{3}$ of the whole.

With regard to the profundity or depth of the Sea, Varenius affirms, that it is in ſome places unfathomable, and in others very various, being in certain places from $\frac{1}{20}$th of a mile to $4\frac{1}{2}$ miles in depth, in other places deeper, but much leſs in bays than in oceans. In general, the depths of the Sea bear a great analogy to the height of mountains on the land, ſo far as is hitherto diſcovered.

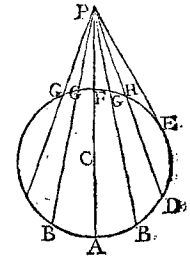
There are two ſpecial reaſons why the Sea does not increaſe by means of rivers, &c, running every where into it. The firſt is, becauſe waters return from the Sea by ſubterranean cavities and aqueducts, through various parts of the earth. Secondly, becauſe the quantity of vapours raiſed from the Sea, and falling in rain upon the land, only cauſe a circulation of the water, but no increaſe of it. It has been found by experiment and calculation, that in a ſummer's day, there may be raiſed in vapours from the ſurface of the Mediterranean Sea, 528 millions of tuns of water; and yet this Sea receiveth not, from all its nine great rivers, above 183 millions of tuns per day, which is but about a third part of what is exhauſted in vapours; and this defect in the ſupply by the rivers, may ſerve to account for the continual influx of a current by the mouth or ſtraits at Gibraltar. Indeed it is rather probable, that the waters of the Sea ſuffer a continual ſlow decreaſe as to their quantity, by ſinking always deeper into the earth, by filtering through the fiſſures in the ſtrata and component parts.

SEASONS, certain portions or quarters of the year, diſtinguiſhed by the ſigns which the ſun then enters. Upon them depend the different temperatures of the air, different works in tillage, &c.

The year is divided into four Seaſons, ſpring, ſummer, autumn, winter, which take their beginnings when the ſun enters the firſt point of the ſigns Aries, Cancer, Libra, Capricorn.

The Seaſons are very well illuſtrated by *fig.* 1, plate viii; where the candle at I repreſents the ſun in the centre, about which the earth moves in the ecliptic ABCD, which cuts the equinoctial *abcd* in the two equinoxes E and G. When the earth is in theſe two points, it is evident that the ſun equally illuminates both the poles, and makes the days and nights equal all over the earth. But while the earth moves from G by C to ♑, the upper or north pole becomes more and more enlightened, the days become longer, and the nights ſhorter; ſo that when the earth is at ♑, or the ſun at ♋, our days are at the longeſt, as at midſummer. While the earth moves from ♑ by D to E, our days continually decreaſe, by the north pole gradually declining from the ſun, till at E or autumn they become equal to the nights, or 12 hours long. Again, while the earth moves from E by A to F, the north pole becomes always more and more involved in darkneſs, and the days grow always ſhorter, till at F or ♋, when it is midwinter to the inhabitants of the northern hemiſphere. Laſtly, while the earth moves from ♋ by B to G, the north parts come more and more out of darkneſs, and the days grow continually longer, till at G the two poles are equally enlightened, and the days equal to the nights again. And ſo on continually year after year.

SECANT, in Geometry, a line that cuts another, whether right or curved; Thus the line PA or PB, &c, is a Secant of the circle ABD, becauſe cutting it in the point F, or G, &c. Properties of ſuch Secants to the circle are as follow:



1. Of ſeveral Secants PA, PB, PD, &c, drawn from the ſame point P, that which paſſes through the centre C is the greateſt; and from thence they decreaſe more and more as they recede farther from the centre; viz. PB leſs than PA, and PD leſs than PB, and ſo on, till they arrive at the tangent at E, which is the limit of all the Secants.

2. Of theſe Secants, the external parts PF, PG, PH, &c, are in the reverſe order, increaſing continually from F to E, the greater Secant having the leſs external part, and in ſuch ſort, that any Secant and its external part are in reciprocal proportion, or the whole is reciprocally as its external part, and conſequently that the rectangle of every Secant and its external part is equal to a conſtant quantity, viz, the ſquare of the tangent. That is,

$$PA : \frac{1}{PF} :: PB : \frac{1}{PG} :: PD : \frac{1}{PH} \text{ &c,}$$

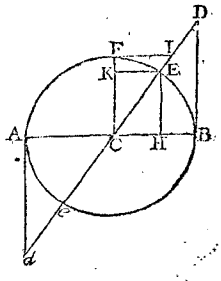
or $PA \times PF = PB \times PG = PD \times PH = PE^2$.

3. The tangent PE is a mean proportional between any Secant and its external part; as between PA and PF, or PB and PG, or PD and PH, &c.

4. The angle DPB, formed by two Secants, is meaſured by half the difference of its intercepted arcs DB and GH.

SECANT, in Trigonometry, denotes a right line drawn from the centre of a circle, and, cutting the circumference, proceeds till it meets with a tangent to the ſame circle.

Thus, the line CD, drawn from the centre C, till it meets the tangent BD, is called a Secant; and particularly the Secant of the arc BE, to which BD is a tangent. In like manner, by producing DC to meet the tangent A*d* in *d*, then C*d*, equal to CD, is the Secant of the arch AE which is the ſupplement of the arch BE.



So

So that an arch and its ſupplement have their Secants equal, only the latter one is negative to the former, being drawn the contrary way. And thus the Secants in the 2d and 3d quadrant are negative, while thoſe in the 1ſt and 4th quadrants are poſitive.

The Secant CI of the arc EF, which is the complement of the former arch BE, is called the *cofecant* of BE, or the Secant of its complement. The cofecants in the 1ſt and 2d quadrants are affirmative, but in the 3d and 4th negative.

The Secant of an arc is reciprocally as the coſine, and the cofecant reciprocally as the ſine; or the rectangle of the Secant and coſine, and the rectangle of the cofecant and ſine, are each equal to the ſquare of the radius.

For CD : CE : : CB : CH, or $f : r :: r : c$,
and CI : CE : : CF : CK, or $\sigma : r :: r : s$;

and conſequently $r^2 = cf = s\sigma$; where r denotes the radius, s the ſine, c the coſine, f the Secant, and σ the cofecant.

An arc a, to the radius r, being given, the Secant f, and cofecant σ, and their logarithms, or the logarithmic Secant and cofecant, may be expreſſed in infinite ſeries, as follows, viz,

$$f = r + \frac{a^2}{2r} + \frac{5a^4}{24r^3} + \frac{61a^6}{720r^5} + \frac{277a^8}{8064r^7} \text{ &c.}$$

$$\sigma = \frac{r^2}{a} + \frac{a}{6} + \frac{7a^3}{360r^2} + \frac{31a^5}{15120r^4} + \frac{127a^7}{604800r^6} \text{ &c.}$$

$$log.\ f = m \times \left(\frac{a^2}{2} + \frac{a^4}{12} + \frac{a^6}{45} + \frac{17a^8}{2520} \text{ &c.}\right)$$

$$log.\sigma = -log.a + m \times \left(\frac{a^2}{6} + \frac{a^4}{180} + \frac{a^6}{2835} + \frac{a^8}{37800} \text{&c.}\right)$$

where m is the modulus of the ſyſtem of logarithms.

SECANTS, *Figure of.* See FIGURE *of Secants.*

SECANTS, *Line of.* See SECTOR, and SCALE.

SECOND, in Geometry, or Aſtronomy, &c, the 60th part of a prime or minute: either in the diviſion of circles, or in the meaſure of time. A degree, or an hour, are each divided into 60 minutes, marked thus ′; a minute is ſubdivided into 60 Seconds, marked thus ″; a Second into 60 thirds, marked thus ‴; &c.

We ſometimes ſay a *Second minute*, a *third minute*, &c, but more uſually only *Second*, *third*, &c.

The Seconds pendulum, or pendulum that vibrates Seconds, in the latitude of London, is $39\frac{1}{8}$ inches long.

SECONDARY *Circles of the Ecliptic*, are circles of longitude of the ſtars; or circles which, paſſing through the poles of the ecliptic, are at right angles to the ecliptic.

By means of theſe Secondary circles, all points in the heavens are referred to the ecliptic; that is, any ſtar, planet, or other phenomenon, is underſtood to be in that point of the ecliptic, which is cut by the Secondary circle that paſſes through ſuch ſtar, &c.

If two ſtars be thus referred to the ſame point of the ecliptic, they are ſaid to be in conjunction; if in oppoſite points, they are in oppoſition; if they are referred to two points at a quadrant's diſtance, they are ſaid to be in a quartile aſpect, if the points differ a 6th part of the ecliptic, they are in ſextile aſpect, &c.

In general, all circles that interſect one of the ſix greater circles of the ſphere at right angles, may be called Secondary circles. As the azimuth or vertical circles in reſpect of the horizon, &c; the meridian in reſpect of the equator, &c.

SECONDARY *Planets*, or *Satellites*, are thoſe moving round other planets as the centres of their motion, and along with them round the ſun.

SECTION, in Geometry, denotes a ſide or ſurface appearing of a body, or figure, cut by another; or the place where lines, planes, &c, cut each other.

The common Section of two planes is always a right line; being the line ſuppoſed to be drawn by one plane in its cutting or entering the other. If a ſphere be cut in any manner by a plane, the figure of the Section will be a circle; alſo the common interſection of the ſurfaces of two ſpheres, is the circumference of a circle; and the two common Sections of the ſurfaces of a right cone and a ſphere, are the circumferences of circles if the axis of the cone paſs through the centre of the ſphere, otherwiſe not; moreover, of the two common Sections of a ſphere and a cone, whether right or oblique, if the one be a circle the other will be a circle alſo, otherwiſe not. See my Tracts, tract 7, prop. 7, 8, 9.

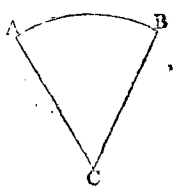
The Sections of a cone by a plane, are five; viz, a triangle, circle, ellipſe, hyperbola, and parabola. See each of theſe terms, as alſo CONIC SECTION.

Sections of Buildings and Bodies, &c, are either vertical, or horizontal, &c. The

Vertical SECTION, or ſimply the SECTION, of a building, denotes its profile, or a delineation of its heights and depths raiſed on the plan; as if the fabric had been cut aſunder by a vertical plane, to diſcover the inſide. And

Horizontal SECTION is the ichnography or ground plan, or a Section parallel to the horizon.

SECTOR, of a Circle, is a portion of the circle comprehended between two radii and their included arc. Thus, the mixt triangle ABC, contained between the two radii AC and BC, and the arc AB, is a Sector of the circle.



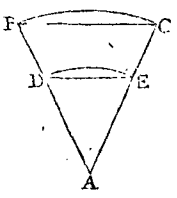
The Sector of a circle, as ABC, is equal to a triangle, whoſe baſe is the arc AB, and its altitude the radius AC or BC. And therefore the radius being drawn into the arc, half the product gives the area.

Similar SECTORS, are thoſe which have equal angles included between their radii. Theſe are to each other as the ſquares of their bounding arcs, or as their whole circles.

SECTOR alſo denotes a mathematical inſtrument, which is of great uſe in geometry, trigonometry, ſurveying, &c, in meaſuring and laying down and finding propoſtional quantities of the ſame kind: as between lines and lines, ſurfaces and ſurfaces, &c: whence the French call it the *compaſs of proportion.*

The great advantage of the Sector above the common scales, &c, is, that it is contrived so as to suit all radii, and all scales. By the lines of chords, sines, &c, on the Sector, we have lines of chords, sines, &c, to any radius between the length and breadth of the Sector when open.

The Sector is founded on the 4th proposition of the 6th book of Euclid; where it is demonstrated, that similar triangles have their like sides proportional. An idea of the theory of its construction may be conceived thus. Let the lines AB, AC represent the legs of the Sector; and AD, AE, two equal sections from the centre: then if the points BC and DE be connected, the lines BC and DE will be parallel; therefore the triangles ABC, ADE will be similar, and consequently the sides AB, BC, AD, DE proportional, that is, as AB : BC :: AD : DE; so that if AD be the half, 3d, or 4th part of AB, then DE will be a half, 3d, or 4th part of BC: and the same holds of all the rest. Hence, if DE be the chord, sine or tangent, of any arc, or of any number of degrees, to the radius AD, then BC will be the same to the radius AB.



The Sector, it is supposed, was the invention of Guido Baldo or Ubaldo, about the year 1568. The first printed account of it was in 1584, by Gaspar Mordente at Antwerp, who indeed says that his brother Fabricius Mordente invented it, in the year 1554. It was next treated of by Daniel Speckle, at Strasburgh, in 1589; after that by Dr. Thomas Hood, at London, in 1598: and afterwards by many other writers on practical geometry, in all the nations of Europe.

Description of the SECTOR. This instrument consists of two rules or legs, the longer the better, made of box, or ivory, or brass, &c, representing the radii, moveable round an axis or joint, the middle of which represents the centre; from whence several scales are drawn on the faces. See the fig. 1, plate xxvi.

The scales usually set upon Sectors, may be distinguished into single and double. The single scales are such as are set upon plane scales: the double scales are those which proceed from the centre; each of these being laid twice on the same face of the instrument, viz. once on each leg. From these scales, dimensions or distances are to be taken, when the legs of the instrument are set in an angular position.

The scales set upon the best Sectors are

Single { 1 2 3 4 5 6 7 8 9 10 11 12 13 14 } A line of { Inches, each divided into 8 and 10 parts; Decimals, containing 100 parts; Chords; Sines; Tangents; Rhumbs; Latitude; Hours; Longitude; Inclin. Merid.; the logarithms of { Numbers; Sines; Versed Sines; Tangents } } marked { Cho. Sin. Tang. Rhum. Lat. Hou. Lon. In. mer. Num. Sin. V. Sin. Tan. }

Double { 1 2 3 4 5 6 7 } a line of { Lines, or equal parts; Chords; Sines; Tangents to 45°; Secants; Tangents to above 45°; Polygons } marked { Lin. Cho. Sin. Tan. Sec. Tan. Pol. }

The manner in which these scales are disposed on the Sector, is best seen in the figure.

The scales of lines, chords, sines, tangents, rhumbs, latitudes, hours, longitude, incl. merid. may be used, with the instrument either shut or open, each of these scales being contained on one of the legs only. The scales of inches, decimals, log. numbers, log. sines, log. versed sines, and log. tangents, are to be used with the Sector quite open, with the two rulers or legs stretched out in the same direction, part of each scale lying on both legs.

The double scales of lines, chords, sines, and lower tangents, or tangents under 45°, are all of the same radius or length; they begin at the centre of the instrument, and are terminated near the other extremity of each leg; viz, the lines at the division 10, the chords at 60, the sines at 90, and the tangents at 45; the remainder of the tangents, or those above 45°, are on other scales beginning at $\frac{1}{4}$ of the length of the former, counted from the centre, where they are marked with 45, and run to about 76 degrees.

The secants also begin at the same distance from the centre, where they are marked with 10, and are from thence continued to as many degrees as the length of the Sector will allow, which is about 75°.

The angles made by the double scales of lines, of chords, of sines, and of tangents to 45 degrees, are always equal. And the angles made by the scales of upper tangents, and of secants, are also equal.

The scales of polygons are set near the inner edge of the legs; and where these scales begin, they are marked with 4, and from thence are figured backwards, or towards the centre, to 12.

From this disposition of the double scales, it is plain, that those angles that are equal to each other while the legs of the Sector were close, will still continue to be equal, although the Sector be opened to any distance.

The scale of inches is laid close to the edge of the Sector, and sometimes on the edge; it contains as many inches as the instrument will receive when opened; each inch being usually divided into 8, and also into 10 equal parts. The decimal scale lies next to this: it is of the length of the Sector when opened, and is divided into 10 equal parts, or primary divisions, and each of these into 10 other equal parts; so that the whole is divided into 100 equal parts: and by this decimal scale, all the other scales, that are taken from tables, may be laid down. The scales of chords, rhumbs, sines, tangents, hours, &c, are such as are described under Plane Scale.

The scale of logarithmic or artificial numbers, called Gunter's scale, or Gunter's line, is a scale expressing the logarithms of common numbers, taken in their natural order.

The construction of the double scale will be evident by inspecting the instrument. As to the scale of polygons,

gons, it uſually comprehends the ſides of the polygons from 6 to 12 ſides incluſive: the diviſions are laid down by taking the lengths of the chords of the angles at the centre of each polygon, and laying them down from the centre of the inſtrument. When the polygons of 4 and 5 ſides are alſo introduced, this line is conſtructed from a ſcale of chords, where the length of 90° is equal to that of 60° of the double ſcale of chords on the Sector.

In deſcribing the uſe of the Sector, the terms *lateral diſtance* and *tranſverſe diſtance* often occur. By the former is meant the diſtance taken with the compaſſes on one of the ſcales only, beginning at the centre of the Sector; and by the latter, the diſtance taken between any two correſponding diviſions of the ſcales of the ſame name, the legs of the Sector being in an angular poſition.

Uſes of the SECTOR.

Of the Line of Lines. This is uſeful, to divide a given line into any number of equal parts, or in any proportion, or to make ſcales of equal parts, or to find 3d and 4th proportionals, or mean proportionals, or to increaſe or decreaſe a given line in any proportion. Ex. 1. To divide a given line into any number of equal parts, as ſuppoſe 9: make the length of the given line a tranſverſe diſtance to 9 and 9, the number of parts propoſed; then will the tranſverſe diſtance of 1 and 1 be one of the equal parts, or the 9th part of the whole; and the tranſverſe diſtance of 2 and 2 will be 2 of the equal parts, or $\frac{2}{9}$ of the whole line; and ſo on. 2. Again, to divide a given line into any number of parts that ſhall be in any aſſigned proportion, as ſuppoſe three parts, in the proportion of 2, 3, and 4. Make the given line a tranſverſe diſtance to 9, the ſum of the propoſed numbers 2, 3, 4; then the tranſverſe diſtances of theſe numbers ſeverally will be the parts required.

Of the Scale of Chords. 1. To open the Sector to any angle, as ſuppoſe 50 degrees: Take the diſtance from the joint to 50 on the chords, the number of degrees propoſed; then open the Sector till the tranſverſe diſtance from 60 to 60, on each leg, be equal to the ſaid lateral diſtance of 50; ſo ſhall the ſcale of chords make the propoſed angle of 50 degrees.—By the converſe of this operation, may be known the angle the Sector is opened to; viz, taking the tranſverſe diſtance of 60, and applying it laterally from the joint.

2. To protract or lay down an angle of any given number of degrees. At any opening of the Sector, take the tranſverſe diſtance of 60°, with which extent deſcribe an arc; then take the tranſverſe diſtance of the number of degrees propoſed, and apply it to that arc; and through the extremities of this diſtance on the arc draw two lines from the centre, and they will form the angle as propoſed. When the angle exceeds 60°, lay it off at twice or thrice.—By the converſe operation any angle may be meaſured; viz, With any radius deſcribe an arc from the angular point; ſet that radius tranſverſely from 60 to 60; then take the diſtance of the intercepted arc and apply it tranſverſely to the chords, which will ſhew the degrees in the given angle.

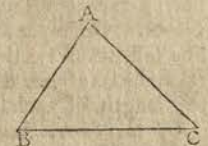
Of the Line of Polygons. 1. In a given circle to inſcribe a regular polygon, for example an octagon. Open the legs of the Sector till the tranſverſe diſtance from 6 to 6 be equal to the radius of the circle; then will the tranſverſe diſtance of 8 and 8 be the ſide of the inſcribed octagon. 2. Upon a line given to deſcribe a regular polygon. Make the given line a tranſverſe diſt. to 5 and 5; and at that opening of the Sector take the tranſverſe diſtance of 6 and 6; with which as a radius, from the extremities of the given line deſcribe arcs to interſect each other, which interſection will be the centre of a circle in which the propoſed polygon may be inſcribed; then from that centre deſcribe the ſaid circle through the extremities of the given line, and apply this line continually round the circumference, for the ſeveral angular points of the polygon.—3. On a given right line as a baſe, to deſcribe an iſoſceles triangle, having the angles at the baſe double the angle at the vertex. Open the Sector till the length of the given line fall tranſverſely on 10 and 10 on each leg; then take the tranſverſe diſtance to 6 and 6, and it will be the length of each of the equal ſides of the triangle.

Of the Sines, Tangents, and Secants. By the ſeveral lines diſpoſed on the ſector, we have ſcales of ſeveral radii. So that, 1. Having a length or radius given, not exceeding the length of the Sector when opened, we can find the chord, ſine, &c, to the ſame: for ex. ſuppoſe the chord, ſine, or tangent of 20 degrees to a radius of 3 inches be required. Make 3 inches the opening or tranſverſe diſtance to 60 and 60 on the chords; then will the ſame extent reach from 45 to 45 on the tangents, and from 90 to 90 on the ſines; ſo that to whatever radius the line of chords is ſet, to the ſame are all the others ſet alſo. In this diſpoſition therefore, if the tranſverſe diſtance between 20 and 20 on the chords be taken with the compaſſes, it will give the chord of 20 degrees; and if the tranſverſe of 20 and 20 be in like manner taken on the ſines, it will be the ſine of 20 degrees; and laſtly, if the tranſverſe diſtance of 20 and 20 be taken on the tangents, it will be the tangent of 20 degrees, to the ſame radius.—2. If the chord or tangent of 70 degrees were required. For the chord, the tranſverſe diſtance of half the arc, viz. 35, muſt be taken, as before; which diſtance taken twice gives the chord of 70 degrees. To find the tangent of 70 degrees, to the ſame radius, the ſcale of upper tangents muſt be uſed, the under one only reaching to 45: making therefore 3 inches the tranſverſe diſtance to 45 and 45 at the beginning of that ſcale, the extent between 70 and 70 degrees on the ſame, will be the tangent of 70 degrees to 3 inches radius.—3. To find the ſecant of an arc; make the given radius the tranſverſe diſtance between 0 and 0 on the ſecants; then will the tranſverſe diſtance of 20 and 20, or 70 and 70, give the ſecant of 20 or 70 degrees.—4. If the radius, and any line repreſenting a ſine, tangent, or ſecant; be given, the degrees correſponding to that line may be found by ſetting the Sector to the given radius, according as a ſine, tangent, or ſecant is concerned; then taking the given line between the compaſſes, and applying the two feet tranſverſely to the proper ſcale, and ſliding the feet along till they both reſt on like diviſions on both legs; then the diviſions will ſhew the degrees and parts correſponding to the given line.

Uſe

Uſe of the Sector in Trigonometry, or in working any other proportions.

By means of the double ſcales, which are the parts more peculiar to the Sector, all proportions are worked by the property of ſimilar triangles, making the ſides proportional to the baſes, that is, on the Sector, the lateral diſtances proportional to the tranſverſe ones; thus, taking the diſtance of the firſt term, and applying it to the 2d, then the diſtance of the 3d term, properly applied, will give the 4th term: obſerving that the ſides of triangles are taken off the line of numbers laterally, and the angles are taken tranſverſely, off the ſines or tangents or ſecants, according to the nature of the proportion. For example, in a plane triangle ABC, given two ſides and an angle oppoſite to one of them, to find the reſt; viz, given AB = 56, AC = 64, and ∠B = 46° 30′, to find BC and the angles A and C. In this caſe, the ſides are proportional to the ſines of their oppoſite angles; hence theſe proportions,



as AC (64) : ſin. ∠B (46° 30′) : : AB (56) : ſin. ∠C, and as ſin. B : AC : : ſin. A : BC.

Therefore, to work theſe proportions by the Sector, take the lateral diſtance of 64 = AC from the lines, and open the Sector to make this a tranſverſe diſtance of 46° 30′ = ∠B, on the ſines; then take the lateral diſtance of 56 = AB on the lines, and apply it tranſverſely on the ſines, which will give 39° 24′ = ∠C. Hence, the ſum of the angles B and C, which is 85° 54′, taken from 180°, leaves 94° 6′ = ∠A. Then, to work the 2d proportion, the Sector being ſet at the ſame opening as before, take the tranſverſe diſtance of 94° 6′ = ∠A, on the ſines, or, which is the ſame thing, the tranſverſe diſtance of its ſupplement 85° 54′; then this applied laterally to the lines, gives 88 = the ſide BC ſought.

For the complete hiſtory of the Sector, with its more ample and particular conſtruction and uſes, ſee Robertſon's *Treatiſe of ſuch Mathematical Inſtruments, as are uſually put into a Portable Caſe*, the Introduction.

SECTOR *of a Sphere*, is the ſolid generated by the revolution of the Sector of a circle about one of its radii; the other radius deſcribing the ſurface of a cone, and the circular arc a circular portion of the ſurface of the ſphere of the ſame radius. So that the ſpherical Sector conſiſts of a right cone, and of a ſegment of the ſphere having the ſame common baſe with the cone. And hence the ſolid content of it will be found by multiplying the baſe or ſpherical ſurface by the radius of the ſphere, and taking a 3d part of the product.

SECTOR *of an ellipſe*, or *of an hyperbola*, &c, is a part reſembling the circular Sector, being contained by three lines, two of which are radii, or lines drawn from the centre of the figure to the curve, and the intercepted arc or part of that curve.

Aſtronomical SECTOR, an inſtrument invented by Mr. George Graham, for finding the difference in right aſcenſion and declination between two objects, whoſe diſtance is too great to be obſerved through a fixed teleſcope, by means of a micrometer. This inſtrument (fig. 2, pl. 26,) conſiſts of a braſs plate, called the Sector, formed like a T, having the ſhank CD, as a radius, about 2½ feet long, and 2 inches broad at the end D, and an inch and a half at C; and the croſs-piece AB, as an arch, about 6 inches long, and one and a half broad; upon which, with a radius of 30 inches, is deſcribed an arch of 10 degrees, each degree being divided in as many parts as are convenient. Round a ſmall cylinder C, containing the centre of this arch, and fixed in the ſhank, moves a plate of braſs, to which is fixed a teleſcope CE, having its line of collimation parallel to the plane of the Sector, and paſſing over the centre C of the arch AB, and the index of a Vernier's dividing plate, whoſe length, being equal to 16 quarters of a degree, is divided into 15 equal parts, fixed to the eye end of the teleſcope, and made to ſlide along the arch; which motion is performed by a long ſcrew, G, at the back of the arch, communicating with the Vernier through a ſlit cut in the braſs, parallel to the divided arch. Round the centre F of a circular braſs plate *abc*, of 5 inches diameter, moves a braſs croſs KLMN, having the oppoſite ends O and P of one bar turned up perpendicularly about 3 inches, to ſerve as ſupporters to the Sector, and ſcrewed to the back of its radius; ſo that the plane of the Sector is parallel to the plane of the circular plate, and can revolve round the centre of that plate in this parallel poſition. A ſquare iron axis HIF, 18 inches long, is ſcrewed flat to the back of the circular plate along one of its diameters, ſo that the axis is parallel to the plane of the Sector. The whole inſtrument is ſupported on a proper pedeſtal, ſo that the ſaid axis ſhall be parallel to the earth's axis, and proper contrivances are annexed to fix it in any poſition. The inſtrument, thus ſupported, can revolve round its axis HI, parallel to the earth's axis, with a motion like that of the ſtars, the plane of the Sector being always parallel to the plane of ſome hour circle, and conſequently every point of the teleſcope deſcribing a parallel of declination; and if the Sector be turned round the joint F of the circular plate, its graduated arch may be brought parallel to an hour-circle; and conſequently any two ſtars, whoſe difference of declination does not exceed the degrees in that arch, will paſs over it.

To obſerve their paſſage, direct the teleſcope to the preceding ſtar, and fix the plane of the Sector a little to the weſtward of it; move the teleſcope by the ſcrew G, and obſerve at the tranſit of each over the croſs wires the time ſhewn by the clock, and alſo the diviſion upon the arch AB, ſhewn by the index; then is the difference of the arches the difference of the declination; and that of the times ſhews the difference of the right aſcenſion of thoſe ſtars. For a more particular deſcription of this inſtrument, ſee Smith's Optics, book iii, chap. 9.

SECULAR *Year*, the ſame with Jubilee.

SECUNDANS, an infinite ſeries of numbers, beginning from nothing, and proceeding according to the ſquares of numbers in arithmetical progreſſion, as 0, 1, 4, 9, 16, 25, 36, 49, 64, &c.

SEEING, the act of perceiving objects by the organ of ſight; or the ſenſe we have of external objects by means of the eye.

For the apparatus, or diſpoſition of the parts neceſſary to Seeing, ſee EYE. And for the manner in which Seeing is performed, and the laws of it, ſee VISION.

Our beſt anatomiſts differ greatly as to the cauſe why we do not ſee double with the two eyes? Galen, and others after him, aſcribe it to a coalition, or decuſſation, of the optic nerve, behind the os ſphenoides. But whether they decuſſate or coaleſce, or only barely touch one another, is not well agreed upon.

The Bartholines and Veſalius ſay expreſsly, they are united by a perfect confuſion of their ſubſtance; Dr. Gibſon allows them to be united by the cloſeſt conjunction, but not by a confuſion of their fibres.

Alhazen, an Arabian philoſopher of the 12th century, accounts for ſingle viſion by two eyes, by ſuppoſing that when two correſponding parts of the retina are affected, the mind perceives but one image.

Des Cartes and others account for the effect another way; viz, by ſuppoſing that the fibrillæ conſtituting the medullary part of thoſe nerves, being ſpread in the retina of each eye, have each of them correſponding parts in the brain, ſo that when any of thoſe fibrillæ are ſtruck by any part of an image, the correſponding parts of the brain are affected by it. Somewhat like which is the opinion of Dr. Briggs, who takes the optic nerves of each eye to conſiſt of homologous fibres, having their riſe in the thalamus nervorum opticorum, and being thence continued to both the retinæ, which are compoſed of them; and farther, that thoſe fibrillæ have the ſame parallelifm, tenſion, &c, in both eyes; conſequently when an image is painted on the ſame correſponding ſympathizing parts of each retina, the ſame effects are produced, the ſame notice carried to the thalamus, and ſo imparted to the ſoul. Hence it is, that double viſion enſues upon an interruption of the parallelifm of the eyes; as when one eye is depreſſed by the finger, or their ſymphony is interrupted by diſeaſe: but Dr. Briggs maintains, that it is but in few ſubjects there is any decuſſation; and in none any conjunction more than mere contact; though his notion is by no means conſonant to facts, and it is attended with many improbable circumſtances.

It was the opinion of Sir Iſaac Newton, and of many others, that objects appear ſingle, becauſe the two optic nerves unite before they reach the brain. But Dr. Porterfield ſhews, from the obſervation of ſeveral anatomiſts, that the optic nerves do not mix or confound their ſubſtance, being only united by a cloſe cohefion; and objects have appeared ſingle, where the optic nerves were found to be diſjoined. To account for this phenomenon, this ingenious writer ſuppoſes, that, by an original law in our natures, we imagine an object to be ſituated ſomewhere in a right line drawn from the picture of it upon the retina, through the centre of the pupil; conſequently the ſame object appearing to both eyes to be in the ſame place, we cannot diſtinguiſh it into two. In anſwer to an objection to this hypotheſis, from objects appearing double when one eye is diſtorted, he ſays, the mind miſtakes the poſition of the eye, imagining, that it had moved in a manner correſponding to the other, in which caſe the concluſion would have been juſt: in this he ſeems to have recourſe to the power of habit, though he diſclaims that hypotheſis. This principle however has been thought ſufficient to account for this appearance.

Originally, every object making two pictures, one in each eye, is imagined to be double; but, by degrees, we find that when two correſponding parts of the retina are impreſſed, the object is but one; but if thoſe correſponding parts be changed by the diſtortion of one of the eyes, the object muſt again appear double as at the firſt. This ſeems to be verified by Mr. Cheſelden, who informs us, that a gentleman, who, from a blow on his head, had one eye diſtorted, found every object to appear double, but by degrees the moſt familiar ones came to appear ſingle again, and in time all objects did ſo without amendment of the diſtortion. A ſimilar caſe is mentioned by Dr. Smith.

On the other hand, Dr. Reid is of opinion, that the correſpondence of the centres of two eyes, on which ſingle viſion depends, does not ariſe from cuſtom, but from ſome natural conſtitution of the eye, and of the mind.

M. du Tour adopts an opinion, long before ſuggeſted by Gaſſendi, that the mind attends to no more than the image made in one eye at a time; in ſupport of which, he produces ſeveral curious experiments; but as M. Buffon obſerves, it is a ſufficient anſwer to this hypotheſis, that we ſee more diſtinctly with two eyes than with one; and that when a round object is near us, we plainly ſee more of the ſurface in one caſe than in the other.

With reſpect to ſingle viſion with two eyes, Dr. Hartley obſerves, that it deſerves particular attention, that the optic nerves of man, and ſuch other animals as look the ſame way with both eyes, unite in the ſella turrica in a ganglion, or little brain, as it may be called, peculiar to themſelves, and that the aſſociations between ſynchronous impreſſions on the two retinas, muſt be made ſooner and cemented ſtronger on this account; alſo that they ought to have a much greater power over one another's image, than in any other part of the body. And thus an impreſſion made on the right eye alone by a ſingle object, propagates itſelf into the left, and there raiſes up an image almoſt equal in vividneſs to itſelf; and, conſequently, when we ſee with one eye only, we may however have pictures in both eyes.

It is a common obſervation, ſays Dr. Smith, that objects ſeen with both eyes appear more vivid and ſtronger than they do to a ſingle eye, eſpecially when both of them are equally good. Porterfield on the Eye, vol. ii, pa. 285, 315. Smith's Optics, Remarks pa. 31. Reid's Inquiry, pa. 267. Mem. Préſentes, pa. 514. Acad. Par. 1747. Mem. Pr. 334. Hartley on Man, vol. i, pa. 207. Prieſtley's Hiſt. of Light and Colours, pa. 663, &c.

Whence it is that we ſee objects erect, when it is certain, that the images thereof are painted invertedly on the retina, is another difficulty in the theory of Seeing. Des Cartes accounts for it hence, that the notice which the ſoul takes of the object, does not depend on any image, nor any action coming from the object, but merely on the ſituation of the minute parts of the brain, whence the nerves ariſe. Ex. gr. the ſituation of a capillament brain, which occaſions the

ſoul

ſoul to ſee all thoſe places lying in a right line with it.

But Mr. Molyneux gives another account of this matter. The eye, he obſerves, is only the organ, or inſtrument; it is the ſoul that ſees. To enquire then, how the ſoul perceives the object erect by an inverted image, is to enquire into the ſoul's faculties. Again, imagine that the eye receives an impulſe on its lower part, by a ray from the upper part of an object; muſt not the viſive faculty be hereby directed to conſider this ſtroke as coming from the top, rather than the bottom of the object, and conſequently be determined to conclude it the repreſentation of the top?

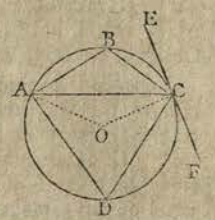
Upon theſe principles, we are to conſider, that inverted is only a relative term, and that there is a very great difference between the real object, and the means or image by which we perceive it. When all the parts of a diſtant proſpect are painted upon the retina (ſuppoſing that to be the ſeat of viſion), they are all right with reſpect to one another, as well as the parts of the proſpect itſelf; and we can only judge of an object being inverted, when it is turned reverſe to its natural poſition with reſpect to other objects which we ſee and compare it with.

The eye or viſive faculty (ſays Molyneux) takes no notice of the internal ſurface of its own parts, but uſes them as an inſtrument only, contrived by nature for the exerciſe of ſuch a faculty. If we lay hold of an upright ſtick in the dark, we can tell which is the upper or lower part of it, by moving our hand upward or downward; and very well know that we cannot feel the upper end by moving our hand downward. Juſt ſo, we find by experience and habit, that by directing our eyes towards a tall object, we cannot ſee its top by turning our eyes downward, nor its foot by turning our eyes upward; but muſt trace the object the ſame way by the eye to ſee it from head to foot, as we do by the hand to feel it; and as the judgement is informed by the motion of the hand in one caſe, ſo it is alſo by the motion of the eye in the other.

Molyneux's Dioptr. pa. 105, &c. Muſſchenbroek's Int. ad Phil. Nat. vol. ii, pa. 762. Ferguſon's Lectures, pa. 132. See SIGHT, VISIBLE, &c.

SEGMENT, in Geometry, is a part cut off the top of a figure by a line or plane; and the part remaining at the bottom, after the Segment is cut off, is called a *fruſtum*, or a *zone*. So, a

SEGMENT *of a Circle*, is a part of the circle cut off by a chord, or a portion comprehended by an arch and its chord; and may be either greater or leſs than a ſemicircle. Thus, the portion ABCA is a Segment leſs than a ſemicircle; and ADCA a Segment greater.



The angle formed by lines drawn from the extremities of a chord to meet in any point of the arc, is called an angle *in* the Segment. So the angle ABC is an angle *in* the Segment ABCA; and the angle ADC, an angle *in* the Segment ADCA.

Alſo the angle B is ſaid to be the angle *upon* the Segment ADC, and D the angle *on* the Segment ABC.

The angle which the chord AC makes with a tangent EF, is called the angle *of* a Segment; and it is equal to the angle in the alternate or ſupplemental Segment, or equal to the ſupplement of the angle in the ſame Segment. So the angle ACE is the angle *of* the Segment ABC, and is equal to the angle ADC, or to the ſupplement of the angle B; alſo the angle ACF is the angle *of* the Segment ADC, and is equal to the angle B, or to the ſupplement of the angle D.

The area of a Segment ABC, is evidently equal to the difference between the ſector OABC of the ſame arc, and the triangle OAC on the ſame chord; the triangle being ſubtracted from the ſector, to give the Segment, when leſs than a ſemicircle; but to be added when greater. See more rules for the Segment in my Menſuration, pa. 122 &c, 2d edition.

Similar SEGMENTS, are thoſe that have their chords directly proportional to their radii or diameters, or that have ſimilar arcs, or ſuch as contain the ſame number of degrees.

SEGMENT *of a Sphere*, is a part cut off by a plane.

The baſe of a Segment is always a circle. And the convex ſurfaces of different Segments, are to each other as their altitudes, or verſed ſines. And as the whole convex ſurface of the ſphere is equal to 4 of its great circles, or 4 circles of the ſame diameter; ſo the ſurface of any Segment, is equal to 4 circles on a diameter equal to the chord of half the arc of the Segment. So that if d denote the diameter of the ſphere, or the chord of half the circumference, and c the chord of half the arc of any other Segment, alſo a the altitude or verſed ſine of the ſame; then,

$3{\cdot}1416d^2$ is the ſurface of the whole ſphere, and
$3{\cdot}1416c^2$, or $3{\cdot}1416ad$, the ſurface of the Segment.

For the ſolid content of a Segment, there are two rules uſually given; viz, 1. To 3 times the ſquare of the radius of its baſe, add the ſquare of its height; multiply the ſum by the height, and the product by ·5236. Or, 2dly, From 3 times the diameter of the ſphere, ſubtract twice the height of the fruſtum; multiply the remainder by the ſquare of the height, and the product by ·5236. That is, in ſymbols, the ſolid content is either

$= {\cdot}5236a \times \overline{3r^2 + a^2}$, or $= {\cdot}5236a^2 \times \overline{3d - 2a}$;

where a is the altitude of the Segment, r the radius of its baſe, and d the diameter of the whole ſphere.

Line of SEGMENTS, are two particular lines, ſo called, on Gunter's ſector. They lie between the lines of ſines and ſuperficies, and are numbered with 5, 6, 7, 8, 9, 10. They repreſent the diameter of a circle, ſo divided into 100 parts, as that a right line drawn through thoſe parts, and perpendicular to the diameter, ſhall cut the circle into two Segments, the greater of which ſhall have the ſame proportion to the whole circle, as the parts cut off have to 100.

SELENOGRAPHY, the deſcription and repreſentation of the moon, with all the parts and appearances of her diſc or face; like as geography does thoſe of the earth.

Since the invention of the telescope, Selenography is very much improved. We have now distinct names for most of the regions, seas, lakes, mountains, &c, visible in the moon's body. Hevelius, a celebrated astronomer of *Dantzic*, and who published the first Selenography, named the several places of the moon from those of the earth. But Riccioli afterwards called them after the names of the most celebrated astronomers and philosophers. Thus, what the one calls *mons Porphyrites*, the other calls *Aristarchus*; what the one calls *Ætna*, *Sinai*, *Alps*, *Apenninus*, &c, the other calls, *Copernicus*, *Posidonius*, *Tycho*, *Gassendus*, &c.

M. Cassini has published a work called *Instructions Seleniques*, and has published the best map of the moon.

SELEUCIDÆ, in Chronology, the era of the Seleucidæ, or the Syro-Macedonian era, which is a computation of time, commencing from the establishment of the Seleucidæ, a race of Greek kings, who reigned as successors of Alexander the Great, in Syria, as the Ptolomies did in Egypt. According to the best accounts, the first year of this era falls in the year 311 before Christ, which was 12 years after the death of Alexander.

SELL, in Building, is of two kinds, viz, *Ground-Sell*, which denotes the lowest piece of timber in a wooden building, and that upon which the whole superstructure is raised. And Sell of a window, or of a door, which is the bottom piece in the frame of them, upon which they rest.

SEMICIRCLE, in Geometry, is half a circle, or a figure comprehended between the diameter of a circle, and half the circumference.

SEMICIRCLE is also an instrument in Surveying, sometimes called the *graphometer*.

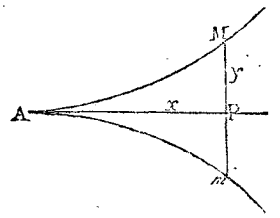
It consists of a semicircular limb or arch, as FIG (fig. 3, pl. 26) divided into 180 degrees, and sometimes subdivided diagonally or otherwise into minutes. This limb is subtended by a diameter FG, having two sights erected at its extremities. In the centre of the Semicircle, or the middle of the diameter, is fixed a box and needle; and on the same centre is fitted an alidade, or moveable index, carrying two other sights, as H, I: the whole being mounted on a staff, with a ball and socket &c.

Hence it appears, that the Semicircle is nothing but half a theodolite; with this only difference, that whereas the limb of the theodolite, being an entire circle, takes in all the 360° successively; while in the Semicircle the degrees only going from 1 to 180, it is usual to have the remaining 180°, or those from 180° to 360°, graduated in another line on the limb within the former.

To take an Angle with a Semicircle.—Place the instrument in such manner, as that the radius CG may hang over one leg of the angle to be measured, with the centre C over the vertex of the same. The first is done by looking through the sights F and G, at the extremities of the diameter, to a mark fixed up in one extremity of the leg; and the latter is had by letting fall a plummet from the centre of the instrument. This done, turn the moveable index HI on its centre towards the other leg of the angle, till through the sights fixed in it, you see a mark in the extremity of the leg. Then the degree which the index cuts on the limb, is the quantity or measure of the angle.

Other uses are the same as in the theodolite.

SEMICUBICAL PARABOLA, a curve of the 2d order, of such a nature that the cubes of the ordinates are proportional to the squares of the abscisses. Its equation is $ay^3 = x^3$. This curve, AM*m*, is one of



Newton's five diverging parabolas, being his 70th species; having a cusp at its vertex at A. It is otherwise named the Neilian parabola, from the name of the author who first treated of it.

The area of the space APM, is $= \frac{4}{7}xy = \frac{4}{7}AP \times PM$, or $\frac{4}{7}$ of the circumscribing rectangle.

The content of the solid generated by the revolution of the space APM about the axis AP, is $\frac{1}{2}pxy^2 = .7854AP \times PM^2$, or $\frac{1}{2}$ of the circumscribing cylinder. And a circle equal to the surface of that solid may be found from the quadrature of an hyperbolic space.

Also the length of any arc AM of the curve may be easily obtained from the quadrature of a space contained under part of the curve of the common parabola, two semiordinates to the axis, and the part of the axis contained between them.

This curve may be described by a continued motion, viz, by fastening the angle of a square in the vertex of a common parabola; and then carrying the intersection of one side of this square and a long ruler (which ruler always moves perpendicularly to the axis of the parabola) along the curve of that parabola. For the intersection of the ruler, and the other side of the square will describe a Semicubical parabola. Maclaurin performs this without a common parabola, in his Geometria Organica.

SEMIDIAMETER, or *Radius*, of a circle or sphere, is a line drawn from the centre to the circumference. And in any curve that has diameters and a centre, it is the radius, or half diameter, or a line drawn from the centre to some point in the curve.

The distances, diameters, &c, of the heavenly bodies, are usually estimated by astronomers in Semidiameters of the earth; the number of which terrestrial Semidiameters, contained in that of each of those planets, is as below.

The Earth	- -	1 Semidiam.
The Sun	- -	111$\frac{1}{4}$
The Moon	- -	0·27
Mercury	- -	0·38
Venus	- -	1·15
Mars	- -	0·65
Jupiter	- -	11·81
Saturn	- -	9·77
Herschel	- -	4·32

SEMIDIAPENTE, in Music, a defective or imperfect fifth, called usually by the Italians, *falsa quinta*, and by us a false fifth.

SEMIDIAPASON, in Muſic, a defective or imperfect octave; or an octave diminiſhed by a leſſer ſemitone, or 4 commas.

SEMIDIATESSARON, in Muſic, a defective fourth, called alſo a falſe fourth.

SEMIDITONE, in Muſic, is the leſſer third, having its terms as 6 to 5.

SEMIORDINATES, in Geometry, the halves of the ordinates or applicates, being the lines applied between the abſciſs and the curve.

SEMIPARABOLA, &c, in Geometry, the half of the whole parabola, &c.

SEMIQUADRATE, or SEMIQUARTILE, is an aſpect of the planets, when diſtant from each other one ſign and a half, or 45 degrees.

SEMIQUAVER, in Muſic, the half of a quaver.

SEMIQUINTILE, is an aſpect of the planets when diſtant from each other the half of a 5th of the circle, or by 36 degrees.

SEMISEXTILE, an aſpect of two planets, when they are diſtant from each other 30 degrees, or the half of a ſextile, which is 2 ſigns or 60°. The Semiſextile is marked *s. s.*

SEMITONE, in Muſic, a half tone or half note, one of the degrees or intervals of concords.

There are three degrees, or leſs intervals, by which a ſound can move upwards and downwards, ſucceſſively from one extreme of any concord to the other, and yet produce true melody. Theſe degrees are the greater tone, the leſs tone, and the ſemitone. The ratios defining theſe intervals are theſe, viz, the greater tone 8 to 9, the leſs tone 9 to 10, and the Semitone 15 to 16. Its compaſs is 5 commas, and it has its name from being nearly half a whole, though it is really ſomewhat more.

There are ſeveral ſpecies of Semitones; but thoſe that uſually occur in practice are of two kinds, diſtinguiſhed by the addition of greater and leſs. The firſt is expreſſed by the ratio of 16 to 15, or $\frac{16}{15}$; and the ſecond by 25 to 24, or $\frac{25}{24}$. The octave contains 10 Semitones major, and 2 dieſes, nearly, or 17 Semitones minor, nearly; for the meaſure of the octave being expreſſed by the logarithm - 1,00000, the Semitone major will be meaſured by 0,09311, and the Semitone minor by - - 0,05889. Theſe two differ by a whole enharmonic dieſis; which is an interval practicable by the voice. It was much in uſe among the Ancients, and is not unknown among modern practitioners. Euler Tent. Nov. Theor. Muſ. pa. 107. See INTERVAL.

Theſe Semitones are called *fictitious notes*; and, with reſpect to the natural ones, they are expreſſed by characters called *flats* and *ſharps*. The uſe of them is to remedy the defects of inſtruments, which, having their ſounds fixed, cannot always be made to anſwer to the diatonic ſcale. By means of theſe, we have a new kind of ſcale, called the

SEMITONIC *Scale*, or the *Scale of Semitones*, which is a ſcale or ſyſtem of muſic, conſiſting of 12 degrees, or 13 notes, in the octave, being an improvement on the natural or diatonic ſcale, by inſerting between each two notes of it, another note, which divides the interval or tone into two unequal parts, called Semitones.

The uſe of this ſcale is for inſtruments that have fixed ſounds, as the organ, harpſichord, &c, which are exceedingly defective on the foot of the natural or diatonic ſcale. For the degrees of the ſcale being unequal, from every note to its octave there is a different number of degrees; ſo that from any note we cannot find every interval in a ſeries of fixed ſounds; which yet is neceſſary, that all the notes of a piece of muſic, carried through ſeveral keys, may be found in their juſt tune, or that the ſame ſong may be begun indifferently at any note, as may be neceſſary for accommodating ſome inſtrument to others, or to the voice, when they are to accompany each other in uniſon.

The diatonic ſcale, beginning at the loweſt note, being firſt ſettled on an inſtrument, and the notes of it diſtinguiſhed by their names *a, b, c, d, e, f, g*; the inſerted notes, or Semitones, are called fictitious notes, and take the name or letter below with a ♯, as *c* ♯ called *c* ſharp; ſignifying that it is a ſemitone higher than the ſound of *c* in the natural ſeries; or this mark ♭, called a flat, with the name of the note above ſignifying it to be a Semitone lower.

Now $\frac{15}{16}$ and $\frac{128}{135}$ being the two Semitones the greater tone is divided into, and $\frac{15}{16}$ and $\frac{24}{25}$, the Semitones the leſs tone is divided into, the whole octave will ſtand as in the following ſcheme, where the ratios of each term to the next are written fraction-wiſe between them below.

Scale of Semitones.

c.	*c*♯.	*d.*	*d*♯.	*e.*	*f.*	*f*♯.	*g.*	*g*♯. *a*♭.	*b.*	*cc.*
$\frac{15}{16}$	$\frac{128}{135}$	$\frac{15}{16}$	$\frac{24}{25}$	$\frac{15}{16}$	$\frac{128}{135}$	$\frac{15}{16}$	$\frac{15}{16}$	$\frac{24}{25}$	$\frac{15}{16}$	$\frac{15}{16}$

for the names of the intervals in this ſcale, it may be conſidered, that as the notes added to the natural ſcale are not deſigned to alter the ſpecies of melody, but leave it ſtill diatonic, and only correct certain defects ariſing from ſomething foreign to the office of the ſcale of muſic, viz, the fixing and limiting the ſounds; we ſee the reaſon why the names of the natural ſcale are continued, only making a diſtinction of each into a greater and leſs. Thus an interval of one Semitone, is called a leſs ſecond; of two Semitones, a greater ſecond; of three Semitones, a leſs third; of four, a greater third, &c.

A ſecond kind of Semitonic ſcale we have from another diviſion of the octave into Semitones, which is performed by taking an harmonical mean between the extremes of the greater and leſs tone of the natural ſcale, which divides it into two Semitones nearly equal. Thus, the greater tone 8 to 9 is divided into two Semitones, which are 16 to 17, and 17 to 18; where 16, 17, 18, is an arithmetical diviſion, the numbers repreſenting the lengths of the chords; but if they repreſent the vibration, the lengths of the chords are reciprocal; viz as 1, $\frac{16}{17}$, $\frac{8}{9}$; which puts the greater

mitone is next the lower part of the tone, and the letter $\frac{7}{8}$ next the upper, which is the property of the harmonical diviſion. And after the ſame manner the leſs tone 9 to 10 is divided into two Semitones, 18 to 19, and 19 to 20; and the whole octave ſtands thus:

c. *c*♯. *d*. *d*♯. *e*. *f*. *f*♯. *g*. *g*♯. *a*. ♭. *b*. *c*.
$\frac{16}{17}$ $\frac{17}{18}$ $\frac{18}{19}$ $\frac{19}{20}$ $\frac{15}{16}$ $\frac{16}{17}$ $\frac{17}{18}$ $\frac{18}{19}$ $\frac{19}{20}$ $\frac{16}{17}$ $\frac{17}{18}$ $\frac{15}{16}$.

This ſcale, Mr. Salmon tells us, in the Philoſophical Tranſactions, he made an experiment of before the Royal Society, on chords, exactly in theſe proportions, which yielded a perfect concert with other inſtruments, touched by the beſt hands. Mr. Malcolm adds, that, having calculated the ratios of them, for his own ſatisfaction, he found more of them falſe than in the preceding ſcale, but then their errors were conſiderably leſs, which made amends. Malcolm's Muſic, chap. 10. § 2.

SENSIBLE *Horizon*, or *Point*, or *Quality*, &c. See the ſubſtantives.

SEPTUAGESIMA, in the Calendar, is the 9th Sunday before Eaſter, ſo called, as ſome have ſuppoſed, becauſe it is near 70 days, though in reality it is only 63 days, before it.

SERIES, in Algebra, denotes a rank or progreſſion of quantities or terms, which uſually proceed according to ſome certain law.

As the Series $1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16}$ &c,

or the Series, $1 + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \frac{1}{5}$ &c.

where the former is a geometrical Series, proceeding by the conſtant diviſion by 2, or the denominators multiplied by 2; and the latter is an harmonical Series, being the reciprocals of the arithmetical Series 1, 2, 3, 4, &c, or the denominators being continually increaſed by 1.

The doctrine and uſe of Series, one of the greateſt improvements of the preſent age, we owe to Nicholas Mercator; though it ſeems he took the firſt hint of it from Dr. Wallis's Arithmetic of Infinites; but the genius of Newton firſt gave it a body and a form.

It is chiefly uſeful in the quadrature of curves; where, as we often meet with quantities which cannot be expreſſed by any preciſe definite numbers, ſuch as is the ratio of the diameter of a circle to the circumference, we are glad to expreſs them by a Series, which, infinitely continued, is the value of the quantity ſought, and which is called an Infinite Series.

The Nature, Origin, &c, of SERIES.

Infinite Series commonly ariſe, either from a continued diviſion, as was practiſed by Mercator, or the extraction of roots, as firſt performed by Newton, who alſo explained other general ways for the expanding of quantities into infinite Series, as by the binomial theorem. Thus, to divide 1 by 3, or to expand the fraction $\frac{1}{3}$ into an infinite Series; by diviſion in decimals in the ordinary way, the ſeries is 0·3333 &c, or $\frac{3}{10} + \frac{3}{100} + \frac{3}{1000} + \frac{3}{10000}$ &c, where the law of continuation is manifeſt. Or, if the ſame fraction $\frac{1}{3}$ be ſet in this form $\frac{1}{2+1}$, and diviſion be performed in the algebraic manner, the quotient will be

$$\frac{1}{3} = \frac{1}{2+1} = \frac{1}{2} - \frac{1}{4} + \frac{1}{8} - \frac{1}{16} + \frac{1}{32} \text{ &c.}$$

Or, if it be expreſſed in this form $\frac{1}{3} = \frac{1}{4-1}$, by a like diviſion there will ariſe the Series,

$$\frac{1}{3} = \frac{1}{4} + \frac{1}{16} + \frac{1}{64} \text{ &c} = \frac{1}{4} + \frac{1}{4^2} + \frac{1}{4^3} \text{ &c.}$$

And, thus, by dividing 1 by 5 — 2, or 6 — 3, or 7 — 4, &c, the Series anſwering to the fraction $\frac{1}{3}$, may be found in an endleſs variety of infinite Series; and the finite quantity $\frac{1}{3}$ is called the value or radix of the Series, or alſo its ſum, being the number or ſum to which the Series would amount, or the limit to which it would tend or approximate, by ſumming up its terms, or by collecting them together one after another.

In like manner, by dividing 1 by the algebraic ſum $a + c$, or by $a - c$, the quotient will be in theſe two caſes, as below, viz,

$$\frac{1}{a+c} = \frac{1}{a} - \frac{c}{a^2} + \frac{c^2}{a^3} - \frac{c^3}{a^4} \text{ &c,}$$

$$\frac{1}{a-c} = \frac{1}{a} + \frac{c}{a^2} + \frac{c^2}{a^3} + \frac{c^3}{a^4} \text{ &c.}$$

where the terms of each Series are the ſame, and they differ only in this, that the ſigns are alternately poſitive and negative in the former, but all poſitive in the latter.

And hence, by expounding a and c by any numbers whatever, we obtain an endleſs variety of infinite Series, whoſe ſums or values are known. So, by taking a or c equal to 1 or 2 or 3 or 4, &c, we obtain theſe Series, and their values;

$$\frac{1}{1+1} = \frac{1}{2} = 1 - 1 + 1 - 1 + 1 - 1 \text{ &c,}$$

$$\frac{1}{3-1} = \frac{1}{2} = \frac{1}{3} + \frac{1}{3^2} + \frac{1}{3^3} + \frac{1}{3^4} \text{ &c,}$$

$$\frac{1}{2+1} = \frac{1}{3} = \frac{1}{2} - \frac{1}{2^2} + \frac{1}{2^3} - \frac{1}{2^4} \text{ &c,}$$

$$\frac{1}{1+2} = \frac{1}{3} = 1 - 2 + 2^2 - 2^3 \text{ &c,}$$

$$\frac{1}{3+1} = \frac{1}{4} = \frac{1}{3} - \frac{1}{3^2} + \frac{1}{3^3} - \frac{1}{3^4} \text{ &c.}$$

And hence it appears, that the ſame quantity or radix may be expreſſed by a great variety of infinite Series, or that many different Series may have the ſame radix or ſum.

Another way in which an infinite Series ariſes, is by the extraction of roots. Thus, by extracting the ſquare root of the number 3 in the common way, we obtain its value in a ſeries as follows, viz, $\sqrt{3} = 1{\cdot}73205$ &c $= 1 + \frac{7}{10} + \frac{3}{100} + \frac{2}{1000} + \frac{5}{100000}$ &c;

in which way of reſolution the law of the progreſſion

of the Series is not visible, as it is when found by division. And the square root of the algebraic quantity $a^2 + c^2$ gives

$$\sqrt{a^2 + c^2} = a + \frac{c^2}{2a} - \frac{c^4}{8a^3} + \frac{c^6}{16a^5} \text{ &c.}$$

And a 3d way is by Newton's binomial theorem, which is a universal method, that serves for all sorts of quantities, whether fractional or radical ones: and by this means the same root of the last given quantity becomes $\sqrt{a^2 + c^2} =$

$$= a + \frac{c^2}{2a} - \frac{1.c^4}{2.4a^3} + \frac{1.3c^6}{2.4.6a^5} + \frac{1.3.5c^8}{2.4.6.8a^7} \text{ &c.}$$

where the law of continuation is visible.

See EXTRACTION *of Roots*, and BINOMIAL *Theorem*.

From the specimens above given, it appears that the signs of the terms may be either all plus, or alternately plus and minus. Though they may be varied in many other ways. It also appears that the terms may be either continually smaller and smaller, or larger and larger, or else all equal. In the first case therefore the Series is said to be a *decreasing* one, in the 2d case an *increasing* one, and in the 3d case an *equal* one. Also the first Series is called a *converging* one, because that by collecting its terms successively, taking in always one term more, the successive sums approximate or converge to the value or sum of the whole infinite Series. So, in the Series

$$\frac{1}{3-1} = \frac{1}{2} = \frac{1}{3} + \frac{1}{9} + \frac{1}{27} + \frac{1}{81}, \text{ &c,}$$

the first term $\frac{1}{3}$ is too little, or below $\frac{1}{2}$ which is the value or sum of the whole infinite Series proposed; the sum of the first two terms $\frac{1}{3} + \frac{1}{9}$ is $\frac{4}{9} = .4444$ &c, is also too little, but nearer to $\frac{1}{2}$ or .5 than the former; and the sum of three terms $\frac{1}{3} + \frac{1}{9} + \frac{1}{27}$ is $\frac{13}{27} = .481481$ &c, is nearer than the last, but still too little; and the sum of four terms

$$\frac{1}{3} + \frac{1}{9} + \frac{1}{27} + \frac{1}{81}, \text{ is } \frac{40}{81} = .493827 \text{ &c.}$$

which is again nearer than the former, but still too little; which is always the case when the terms are all positive. But when the converging Series has its terms alternately positive and negative, then the successive sums are alternately too great and too little, though still approaching nearer and nearer to the final sum or value. Thus in the Series

$$\frac{1}{3+1} = \frac{1}{4} = 0.25 = \frac{1}{3} - \frac{1}{9} + \frac{1}{27} - \frac{1}{81} \text{ &c,}$$

the 1st term $\frac{1}{3} = .333$ &c, is too great,

two terms $\frac{1}{3} - \frac{1}{9} = .222$ &c, are too little,

three terms $\frac{1}{3} - \frac{1}{9} + \frac{1}{27} = .259259$ &c, are too great,

four terms $\frac{1}{3} - \frac{1}{9} + \frac{1}{27} - \frac{1}{81} = .246913$ &c,

too great, and so on, alternately too great and too small, but every succeeding sum still nearer than the former, or converging.

In the second case, or when the terms grow larger and larger, the Series is called a *diverging* one, because that by collecting the terms continually, the successive sums diverge, or go always farther and farther from the true value or radix of the Series; being all too great when the terms are all positive, but alternately too great and too little when they are alternately positive and negative. Thus, in the Series

$$\frac{1}{1+2} = \frac{1}{3} = 1 - 2 + 4 - 8 \text{ &c,}$$

the first term + 1 is too great,
two terms $1 - 2 = -1$ are too little,
three terms $1 - 2 + 4 = +3$ are too great,
four terms $1 - 2 + 4 - 8 = -5$ are too little,

and so on continually, after the 2d term, diverging more and more from the true value or radix $\frac{1}{3}$, but alternately too great and too little, or positive and negative. But the alternate sums would be always more and more too great if the terms were all positive, and always too little if negative.

But in the third case, or when the terms are all equal, the Series of equals, with alternate signs, is called a *neutral* one, because the successive sums, found by a continual collection of the terms, are always at the same distance from the true value or radix, but alternately positive and negative, or too great and too little. Thus, in the Series

$$\frac{1}{1+1} = \frac{1}{2} = 1 - 1 + 1 - 1 + 1 - 1 \text{ &c,}$$

the first term 1 is too great,
two terms $1 - 1 = 0$ are too little,
three terms $1 - 1 + 1 = 1$ too great,
four terms $1 - 1 + 1 - 1 = 0$ too little,

and so on continually, the successive sums being alternately 1 and 0, which are equally different from the true value or radix $\frac{1}{2}$, the one as much above it, as the other below it.

A Series may be terminated and rendered finite, and accurately equal to the sum or value, by assuming the supplement, after any particular term, and combining it with the foregoing terms. So, in the Series $\frac{1}{2} - \frac{1}{4} + \frac{1}{8} - \frac{1}{16}$ &c, which is equal to $\frac{1}{3}$, and found by dividing 1 by 2 + 1, after the first term, $\frac{1}{2}$, of the quotient, the remainder is $-\frac{1}{2}$, which divided by 2 + 1, or 3, gives $-\frac{1}{6}$ for the supplement, which combined

combined with the firſt term $\frac{1}{2}$, gives $\frac{1}{2} - \frac{1}{6} = \frac{1}{3}$ the true ſum of the Series. Again, after the firſt two terms $\frac{1}{2} - \frac{1}{4}$, the remainder is $+\frac{1}{4}$, which divided by the ſame diviſor 3, gives $\frac{1}{12}$ for the ſupplement, and this combined with thoſe two terms $\frac{1}{2} - \frac{1}{4}$, makes $\frac{1}{2} - \frac{1}{4} + \frac{1}{12} = \frac{1}{4} + \frac{1}{2} = \frac{4}{12}$ or $\frac{1}{3}$ the ſame ſum or value as before. And in general, by dividing 1 by $a + c$, there is obtained

$$\frac{1}{a+c} = \frac{1}{a} - \frac{c}{a^2} + \frac{c^2}{a^3} \cdots \pm \frac{c^n}{a^{n+1}} \mp \frac{c^{n+1}}{a^{n+1}(a+c)};$$

where, ſtopping the diviſion at any term as $\frac{c^n}{a^{n+1}}$, the remainder after this term is $\frac{c^{n+1}}{a^{n+1}}$, which being divided by the ſame diviſor $a + c$, gives $\frac{c^{n+1}}{a^{n+1}(a+c)}$ for the ſupplement as above.

The Law of Continuation.—A Series being propoſed, one of the chief queſtions concerning it, is to find the law of its continuation. Indeed, no univerſal rule can be given for this; but it often happens that the terms of the Series, taken two and two, or three and three, or in greater numbers, have an obvious and ſimple relation, by which the Series may be determined and produced indefinitely. Thus, if 1 be divided by $1 - x$, the quotient will be a geometrical progreſſion, viz, $1 + x + x^2 + x^3$ &c, where the ſucceeding terms are produced by the continual multiplication by x. In like manner, in other caſes of diviſion, other progreſſions are produced.

But in moſt caſes the relation of the terms of a Series is not conſtant, as it is in thoſe that ariſe by diviſion. Yet their relation often varies according to a certain law, which is ſometimes obvious on inſpection, and ſometimes it is found by dividing the ſucceſſive terms one by another, &c. Thus, in the Series

$$1 + \frac{2}{3}x + \frac{8}{15}x^2 + \frac{16}{35}x^3 + \frac{128}{315}x^4 \text{ &c},$$

by dividing the 2d term by the 1ſt, the 3d by the 2d, the 4th by the 3d, and ſo on, the quotients will be

$$\frac{2}{3}x, \frac{4}{5}x, \frac{6}{7}x, \frac{8}{9}x, \text{ &c};$$

and therefore the terms may be continued indefinitely by the ſucceſſive multiplication by theſe fractions. Alſo in the following Series

$$1 + \frac{1}{6}x + \frac{3}{40}x^2 + \frac{5}{128}x^3 + \frac{35}{1152}x^4 \text{ &c},$$

by diviſion of the adjacent terms ſucceſſively by each other, the Series of quotients is

$$\frac{1}{6}x, \frac{9}{20}x, \frac{25}{42}x, \frac{49}{72}x, \text{ &c, or}$$

$$\frac{1 \cdot 1}{2 \cdot 3}x, \frac{3 \cdot 3}{4 \cdot 5}x, \frac{5 \cdot 5}{6 \cdot 7}x, \frac{7 \cdot 7}{8 \cdot 9}x, \text{ &c};$$

and therefore the terms of the Series may be continued by the multiplication of theſe fractions.

Another method of expreſſing the law of a Series, is one that defines the Series itſelf, by its *general term*, ſhewing the relation of the terms generally by their diſtances from the beginning, or by differential equations. To do this, Mr. Stirling conceives the terms of the Series to be placed as ſo many ordinates on a right line given by poſition, taking unity as the common interval between theſe ordinates. The terms of the Series he denotes by the initial letters of the alphabet, A, B, C, D, &c; A being the firſt, B the 2d, C the 3d, &c: and he denotes any term in general by the letter T, and the reſt following it in order by T′, T″, T‴, T⁗, &c; alſo the diſtance of the term T from any given term, or from any given intermediate point between two terms, he denotes by the indeterminate quantity z: ſo that the diſtances of the terms T′, T″, T‴, &c, from the ſaid term or point, will be $z + 1$, $z + 2$, $z + 3$, &c; becauſe the increment of the abſciſs is the common interval of the ordinates, or terms of the Series, applied to the abſciſs.

Theſe things being premiſed, let this Series be propoſed, viz,

$$1, \frac{1}{2}x, \frac{3}{8}x^2, \frac{5}{16}x^3, \frac{35}{128}x^4, \frac{63}{256}x^5, \text{ &c};$$

in which it is found, by dividing the terms by each other, that the relations of the terms are,

$$B = \frac{1}{2}Ax, C = \frac{3}{4}Bx, D = \frac{5}{6}Cx, E = \frac{7}{8}Dx, \text{ &c};$$

then the relation in general will be defined by the equation $T' = \frac{2z+1}{2z+2}Tx$ or $\frac{z+\frac{1}{2}}{z+1}Tx$, where z denotes the diſtance of T from the firſt term of the Series. For by ſubſtituting 0, 1, 2, 3, 4, &c, ſucceſſively inſtead of z, the ſame relations will ariſe as in the propoſed Series above. In like manner, if z be the diſtance of T from the 2d term of the Series, the equation will be $T' = \frac{2z+3}{2z+4}Tx$ or $\frac{z+\frac{3}{2}}{z+2}Tx$, as will appear by ſubſtituting the numbers -1, 0, 1, 2, 3, &c, ſucceſſively for z. Or, if z denote the place or number of the term T in the Series, its ſucceſſive values will be 1, 2, 3, 4, &c, and the equation or general term will be $T' = \frac{2z-1}{2z}Tx$.

It appears therefore, that innumerable differential equations may define one and the ſame Series, according to the different points from whence the origin of the abſciſs z is taken. And, on the contrary, the ſame equation defines innumerable different Series, by taking different ſucceſſive values of z. For in the equation $T' = \frac{2z-1}{2z}Tx$, which defines the foregoing Series

when

when 1, 2, 3, 4, &c are the ſucceſſive values of the abſciſſes; if $1\frac{1}{2}$, $2\frac{1}{2}$, $3\frac{1}{2}$, $4\frac{1}{2}$, &c, be ſucceſſively ſubſtituted for z, the relations of the terms ariſing will be,

$$B = \frac{2}{3}Ax,\ C = \frac{4}{5}Bx,\ D = \frac{6}{7}Cx,\ \&c,$$ from whence will ariſe the Series

$$A,\ \frac{2}{3}Ax,\ \frac{8}{15}Ax^2,\ \frac{16}{35}Ax^3,\ \frac{128}{315}Ax^4,\ \&c,$$

which is different from the former.

And thus the equation will always determine the Series from the given values of the abſciſs and of the firſt term, when the equation includes but two terms of the Series, as in the laſt example, where the firſt term being given, all the reſt will be given.

But when the equation includes three terms, then two muſt be given; and three muſt be given, when it includes four; and ſo on. So, if there be propoſed the

Series $x,\ \frac{1}{6}x^3,\ \frac{3}{40}x^5,\ \frac{5}{128}x^7,\ \frac{35}{1152}x^9,$ &c,

where the relations of the terms are,

$$B = \frac{1\cdot 1}{2\cdot 3}Ax^2,\ C = \frac{3\cdot 3}{4\cdot 5}Bx^2,\ D = \frac{5\cdot 5}{6\cdot 7}Cx^2,\ \&c.$$

the equation defining this Series will be

$$T = \frac{\overline{2z-1}\cdot\overline{2z-1}}{\overline{2z}\cdot\overline{2z+1}}Tx^2 = \frac{4zz-4z+1}{4zz+2z}Tx^2,$$

where the ſucceſſive values of z are 1, 2, 3, 4, &c. See Stirling's Methodus Differentialis, in the introduction.

This may ſuffice to give a notion of theſe differential equations, defining the nature of Series. But as to the application of theſe equations in interpolations, and finding the ſums of Series, it would require a treatiſe to explain it. We muſt therefore refer to that excellent one juſt quoted, as alſo to De Moivre's Miſcellanea Analytica; and ſeveral curious papers by Euler in the Acta Petropolitana.

A Series often converges ſo ſlowly, as to be of no uſe in practice. Thus, if it were required to find the ſum of the Series

$$\frac{1}{1.2} + \frac{1}{3.4} + \frac{1}{5.6} + \frac{1}{7.8} + \frac{1}{9.10}\ \&c,$$

which Lord Brouncker found for the quadrature of the hyperbola, true to 9 figures, by the mere addition of the terms of the Series; Mr. Stirling computes that it would be neceſſary to add a thouſand millions of terms for that purpoſe; for which the life of man would be too ſhort. But by that gentleman's method, the ſum of the Series may be found by a very moderate computation. See Method. Differ. pa. 26.

Series are of various kinds or deſcriptions. So,

An *Aſcending* SERIES, is one in which the powers of the indeterminate quantity increaſe; as

$$1 + ax + bx^2 + cx^3\ \&c.$$ And a

Deſcending SERIES, is one in which the powers decreaſe, or elſe increaſe in the denominators, which is the ſame thing; as

$$1 + ax^{-1} + bx^{-2} + cx^{-3}\ \&c, \text{ or } 1 + \frac{a}{x} + \frac{b}{x^2} + \frac{c}{x^3}\ \&c.$$

A Circular SERIES, which denotes a Series whoſe ſum depends on the quadrature of the circle. Such is the Series $1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9}$ &c. See Demoivre Miſcel. Analyt. pa. 111, or my Menſur. pa. 116. Or the ſum of the Series $1 + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \frac{1}{25}$ &c. continued ad infinitum, according to Euler's diſcovery.

Continued Fraction or *Series*, is a fraction of this kind, to infinity,

$$\cfrac{a}{b + \cfrac{c}{d + \cfrac{e}{f + \cfrac{g}{h}\ \&c.}}}$$

The firſt Series of this kind was given by Lord Brouncker, firſt preſident of the Royal Society, for the quadrature of the circle, as related by Dr. Wallis, in his Algebra, pa. 317. *His ſeries is*

$$1 + \cfrac{1}{2 + \cfrac{9}{2 + \cfrac{25}{2 + \cfrac{49}{2 + \cfrac{81}{2 + \&c,}}}}}$$

which denotes the ratio of the ſquare of the diameter of a circle to its area. Mr. Euler has treated on this kind of Series, in the Peterſburgh Commentaries, vol. 11, and in his Analyſ. Infinit. vol. 1, pa. 295, where he ſhews various uſes of it, and how to transform ordinary fractions and common Series into continued fractions. A common fraction is transformed into a continued one, after the manner of ſeeking the greateſt common meaſure of the numerator and denominator, by dividing the greater by the leſs, and the laſt diviſor always by the laſt remainder. Thus to change $\frac{1461}{59}$ to a continued fraction.

```
59) 1461 (24
   118
   281
   236
    45) 59 (1
        45
        14) 45 (3
            42
             3) 14 (4
                12
                 2) 3 (1
                    2
                    1 ) 2 (2
                        2
                        0
```

Therefore $\frac{1461}{59} = 24 + \cfrac{1}{1 + \cfrac{1}{3 + \cfrac{1}{4 + \cfrac{1}{1 + \frac{1}{2}}}}}$.

Alſo $\sqrt{2} = 1 + \cfrac{1}{2 + \cfrac{1}{2 + \cfrac{1}{2 + \&c.}}}$

Converging

Converging SERIES, is a Series whose terms continually decrease, or the successive sums of whose terms approximate or converge always nearer to the ultimate sum of the whole Series. And, on the contrary, a

Diverging SERIES, is one whose terms continually increase, or that has the successive sums of its terms diverging, or going off always the farther, from the sum or value of the Series.

Determinate SERIES, is a Series whose terms proceed by the powers of a determinate quantity; as $1 + \frac{1}{2} + \frac{1}{2^2} + \frac{1}{2^3}$ + &c. If that determinate quantity be unity, the Series is said to be determined by unity. De Moivre, Miscel. Analyt. pa. 111. And an

Indeterminate SERIES is one whose terms proceed by the powers of an indeterminate quantity x; as

$x + \frac{1}{2}x^2 + \frac{1}{3}x^3 + \frac{1}{4}x^4$ &c; or sometimes also with indeterminate exponents, or indeterminate coefficients.

The *Form of a* SERIES, is used for that affection of an indeterminate Series, such as

$ax^n + bx^{n+r} + cx^{n+2r} + dx^{n+3r}$ &c, which arises from the different values of the indices of x. Thus,

If $n = 1$, and $r = 1$, the Series will take the form
$ax + bx^2 + cx^3 + dx^4$ &c.

If $n = 1$, and $r = 2$, the form will be
$ax + bx^3 + cx^5 + dx^7$ &c.

If $n = \frac{1}{2}$, and $r = 1$, the form is
$ax^{\frac{1}{2}} + bx^{\frac{3}{2}} + cx^{\frac{5}{2}} + dx^{\frac{7}{2}}$ &c. And

If $n = 0$, and $r = -1$, the form will be
$a + bx^{-1} + cx^{-2} + dx^{-3}$ &c.

When the value of a quantity cannot be found exactly, it is of use in algebra, as well as in common arithmetic, to seek an approximate value of that quantity, which may be useful in practice. Thus, in arithmetic, as the true value of the square root of 2 cannot be assigned, a decimal fraction is found to a sufficient degree of exactness in any particular case; which decimal fraction is in reality, no more than an infinite series of fractions converging or approximating to the true value of the root sought. For the expression $\sqrt{2} = 1.414213$ &c, is equivalent to this $\sqrt{2} = 1 + \frac{4}{10} + \frac{1}{100} + \frac{4}{1000}$ &c; or supposing $x = 10$, to this

$$\sqrt{2} = 1 + \frac{4}{x} + \frac{1}{x^2} + \frac{4}{x^3} + \frac{2}{x^4} \text{ &c.}$$

$$\text{or} = 1 + 4x^{-1} + x^{-2} + 4x^{-3} + 2x^{-4} \text{ &c,}$$

which last Series is a particular case of the more general indeterminate Series $ax^n + bx^{n+r} + cx^{n+2r}$ &c, viz, when $n = 0$, $r = -1$, and the coefficients $a = 1$, $b = 4$, $c = 1$, $d = 4$, &c.

But the application of the notion of approximations in numbers, to species, or to algebra, is not so obvious. Newton, with his usual sagacity, took the hint, and prosecuted it; by which were discovered general methods in the doctrine of infinite Series, which had before been treated only in a particular manner, though with great acuteness, by Wallis and a few others. See Newton's Method of Fluxions and Infinite Series, with Colson's Comment; as also the Analysis per Æquationes Numero Terminorum Infinitas, published by Jones in 1711, and since translated and explained by Stewart, together with Newton's Tract on Quadratures, in 1745. To these may be added Maclaurin's Algebra, part 2, chap. 10, pa. 244; and Cramer's Analyse des Lignes Courbes Algebraiques, chap. 7, pa. 148; and many other authors.

Among the various methods for determining the value of a quantity by a converging Series, that seems preferable to the rest, which consists in assuming an indeterminate Series as equal to the quantity whose value is sought, and afterwards determining the values of the terms of this assumed Series. For instance, suppose a logarithm were given, to find the natural number answering to it. Suppose the logarithm to be z, and the corresponding number sought $1 + x$: then by the nature of logarithms and fluxions, $\dot{z} = \frac{\dot{x}}{1 + x}$, or $\dot{z} + x\dot{z} = \dot{x}$. Now assume a Series for the value of the unknown quantity x, and substitute it and its fluxion instead of x and $\dot{x}$ in the last equation, then determine the assumed coefficients by comparing or equating the like terms of the equation. Thus,

assume $x = az + bz^2 + cz^3 + dz^4$ &c,
then $\dot{x} = a\dot{z} + 2bz\dot{z} + 3cz^2\dot{z} + 4dz^3\dot{z}$ &c;
and $\dot{x} = (\dot{z} + x\dot{z}) = \dot{z} + az\dot{z} + bz^2\dot{z} + cz^3\dot{z}$ &c;

hence, comparing the like terms of these two values of $\dot{x}$, there arises $a = 1$, $b = \frac{1}{2}$, $c = \frac{1}{6}$, $d = \frac{1}{24}$, &c; which values being substituted for a, b, c, &c, in the assumed Series $ax + bx^2 + cx^3$ &c, it gives

$$x = z + \frac{1}{2}z^2 + \frac{1}{6}z^3 + \frac{1}{24}z^4 + \frac{1}{120}z^5, \text{ &c, or}$$

$$x = z + \frac{1}{1.2}z^2 + \frac{1}{1.2.3}z^3 + \frac{1}{1.2.3.4}z^4 + \frac{1}{1.2.3.4.5}z^5$$

&c; and consequently the number sought will be

$$1 + x = 1 + z + \frac{1}{1.2}z^2 + \frac{1}{1.2.3}z^3 \text{ &c.}$$

But the indeterminate Series $az + bz^2 + cz^3$ &c, was here assumed arbitrarily, with regard to its exponents 1, 2, 3, &c, and will not succeed in all cases, because some quantities require other forms for the exponents. For instance, if from an arc given, it were required to find the tangent. Let $x =$ the tangent, and z the arc, the radius being $= 1$. Then, from the nature of the circle we shall have $\frac{\dot{x}}{1 + x^2} = \dot{z}$, or $\dot{x} = \dot{z} + x^2\dot{z}$. Now if, to find the value of x, we suppose $x = az + bz^2 + cz^3$ &c, and proceed as before, we shall find all the alternate coefficients b, d, f, &c, or those of the even powers of z, to be each $= 0$; and therefore the Series assumed is not of a proper form.

But

But ſuppoſing $x = az + bz^3 + cz^5 + dz^7$, &c, then we find $a = 1$, $b = \frac{1}{3}$, $c = \frac{2}{15}$, $d = \frac{17}{315}$, &c, and conſequently $x = z + \frac{1}{3}z^3 + \frac{2}{15}z^5 + \frac{17}{315}z^7$ &c.

And other quantities require other forms of Series.

Now to find a proper indeterminate Series in all caſes, tentatively, would often be very laborious, and even impracticable. Mathematicians have therefore endeavoured to find out a general rule for this purpoſe; though till lately the method has been but imperfectly underſtood and delivered. Moſt authors indeed have explained the manner of finding the coefficients a, b, c, d, &c, of the indeterminate Series $ax^n + bx^{n+r} + cx^{n+2r}$ &c, which is eaſy enough; but the values of n and r, in which the chief difficulty lies, have been aſſigned by many in a manner as if they were ſelf-evident, or at leaſt diſcoverable by an eaſy trial or two, as in the laſt example.

As to the number n, Newton himſelf has ſhewn the method of determining it, by his rule for finding the firſt term of a converging Series, by the application of his parallelogram and ruler. For the particulars of this method, ſee the authors above cited; ſee alſo PARALLELOGRAM.

Taylor, in his Methodus Incrementorum, inveſtigates the number r; but Stirling obſerves that his rule ſometimes fails. Lineæ Tert. Ordin. Newton. pa. 28. Mr. Stirling gives a correction of Taylor's rule, but ſays he cannot affirm it to be univerſal, having only found it by chance. And again

Graveſande obſerves, that though he thinks Stirling's rule never leads into an error, yet that it is not perfect. See Graveſande, De Determin. Form. Seriei Infinit. printed at the end of his Matheſeos Univerſalis Elementa. This learned profeſſor has endeavoured to rectify the rule. But Cramer has ſhewn that it is ſtill defective in ſeveral reſpects; and he himſelf, to avoid the inconveniences to which the methods of former authors are ſubject, has had recourſe to the firſt principles of the method of infinite Series, and has entered into a more exact and inſtructive detail of the whole method, than is to be met with elſewhere; for which reaſon, and many others, his treatiſe deſerves to be particularly recommended to beginners.

But it is to be obſerved, that in determining the value of a quantity by a converging Series, it is not always neceſſary to have recourſe to an indeterminate Series: for it is often better to find it by diviſion, or by extraction of roots. See Newton's Meth. of Flux. and Inf. Series, above cited. Thus, if it were required to find the arc of a circle from its given tangent, that is, to find the value of z in the given fluxional equation, $\dot{z} = \frac{\dot{x}}{1 + xx}$, by an infinite Series: dividing $\dot{x}$ by $1 + xx$, the quotient will be the Series $\dot{x} - x^2\dot{x} + x^4\dot{x} - x^6\dot{x}$ &c $= \dot{z}$; and taking the fluents of the terms, there reſults $z = x - \frac{1}{3}x^3 + \frac{1}{5}x^5 - \frac{1}{7}x^7$ &c, which is the Series often uſed for the quadrature of the circle. If $x = 1$, or the tangent of 45°, then will $z = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7}$ &c $=$ the length of the arc of 45°, or $\frac{1}{8}$ of the circumference, to the radius 1, or $\frac{1}{4}$ of the circumference to the diameter 1. Conſequently, if 1 be the diameter, then $1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7}$ &c will be the area of the circle, becauſe $\frac{1}{4}$ of the circumference multiplied by the diameter, gives the area of the circle. And this Series was firſt given by Leibnitz and James Gregory.

See the form of the Series for the binomial theorem, determined, both as to the coefficients and exponents, in my Tracts, vol. 1, pa. 79.

Harmonical SERIES, the reciprocal of arithmeticals. See HARMONICAL.

Hyperbolic SERIES, is uſed for a Series whoſe ſum depends upon the quadrature of the hyperbola. Such is the Series $\frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{4}$ &c. De Moivre's Miſcel. Analyt. pa. 111.

Interpolation of SERIES, the inſerting of ſome terms between others, &c. See INTERPOLATION.

Interſcendent SERIES. See INTERSCENDENT.

Mixt SERIES, one whoſe ſum depends partly on the quadrature of the circle, and partly on that of the hyperbola. De Moivre, Miſcel. Analyt. pa. 111.

Recurring SERIES, is uſed for a Series which is ſo conſtituted, that having taken at pleaſure any number of its terms, each following term ſhall be related to the ſame number of preceding terms according to a conſtant law of relation. Thus, in the following Series,

$$\begin{matrix} a & b & c & d & e & f \\ 1 + 2x + 3x^2 + 10x^3 + 34x^4 + 97x^5 \text{ &c,} \end{matrix}$$

in which the terms being reſpectively repreſented by the letters a, b, c, &c, ſet over them, we ſhall have

$$d = 3cx - 2bx^2 + 5ax^3,$$
$$e = 3dx - 2cx^2 + 5bx^3,$$
$$f = 3ex - 2dx^2 + 5cx^3,$$
&c, &c,

where it is evident that the law of relation between d and e, is the ſame as between e and f, each being formed in the ſame manner from the three terms which precede it in the Series.

The quantities $3x - 2x^2 + 5x^3$, taken together and connected by their proper ſigns, form what De Moivre calls the *index*, or the *ſcale of relation*: though ſometimes the bare coefficients $3 - 2 + 5$ are called the ſcale of relation. And the ſcale of relation ſubtracted from unity, is called the *differential ſcale*. On the ſubject of Recurring Series, ſee De Moivre's Miſcel. Analyt. pa. 27 and 72, and his Doctrine of Chances, 3d edit. pa. 220; alſo Euler's Analyſ. Infinit. tom. 1, pa. 175.

Having given a recurring Series, with its ſcale of relation, the ſum of the whole infinite Series will alſo be given. For inſtance, ſuppoſe a Series

$a + bx + cx^2 + dx^3$ &c, where the relation between the coefficient of any term and the coefficients of any two preceding terms may be expreſſed by $f - g$; that is, $e = fd - gc$, and $d = fc - gb$, &c; then will the ſum of the Series, infinitely continued, be $\frac{a + (b - fa)x}{1 - fx + gx^2}$.

Thus, for example, aſſume 2 and 5 for the coefficients of the firſt two terms of a recurring Series; and ſuppoſe f and g to be reſpectively 2 and 1; then the recurring Series will be

$$2 + 5x + 8x^2 + 11x^3 + 14x^4 + 18x^5 \text{ &c},$$

and its ſum $= \frac{2 + 5x - 4x}{1 - 2x + xx} = \frac{2 + x}{(1 - x)^2}$. For the proof of which divide $2 + x$ by $(1 - x)^2$, and there ariſes the ſaid Series $2 + 5x + 8x^2 + 11x^3$ &c. And ſimilar rules might be derived for more complex caſes.

De Moivre's general rule is this: 1. Take as many terms of the Series as there are parts in the ſcale of relation. 2. Subtract the ſcale of relation from unity, and the Remainder is the differential ſcale. 3. Multiply the terms taken in the Series by the differential ſcale, beginning at unity, and ſo proceeding orderly, remembering to leave out what would naturally be extended beyond the laſt of the terms taken. Then will the product be the numerator, and the differential ſcale will be the denominator of the fraction expreſſing the ſum required.

But it muſt here be obſerved, that when the ſum of a recurring Series extended to infinity, is found by De Moivre's rule, it ought to be ſuppoſed that the Series converges indefinitely, that is, that the terms may become leſs than any aſſigned quantity. For if the Series diverge, that is, if its terms continually increaſe, the rule does not give the true ſum. For the ſum in ſuch caſe is infinite, or greater than any given quantity, whereas the ſum exhibited by the rule, will often be finite. The rule therefore in this caſe only gives a fraction expreſſing the radix of the Series, by the expanſion of which the Series is produced. Thus $\frac{1}{(1-x)^2}$ by expanſion becomes the recurring Series $1 + 2x + 3x^2$ &c, whoſe ſcale of relation is $2 - 1$, and its ſum by the rule will be $\frac{a + bx - fax}{1 - fx + gxx} = \frac{1 + 2x - 2x}{1 - 2x + xx} = \frac{1}{(1-x)^2}$, the quantity from which the Series aroſe. But this quantity cannot in all caſes be deemed equal to the infinite Series $1 + 2x + 3x^2$ &c: for ſtop where you will, there will always want a ſupplement to make the product of the quotient by the diviſor equal to the dividend. Indeed when the Series converges infinitely, the ſupplement, diminiſhing continually, becomes leſs than any aſſigned quantity, or equal to nothing; but in a diverging Series, this ſupplement becomes infinitely great, and the Series deviates indefinitely from the truth. See Colſon's Comment on Newton's Method of Fluxions and Infinite Series, pa. 152; Stirling's Method. Differ. pa. 36; Bernoulli de Serieb. Infin. pa. 249; and Cramer's Analyſe des Lignes Courbes, pa. 174.

A recurring Series being given, the ſum of any finite number of the terms of that Series may be found. This is prob. 3, pa. 73, De Moivre's Miſcel. Analyt. and prob. 5, pa. 223 of his Doctrine of Chances. The ſolution is effected, by taking the difference between the ſums of two infinite Series, differing by the terms anſwering to the given number; viz, from the ſum of the whole infinite Series, commencing from the beginning, ſubtract the ſum of another infinite number of terms of the ſame Series, commencing after ſo many of the firſt terms whoſe ſum is required; and the difference will evidently be the ſum of that number of terms of the Series. For example, to find the ſum of n terms of the infinite geometrical Series $a + ax + ax^2 + ax^3$ &c. Here are two infinite Series; the one beginning with a, and the other with ax^n, which is the next term after the firſt n terms of the original Series. By the rule, the ſum of the firſt infinite progreſſion will be $\frac{a}{1 - x}$, and the ſum of the ſecond $\frac{ax^n}{1 - x}$; the difference of which is $\frac{a - ax^n}{1 - x}$, which is therefore the ſum of the firſt n terms of the Series. This quantity $\frac{a - ax^n}{1 - x}$ is equal to $\frac{ax^n - a}{x - 1}$ which laſt expreſſion, putting $ax^{n-1} = l$, will be equivalent to this, $\frac{lx - a}{x - 1}$, which is the common rule for finding the ſum of any geometric progreſſion, having given the firſt term a, the laſt term l, and the ratio x. See Miſcel. Analyt. pa. 167, 168.

In a recurring Series, any term may be obtained whoſe place is aſſigned. For after having taken ſo many terms of the Series as there are terms in the ſcale of relation, the Series may be protracted till it reach the place aſſigned. But when that place is very diſtant from the beginning of the Series, the continuing the terms is very laborious; and therefore other methods have been contrived. See Miſcel. Analyt. pa. 33; and Doctrine of Chances, pa. 224.

Theſe queſtions have been reſolved in many caſes, beſides thoſe of recurring Series. But as there is no univerſal method for the quadrature of curves, neither is there one for the ſummation of Series; indeed there is a great analogy between theſe things, and ſimilar difficulties ariſing in both. See the authors above cited.

The inveſtigation of Daniel Bernoulli's method for finding the roots of algebraic equations, which is inſerted in the Peterſburgh Acts, tom. 3, pa. 92, depends upon the doctrine of recurring Series. See Euler's Analyſis Infinitorum, tom. 1, pa. 276.

Reverſion of SERIES. See REVERSION *of Series*.

Summable SERIES, is one whoſe ſum can be accurately found. Such is the Series $\frac{1}{2} + \frac{1}{4} + \frac{1}{8}$ &c, the ſum of which is ſaid to be unity, or, to ſpeak more accurately, the limit of its ſum is unity or 1.

An indefinite number of ſummable infinite Series may

may be assigned: such are, for instance, all infinite recurring converging Series, and many others, for which, consult De Moivre, Bernoulli, Stirling, Euler, and Maclaurin; viz, Miscel. Analyt. pa. 110; De Serieb. Infinit. passim; Method. Different. pa. 34; Acta Petrop. passim; Fluxions, art. 359.

The obtaining the sums of infinite Series of fractions has been one of the principal objects of the modern method of computation; and these sums may often be found, and often not. Thus the sums of the two following Series of geometrical progressionals are easily found to be 1 and $\frac{1}{2}$,

$$\text{viz, } 1 = \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16} \text{ &c,}$$

$$\text{and } \frac{1}{2} = \frac{1}{3} + \frac{1}{9} + \frac{1}{27} + \frac{1}{81} \text{ &c.}$$

But the Series of fractions that occur in the solution of problems, can seldom be reduced to geometric progressions; nor can any general rule, in cases so infinitely various, be given. The art here, as in most other cases, is only to be acquired by examples, and by a careful observation of the arts used by great authors in the investigation of such Series of fractions as they have considered. And the general methods of infinite Series, which have been carried so far by De Moivre, Stirling, Euler, &c, are often found necessary to determine the sum of a very simple Series of fractions. See the quotations above.

The sum of a Series of fractions, though decreasing continually, is not always finite. This is the case of the Series $\frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \frac{1}{5}$ &c, which is the harmonic Series, consisting of the reciprocals of arithmeticals, the sum of which exceeds any given number whatever; and this is shewn from the analogy between this progression and the space comprehended by the common hyperbola and its asymptote; though the same may be shewn also from the nature of progressions. See James Bernoulli, de Seriebus Infin. But, what is curious, the square of it is finite, for if the same terms of the harmonic Series, $\frac{1}{1} + \frac{1}{2} + \frac{1}{3}$ &c, be squared, forming the Series $\frac{1}{1} + \frac{1}{4} + \frac{1}{9}$ &c, being the reciprocals of the squares of the natural Series of numbers; the sum of this Series of fractions will not only be limited, but it is remarkable that this sum will be precisely equal to the 6th part of the number which expresses the ratio of the square of the circumference of a circle to the square of its diameter. That is, if c denote 3·14159 &c, the ratio of the circumference to the diameter, then is $\frac{1}{6}c^2 = \frac{1}{1} + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \frac{1}{25}$ &c. This property was first discovered by Euler; and his investigation may be seen in the Acta Petrop. vol. 7. And Maclaurin has since observed, that this may easily be deduced from his Fluxions, art. 822. Philos. Transf. numb. 469.

It would require a whole treatise to enumerate the various kinds of Series of fractions which may or may not be summed. Sometimes the sum cannot be assigned, either because it is infinite, as in the harmonic Series $\frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{4}$ &c, or although the sum be finite (as in the Series $\frac{1}{1} + \frac{1}{4} + \frac{1}{9}$ &c), yet its sum cannot be assigned in finite terms, or by the quadrature of the circle or hyperbola, which was the case of this Series before Euler's discovery; but yet the sum of any given number of the terms of the Series may be expeditiously found, and the whole sum may be assigned by approximation, independent of the circle. See Stirling's Method. Different. and De Moivre's Miscel. Analyt.

Besides the Series of fractions, the sums of which converge to a certain quantity, there sometimes occur others, which converge by a continued multiplication. Of this kind is the Series found by Wallis, for the quadrature of the circle, which he expresses thus,

$$\square = \frac{3 \times 3 \times 5 \times 5 \times 7 \times 7 \times 9 \times 9 \times \text{ &c}}{2 \times 4 \times 4 \times 6 \times 6 \times 8 \times 8 \times 10 \times \text{ &c}},$$

where the character $\square$ denotes the ratio of the square of the diameter to the area of the circle. Hence the denominator of this fraction, is to its numerator, both infinitely continued, as the circle is to the square of the diameter. It may farther be observed that this Series is equivalent to

$$\frac{9}{8} \times \frac{25}{24} \times \frac{49}{48} \times \text{ &c, or to } \frac{3^2}{3^2-1} \times \frac{5^2}{5^2-1} \times \frac{7^2}{7^2-1} \times$$

&c, that is, the product of the squares of all the odd numbers 3, 5, 7, 9, &c, is to the product of the same squares severally diminished by unity, as the square of the diameter is to the area of the circle. See Arithmet. Infinit. prop. 191, Oper. vol. 1, pa. 469. Id. Oper. vol. 2, pa. 819. And these products of fractions, and the like quantities arising from the continued multiplication of certain factors, have been particularly considered by Euler, in his Analysis Infinit. vol. 1, chap. 15, pa. 221.

For an easy and general method of summing all alternate Series, such as $a - b + c - d$ &c, see my Tracts, vol. 1, pa. 11; and in the same vol. may be seen many other curious tracts on infinite Series.

Summation of Infinite SERIES, is the finding the value of them, or the radix from which they may be raised. For which, consult all the authors upon this science.

To find an infinite Series by extracting of roots; and to find an infinite Series by a presupposed Series; see QUADRATURE *of the Circle*.

To extract the roots of an infinite Series, see EXTRACTION *of Roots*.

To raise an infinite Series to any power, see INVOLUTION, and POWER.

Transcendental SERIES. See TRANSCENDENTAL.

There are many other important writings upon the subject of Infinite Series, besides those above quoted. A very good elementary tract on the subject is that of James Bernoulli, intituled, *Tractatus de Seriebus Infinitis*.

tis, and annexed to his *Ars Conjectandi*, publiſhed in 4to, 1713.

SERPENS, in Aſtronomy, a conſtellation in the northern hemiſphere, being one of the 48 old conſtellations mentioned by all the Ancients, and is called more particularly *Serpens Ophiuchi*, being graſped in the hands of the conſtellation Ophiuchus. The Greeks, in their fables, have aſcribed it ſometimes to one of Triptolemus's dragons, killed by Carnabos; and ſometimes to the ſerpent of the river Segaris, deſtroyed by Hercules. This is by ſome ſuppoſed to be the ſame as the author of the book of Job calls the *Crooked Serpent*; but this expreſſion more probably meant the conſtellation Draco, near the north pole.

The ſtars in the conſtellation Serpens, in Ptolomy's catalogue are 18, in Tycho's 13, in Hevelius's 22, and in the Britannic catalogue 64.

SERPENTARIUS, a conſtellation of the northern hemiſphere, being one of the 48 old conſtellations mentioned by all the Ancients. It is called alſo Ophiuchus, and anciently Æſculapius. It is in the figure of a man graſping the ſerpent.

The Greeks had different fables about this, and other conſtellations, becauſe they were ignorant of the true meaning of them. Some of them ſay, it repreſents Carnabos, who killed one of the dragons of Triptolemus. Others ſay, it was Hercules, killing the ſerpent at the river Segaris. And others again ſay, it repreſents the celebrated phyſician Æſculapius, to denote his ſkill in medicine to cure the bite of the ſerpent.

The ſtars in the conſtellation Serpentarius, in Ptolomy's catalogue are 29, in Tycho's 15, in Hevelius's 40, and in the Britannic catalogue they are 74.

SERPENTINE *Line*, the ſame with ſpiral.

SESQUI, an expreſſion of a certain ratio, viz, the ſecond ratio of inequality, called alſo *ſuperparticular* ratio; being that in which the greater term contains the leſs once, and ſome certain part over; as 3 to 2, where the firſt term contains the ſecond once, and unity over, which is a quota part of 2. Now if this part remaining be juſt half the leſs term, the ratio is called *ſeſquialtera*; if the remaining part be a 3d part of the leſs term, as 4 to 3, the ratio is called *ſeſquitertia*, or *ſeſquiterza*; if a 4th part, as 5 to 4, the ratio is called *ſeſquiquarta*; and ſo on continually, ſtill adding to Seſqui the ordinal number of the ſmaller term.

In Engliſh we ſometimes ſay, *ſeſquialteral*, or *ſeſquialterate*, *ſeſquithird*, *ſeſquifourth*, &c.

As to the kinds of triples expreſſed by the particle *ſeſqui*, they are theſe:

SESQUIALTERATE, *the greater perfect*, which is a triple, where the breve is three meaſures, or ſemibreves.

SESQUIALTERATE, *greater imperfect*, which is where the breve, when pointed, contains three meaſures, and without any point, two.

SESQUIALTERATE, *leſs imperfect*, a triple, where the ſemibreve with a point contains three meaſures, and two without.

SESQUIALTERATE, in Arithmetic and Geometry, is a ratio between two numbers, or lines, &c, where the greater is equal to once and a half of the leſs. Thus 6 and 9 are in a Seſquialterate ratio, as alſo 20 and 30.

SESQUIDITONE, in Muſic, a concord reſulting from the ſounds of two ſtrings whoſe vibrations, in equal times, are to each other in the ratio of 5 to 6.

SESQUIDUPLICATE *Ratio*, is that in which the greater term contains the leſs, twice and a half; as the ratio of 15 to 6, or 50 to 20.

SESQUIQUADRATE, an aſpect or poſition of the planets, when they are diſtant by 4 ſigns and a half, or 135 degrees.

SESQUIQUINTILE, is an aſpect of the planets when they are diſtant $\frac{1}{5}$ of the circle and a half, or 108 degrees.

SESQUITERTIONAL *Proportion*, is that in which the greater term contains the leſs once and one third; as 4 to 3, or 12 to 9.

SETTING, in Aſtronomy, the withdrawing of a ſtar or planet, or its ſinking below the horizon.

Aſtronomers and poets count three different kinds of Setting of the ſtars, viz, ACHRONICAL, COSMICAL, and HELIACAL. See theſe terms reſpectively.

SETTING, in Navigation, Surveying, &c, denotes the obſerving the bearing or ſituation of any diſtant object by the compaſs, &c, to diſcover the angle it makes with the neareſt meridian, or with ſome other line. See BEARING.

Thus, to *ſet the land*, or *the ſun*, by the compaſs, is to obſerve how the land bears on any point of the compaſs, or on what point of the compaſs the ſun is. Alſo, when two ſhips come in ſight of each other, to mark on what point the chace bears, is termed *Setting the chace by the compaſs*.

SETTING alſo denotes the direction of the wind, current, or ſea, particularly of the two latter.

SEVEN STARS, a common denomination given to the cluſter of ſtars in the neck of the ſign Taurus, the bull, properly called the pleiades. They are ſo called from their number Seven which appear to the naked eye, though ſome eyes can diſcover only 6 of them; but by the help of teleſcopes there appears to be a great multitude of them.

SEVENTH, *Septima*, an interval in Muſic, called by the Greeks *heptachordon*.

SEXAGENARY, ſomething relating to the number 60.

SEXAGENARY *Arithmetic*. See SEXAGESIMAL.

SEXAGENARY *Tables*, are tables of proportional parts, ſhewing the product of two Sexagenaries that are to be multiplied, or the quotient of two that are to be divided.

SEXAGESIMA, the eighth Sunday before Eaſter; being ſo called becauſe near 60 days before it.

SEXAGESIMAL or SEXAGENARY *Arithmetic*, a method of computation proceeding by 60ths. Such is that uſed in the diviſion of a degree into 60 minutes, of the minute into 60 ſeconds, of the ſecond into 60 thirds, &c.

SEXAGESIMALS, or SEXAGESIMAL *Fractions*, are fractions whoſe denominators proceed in a ſexagecuple ratio; that is, a prime, or the firſt minute $= \frac{1}{60}$, a ſecond $= \frac{1}{3600}$, a third $= \frac{1}{216000}$.

Anciently there were no other than Sexageſimals uſed in aſtronomical operations, for which reaſon they are ſometimes called *aſtronomical fractions*, and they are ſtill retained in many caſes, as in the diviſions of time and of a circle; but decimal arithmetic is now much

uſed in the calculations. Sexageſimals were probably firſt uſed for the diviſions of a circle, 360, or 6 times 60 making up the whole circumference, on account that 360 days made up the year of the Ancients, in which time the ſun was ſuppoſed to complete his courſe in the circle of the ecliptic.

In theſe fractions, the denominator being always 60, or a multiple of it, it is uſually omitted, and the numerator only written down: thus, $3^{\circ}\ 45'\ 24''\ 40'''$ &c, is to be read, 3 degrees, 45 minutes, 24 ſeconds, 40 thirds, &c.

SEXANGLE, in Geometry, a figure having 6 angles, and conſequently 6 ſides alſo.

SEXTANS, a ſixth part of certain things.

The Romans divided their *as*, which was a pound of braſs, into 12 ounces, called *uncia*, from *unum*; and the quantity of 2 ounces was called *ſextans*, as being the 6th part of the pound.

SEXTANS was alſo a meaſure, which contained 2 ounces of liquor, or 2 cyathi.

SEXTANS, the Sextant, in Aſtronomy, a new conſtellation, placed acroſs the equator, but on the ſouth ſide of the ecliptic, and by Hevelius made up of ſome unformed ſtars, or ſuch as were not included in any of the 48 old conſtellations. In Hevelius's catalogue it contains 11 ſtars, but in the Britannic catalogue 41.

SEXTANT, denotes the 6th part of a circle, or an arch containing 60 degrees.

SEXTANT is more particularly uſed for an aſtronomical inſtrument. It is made like a quadrant, excepting that its limb only contains 60 degrees. Its uſe and application are the ſame with thoſe of the QUADRANT; which ſee.

SEXTARIUS, an ancient Roman meaſure, containing 2 cotylæ, or 2 heminæ.

SEXTILE, the aſpect or poſition of two planets, when they are diſtant the 6th part of the circle, viz, 2 ſigns or 60 degrees; and it is marked thus ⚹.

SEXTUPLE, denotes 6 fold in general. But in muſic it denotes a mixed ſort of triple time, which is beaten in double time.

SHADOW, *Shade*, in Optics, a certain ſpace deprived of light, or where the light is weakened by the interpoſition of ſome opaque body before the luminary.

The doctrine of Shadows makes a conſiderable article in optics, aſtronomy, and geography; and is the general foundation of dialling.

As nothing is ſeen but by light, a mere ſhadow is inviſible; and therefore when we ſay we ſee a ſhadow, we mean, partly that we ſee bodies placed in the Shadow, and illuminated by light reflected from collateral bodies, and partly that we ſee the confines of the light.

When the opaque body, that projects the Shadow, is perpendicular to the horizon, and the plane it is projected on is horizontal, the Shadow is called a *right* one: ſuch as the Shadows of men, trees, buildings, mountains, &c. But when the body is placed parallel to the horizon, it is called a *verſed Shadow*; as the arms of a man when ſtretched out, &c.

Laws of the Projection of Shadows.

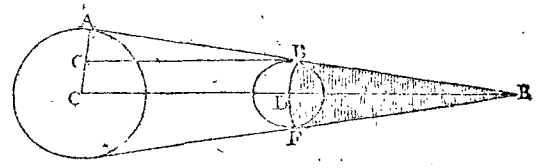
1. Every opaque body projects a Shadow in the ſame direction with the rays of light; that is, towards the part oppoſite to the light. Hence, as either the luminary or the body changes place, the Shadow likewiſe changes its place.

2. Every opaque body projects as many Shadows as there are luminaries to enlighten it.

3. As the light of the luminary is more intenſe, the ſhadow is the deeper. Hence, the intenſity of the Shadow is meaſured by the degrees of light that ſpace is deprived of. In reality, the Shadow itſelf is not deeper; but it appears ſo, becauſe the ſurrounding bodies are more intenſely illuminated.

4. When the luminous body and opaque one are equal, the Shadow is always of the ſame breadth with the opaque body. But when the luminous body is the larger, the Shadow grows always leſs and leſs, the farther from the body. And when the luminous body is the ſmaller of the two, the Shadow increaſes always the wider, the farther from the body. Hence, the Shadow of an opaque globe is, in the firſt caſe a cylinder, in the ſecond caſe it is a cone verging to a point, and in the third caſe a truncated cone that enlarges ſtill the more the farther from the body. Alſo, in all theſe caſes, a tranſverſe Section of the Shadow, by a plane, is a circle, reſpectively, in the three caſes, equal, leſs, or greater than a great circle of the globe.

5. To find the length of the Shadow, or the axis of the ſhady cone, projected by a ſphere, when it is illuminated by a larger one; the diameters and diſtance of the two ſpheres being known. Let C and D be the



centres of the two ſpheres, CA the ſemidiameter of the larger, and DB that of the ſmaller, both perpendicular to the ſide of the conical Shadow BEF, whoſe axis is DE, continued to C; and draw BG parallel to the ſame axis. Then, the two triangles AGB and BDE being ſimilar, it will be AG : GB or CD :: BD : DE, that is, as the difference of the ſemidiameters is to the diſtance of the centres, ſo is the ſemidiameter of the opaque ſphere to the axis of the Shadow, or the diſtance of its vertex from the ſaid opaque ſphere.

Ex. gr. If BD = 1 be the ſemidiameter of the earth, and AC = 101 the mean ſemidiameter of the ſun, alſo their diſtance CD or GB = 24000; then as 100 : 24000 :: 1 : 240 = DE, which is the mean height of the earth's Shadow, in ſemidiameters of the baſe.

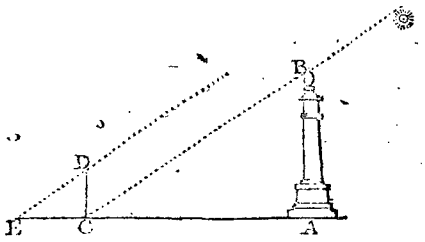
6. To find the length of the ſhadow AC projected by an opaque body AB; having given the altitude of the luminary, for ex. of the ſun, above the horizon, viz, the angle C, and the height of the object AB. Here the proportion is, as tang. ∠ C : radius :: AB : AC.

Or, if the length of the Shadow AC be given, to find the height AB, it will be,

as radius : tang. ∠ C :: AC : AB.

Or,

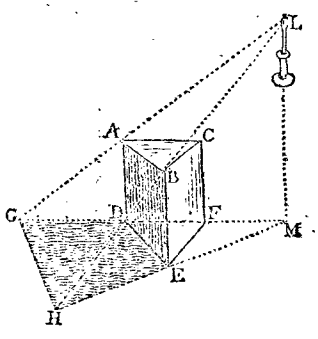
Or, if the length of the Shadow AC, and of the object AB, be given, to find the ſun's altitude above the horizon, or the angle at C. It will be, as AC : AB : : radius : tang. ∠ C ſought.



7. To meaſure the height of any object, ex. gr. a tower AB, by means of its ſhadow projected on an horizontal plane.—At the extremity of the ſhadow, at C, erect a ſtick or pole CD, and meaſure the length of its ſhadow CE; alſo meaſure the length of the Shadow AC of the tower. Then, by ſimilar triangles, it will be, as EC : CD : : CA : AB. So if EC = 10 feet, CD = 6 feet, and CA = 95 feet; then as 10 : 6 :: 95 : 57 feet = AB, the height of the tower ſought.

SHADOW, in Geography. The inhabitants of the earth are divided, with reſpect to their ſhadows, into ASCII, AMPHISCII, HETEROSCII, and PERISCII. See theſe terms in their places.

SHADOW, in Perſpective, is of great uſe in this art.—Having given the appearance of an opaque body, and a luminous one, whoſe rays diverge, as a candle, or lamp, &c; to find the juſt appearance of the Shadow, according to the laws of perſpective. The method is this: From the luminous body, which is here conſidered as a point, let fall a perpendicular to the perſpective plane or table; and from the ſeveral angles, or raiſed points of the body, let fall perpendiculars to the ſame plane; then connect the points on which theſe latter perpendiculars fall, by right lines, with the point on which the firſt falls; continuing theſe lines beyond the ſide oppoſite to the luminary, till they meet with as many other lines drawn from the centre of the luminary through the ſaid angles or raiſed points; ſo ſhall the points of interſection of theſe lines be the extremes or bounds of the Shadow.



For Example, to project the appearance of the Shadow of a priſm ABCDEF, ſcenographically delineated. Here M is the place of the perpendicular of the light L, and D, E, F thoſe of the raiſed points A, B, C, of the priſm; therefore, draw MEH, MDG, &c, and LBH, LAG, &c, which will give DEGH &c for the appearance of the Shadow.

As for thoſe Shadows that are intercepted by other objects, it may be obſerved, that when the Shadow of a line falls upon any object, it muſt neceſſarily take the form of that object. If it fall upon another plane, it will be a right line; if upon a globe, it will be circular; and if upon a cylinder or cone, it will be circular, or oval, &c. If the body intercepting it be a plane, whatever be the ſituation of it, the ſhadow falling upon it might be found by producing that plane till it intercepted the perpendicular let fall upon it from the luminous body; for then a line drawn from that point would determine the Shadow, juſt as if no other plane had been concerned. But the appearance of all theſe Shadows may be drawn with leſs trouble, by firſt drawing it through theſe intercepted objects, as if they had not been in the way, and then making the Shadow to aſcend perpendicularly up every perpendicular plane, and obliquely on thoſe that are ſituated obliquely, in the manner deſcribed by Dr. Prieſtley, in his Perſpective, pa. 73 &c.

Here we may obſerve in general, that ſince the Shadows of all objects which are caſt upon the ground, will vaniſh into the horizontal line; ſo, for the ſame reaſon, the vaniſhing points of all Shadows, which are caſt upon any inclined or other plane, will be ſomewhere in the vaniſhing line of that plane.

When objects are not ſuppoſed to be viewed by the light of the ſun, or of a candle, &c, but only in the light of a cloudy day, or in a room into which the ſun does not ſhine, there is no ſenſible Shadow of the upper part of the object, and the lower part only makes the neighbouring parts of the ground, on which it ſtands, a little darker than the reſt. This imperfect obſcure kind of Shadow is eaſily made, being nothing more than a ſhade on the ground, oppoſite to the ſide on which the light comes; and it may be continued to a greater or leſs diſtance, according to the ſuppoſed brightneſs of the light by which it is made. It is in this manner (in order to ſave trouble, and ſometimes to prevent confuſion) that the Shadows in moſt drawings are made. On this ſubject, ſee Prieſtley's Perſpect. above quoted; alſo Kirby's Perſp. book 2, ch. 4.

SHAFT *of a Column*, in Building, is the body of it; thus called from its ſtraightneſs: but by architects more commonly the Fuſt.

SHAFT is alſo uſed for the ſpire of a church ſteeple; and for the ſhank or tunnel of a chimney.

SHARP (ABRAHAM), an eminent mathematician, mechaniſt, and aſtronomer, was deſcended from an ancient family at Little-Horton, near Bradford, in the Weſt Riding of Yorkſhire, where he was born about the year 1651. At a proper age he was put apprentice to a merchant at Mancheſter; but his genius led him ſo ſtrongly to the ſtudy of mathematics, both theoretical and practical, that he ſoon became uneaſy in that ſituation of life. By the mutual conſent therefore of his maſter and himſelf, though not altogether with that of his father, he quitted the buſineſs of a merchant. Upon this he removed to Liverpool, where he

give

gave himſelf up wholly to the ſtudy of mathematics, aſtronomy, &c; and where, for a ſubſiſtance, he opened a ſchool, and taught writing and accounts, &c.

He had not been long at Liverpool when he accidentally fell in company with a merchant or tradeſman viſiting that town from London, in whoſe houſe it ſeems the aſtronomer Mr. Flamſteed then lodged. With the view therefore of becoming acquainted with this eminent man, Mr. Sharp engaged himſelf with the merchant as a book-keeper. In conſequence he ſoon contracted an intimate acquaintance and friendſhip with Mr. Flamſteed, by whoſe intereſt and recommendation he obtained a more profitable employment in the dock-yard at Chatham; where he continued till his friend and patron, knowing his great merit in aſtronomy and mechanics, called him to his aſſiſtance, in contriving, adapting, and fitting up the aſtronomical apparatus in the Royal Obſervatory at Greenwich, which had been lately built, namely about the year 1676; Mr. Flamſteed being then 30 years of age, and Mr. Sharp 25.

In this ſituation he continued to aſſiſt Mr. Flamſteed in making obſervations (with the mural arch, of 80 inches radius, and 140 degrees on the limb, contrived and graduated by Mr. Sharp) on the meridional zenith diſtances of the fixed ſtars, ſun, moon, and planets, with the times of their tranſits over the meridian; alſo the diameters of the ſun and moon, and their eclipſes, with thoſe of Jupiter's ſatellites, the variation of the compaſs, &c. He aſſiſted him alſo in making a catalogue of near 3000 fixed ſtars, as to their longitudes and magnitudes, their right aſcenſions and polar diſtances, with the variations of the ſame while they change their longitude by one degree.

But from the fatigue of continually obſerving the ſtars at night, in a cold thin air, joined to a weakly conſtitution, he was reduced to a bad ſtate of health; for the recovery of which he deſired leave to retire to his houſe at Horton; where, as ſoon as he found himſelf on the recovery, he began to fit up an obſervatory of his own; having firſt made an elegant and curious engine for turning all kinds of work in wood or braſs, with a maundril for turning irregular figures, as ovals, roſes, wreathed pillars, &c. Beſide theſe, he made himſelf moſt of the tools uſed by joiners, clockmakers, opticians, mathematical inſtrument-makers, &c. The limbs or arcs of his large equatorial inſtrument, ſextant, quadrant, &c, he graduated with the niceſt accuracy, by diagonal diviſions into degrees and minutes. The teleſcopes he made uſe of were all of his own making, and the lenſes ground, figured, and adjuſted with his own hands.

It was at this time that he aſſiſted Mr. Flamſteed in calculating moſt of the tables in the ſecond volume of his *Hiſtoria Cœleſtis*, as appears by their letters, to be ſeen in the hands of Mr. Sharp's friends at Horton. Likewiſe the curious drawings of the charts of all the conſtellations viſible in our hemiſphere, with the ſtill more excellent drawings of the planiſpheres both of the northern and ſouthern conſtellations. And though theſe drawings of the conſtellations were ſent to be engraved at Amſterdam by a maſterly hand, yet the originals far exceeded the engravings in point of beauty and elegance: theſe were publiſhed by Mr. Flamſteed, and both copies may be ſeen at Horton.

The mathematician meets with ſomething extraordinary in Sharp's elaborate treatiſe of *Geometry Improved* (in 4to 1717, ſigned A. S. Philomath.), 1ſt, by a large and accurate table of ſegments of circles, its conſtruction and various uſes in the ſolution of ſeveral difficult problems, with compendious tables for finding a true proportional part; and their uſe in theſe or any other tables exemplified in making logarithms, or their natural numbers, to 60 places of figures; there being a table of them for all primes to 1100, true to 61 figures. 2d, His conciſe treatiſe of Polyedra, or ſolid bodies of many baſes, both the regular ones and others: to which are added twelve new ones, with various methods of forming them, and their exact dimenſions in ſurds, or ſpecies, and in numbers: illuſtrated with a variety of copper-plates, neatly engraved by his own hands. Alſo the models of theſe polyedra he cut out in box wood with amazing neatneſs and accuracy. Indeed few or none of the mathematical inſtrument-makers could exceed him in exactly graduating or neatly engraving any mathematical or aſtronomical inſtrument, as may be ſeen in the equatorial inſtrument above mentioned, or in his ſextant, quadrants and dials of various ſorts; alſo in a curious armillary ſphere, which, beſide the common properties, has moveable circles &c, for exhibiting and reſolving all ſpherical triangles; alſo his double ſector, with many other inſtruments; all contrived, graduated and finiſhed, in a moſt elegant manner, by himſelf. In ſhort, he poſſeſſed at once a remarkably clear head for contriving, and an extraordinary hand for executing, any thing, not only in mechanics, but likewiſe in drawing, writing, and making the moſt exact and beautiful ſchemes or figures in all his calculations and geometrical conſtructions.

The quadrature of the circle was undertaken by him for his own private amuſement in the year 1699, deduced from two different ſeries, by which the truth of it was proved to 72 places of figures; as may be ſeen in the introduction to Sherwin's tables of logarithms; that is, if the diameter of a circle be 1, the circumference will be found equal to 3·14159265358979323846264338327950288419716939937510582097494459230781640 6, &c. In the ſame book of Sherwin's may alſo be ſeen his ingenious improvements on the making of logarithms, and the conſtructing of the natural ſines, tangents, and ſecants.

He alſo calculated the natural and logarithmic ſines, tangents, and ſecants, to every ſecond in the firſt minute of the quadrant: the laborious inveſtigation of which may probably be ſeen in the archives of the Royal Society, as they were preſented to Mr. Patrick Murdoch for that purpoſe; exhibiting his very neat and accurate manner of writing and arranging his figures, not to be equalled perhaps by the beſt penman now living.

The late ingenious Mr. Smeaton ſays (Philoſ. Tranſ. an. 1786, pa. 5, &c):

"In the year 1689, Mr. Flamſteed completed his mural arc at Greenwich; and, in the Prolegomena to his Hiſtoria Cœleſtis, he makes an ample acknowledgment of the particular aſſiſtance, care, and induſtry of Mr. Abraham Sharp; whom, in the month of Auguſt 1688, he brought into the obſervatory, as his amanuenſis; and being as Mr. Flamſteed tells us, not only

only a very skilful mathematician, but exceedingly expert in mechanical operations, he was principally employed in the conſtruction of the mural arc; which in the compaſs of 14 months he finiſhed, ſo greatly to the ſatisfaction of Mr. Flamſteed, that he ſpeaks of him in the higheſt terms of praiſe.

"This celebrated inſtrument, of which he alſo gives the figure at the end of the Prolegomena, was of the radius of 6 feet 7½ inches; and, in like manner as the ſextant, was furniſhed both with ſcrew and diagonal diviſions, all performed by the accurate hand of Mr. Sharp. But yet, whoever compares the different parts of the table for converſion of the revolutions and parts of the ſcrew belonging to the mural arc into degrees, minutes, and ſeconds, with each other, at the ſame diſtance from the zenith on different ſides; and with their halves, quarters, &c, will find as notable a diſagreement of the ſcrew-work from the hand diviſions, as had appeared before in the work of Mr. Tompion: and hence we may conclude, that the method of Dr. Hook, being executed by two ſuch maſterly hands as Tompion and Sharp, and found defective, is in reality not to be depended upon in nice matters.

"From the account of Mr. Flamſteed it appears alſo, that Mr. Sharp obtained the zenith point of the inſtrument, or line of collimation, by obſervation of the zenith ſtars, with the face of the inſtrument on the eaſt and on the weſt ſide of the wall: and that having made the index ſtronger (to prevent flexure) than that of the ſextant, and thereby heavier, he contrived, by means of pulleys and balancing weights, to relieve the hand that was to move it from a great part of its gravity. Mr. Sharp continued in ſtrict correſpondence with Mr. Flamſteed as long as he lived, as appeared by letters of Mr. Flamſteed's found after Mr. Sharp's death; many of which I have ſeen.

"I have been the more particular relating to Mr. Sharp, in the buſineſs of conſtructing this mural arc; not only becauſe we may ſuppoſe it the firſt good and valid inſtrument of the kind, but becauſe I look upon Mr. Sharp to have been the firſt perſon that cut accurate and delicate diviſions upon aſtronomical inſtruments; of which, independent of Mr. Flamſteed's teſtimony, there ſtill remain conſiderable proofs: for, after leaving Mr. Flamſteed, and quitting the department above-mentioned, he retired into Yorkſhire, to the village of Little Horton, near Bradford, where he ended his days about the year 1743 (ſhould be, in 1742); and where I have ſeen not only a large and very fine collection of mechanical tools, the principal ones being made with his own hands, but alſo a great variety of ſcales and inſtruments made with them, both in wood and braſs, the diviſions of which were ſo exquiſite, as would not diſcredit the firſt artiſts of the preſent times: and I believe there is now remaining a quadrant, of 4 or 5 feet radius, framed of wood, but the limb covered with a braſs plate; the ſubdiviſions being done by diagonals, the lines of which are as finely cut as thoſe upon the quadrants at Greenwich. The delicacy of Mr. Sharp's hand will indeed permanently appear from the copper-plates in a quarto book, publiſhed in the year 1718, intituled *Geometry Improved* by A. Sharp, Philomath." (or rather 1717, by A. S. Philomath.) "whereof not only the geometrical lines upon the plates, but the whole of the engraving of letters and figures, were done by himſelf, as I was told by a perſon in the mathematical line, who very frequently attended Mr. Sharp in the latter part of his life. I therefore look upon Mr. Sharp as the firſt perſon that brought the affair of hand diviſion to any degree of perfection."

Mr. Sharp kept up a correſpondence by letters with moſt of the eminent mathematicians and aſtronomers of his time, as Mr. Flamſteed, Sir Iſaac Newton, Dr. Halley, Dr. Wallis, Mr. Hodgſon, Mr. Sherwin, &c, the anſwers to which letters are all written upon the backs, or empty ſpaces, of the letters he received, in a ſhort-hand of his own contrivance. From a great variety of letters (of which a large cheſt full remain with his friends) from theſe and many other celebrated mathematicians, it is evident that Mr. Sharp ſpared neither pains nor time to promote real ſcience. Indeed, being one of the moſt accurate and indefatigable computers that ever exiſted, he was for many years the common reſource for Mr. Flamſteed, Sir Jonas Moore, Dr. Halley, and others, in all ſorts of troubleſome and delicate calculations.

Mr. Sharp continued all his life a bachelor, and ſpent his time as recluſe as a hermit. He was of a middle ſtature, but very thin, being of a weakly conſtitution; he was remarkably feeble the laſt three or four years before he died, which was on the 18th of July 1742, in the 91ſt year of his age.

In his retirement at Little Horton, he employed four or five rooms or apartments in his houſe for different purpoſes, into which none of his family could poſſibly enter at any time without his permiſſion. He was ſeldom viſited by any perſons, except two gentlemen of Bradford, the one a mathematician, and the other an ingenious apothecary: theſe were admitted, when he choſe to be ſeen by them, by the ſignal of rubbing a ſtone againſt a certain part of the outſide wall of the houſe. He duly attended the diſſenting chapel at Bradford, of which he was a member, every Sunday; at which time he took care to be provided with plenty of halfpence, which he very charitably ſuffered to be taken ſingly out of his hand, held behind him during his walk to the chapel, by a number of poor people who followed him, without his ever looking back, or aſking a ſingle queſtion.

Mr. Sharp was very irregular as to his meals, and remarkably ſparing in his diet, which he frequently took in the following manner. A little ſquare hole, ſomething like a window, made a communication between the room where he was uſually employed in calculations, and another chamber or room in the houſe where a ſervant could enter; and before this hole he had contrived a ſliding board: the ſervant always placed his victuals in this hole, without ſpeaking or making any the leaſt noiſe; and when he had a little leiſure he viſited his cupboard to ſee what it afforded to ſatisfy his hunger or thirſt. But it often happened, that the breakfaſt, dinner, and ſupper have remained untouched by him, when the ſervant has gone to remove what was left—ſo deeply engaged had he been in calculations.—Cavities might eaſily be perceived in an old Engliſh oak table where he ſat to write, by the frequent rubbing and wearing of his elbows.—*Gutta cavat lapidem, &c.*

By

By Mr. Sharp's epitaph it appears that he was related to archbiſhop Sharp. And Mr. Sharp the eminent ſurgeon, who it ſeems has lately retired from buſineſs, is the nephew of our author. Another nephew was the father of Mr. Ramſden, the preſent celebrated inſtrument maker, who ſays that his grand uncle Abraham, our author, was ſome time in his younger days an exciſeman; which occupation he quitted on coming to a patrimonial eſtate of about 200l. a year.

SHARP, in Muſic, a kind of artificial note, or character, thus formed ♯: this being prefixed to any note, ſhews that it is to be ſung or played a ſemitone or half note higher than the natural note is. When a Sharp is placed at the beginning of a ſtave or movement, it ſhews that all notes that are found on the ſame line, or ſpace, throughout, are to be raiſed half a tone above their natural pitch, unleſs a natural intervene. When a Sharp occurs accidentally, it only affects as many notes as follow it on the ſame line or ſpace, without a natural, in the compaſs of a bar.

SHEAVE, in Mechanics, a ſolid cylindrical wheel, fixed in a channel, and moveable about an axis, as being uſed to raiſe or increaſe the mechanical powers applied to remove any body.

SHEERS, aboard a ſhip, an engine uſed to hoiſt or diſplace the lower maſts of a ſhip.

SHEKEL, or SHEKLE, an ancient Hebrew coin and weight, equal to 4 Attic drachmas, or 4 Roman denarii, or 2s. 9½d. ſterling. According to father Merſenne, the Hebrew Shekel weighs 268 grains, and is compoſed of 20 oboli, each obolus weighing 16 grains of wheat.

SHILLING, an Engliſh ſilver coin, equal to 12 pence, or the 20th part of a pound ſterling.

This was a Saxon coin, being the 48th part of their pound weight. Its value at firſt was 5 pence; but it was reduced to 4 pence about a century before the conqueſt. After the conqueſt, the French ſolidus of 12 pence, which was in uſe among the Normans, was called by the Engliſh name of Shilling; and the Saxon Shilling of 4 pence took a Norman name, and was called the *groat*, or *great* coin, becauſe it was the largeſt Engliſh coin then known in England. From this time, the Shilling underwent many alterations.

Many other nations have alſo their Shillings. The Engliſh Shilling is worth about 23 French ſols; thoſe of Holland and Germany about half as much, or 11½ ſols; thoſe of Flanders about 9. The Dutch Shillings are alſo called *ſols de gros*, becauſe equal to 12 groſs. The Danes have copper Shillings, worth about one fourth of a farthing ſterling.

In the time of Edward the 1ſt, the pound troy was the ſame as the pound ſterling of ſilver, conſiſting of 20 Shillings; ſo that the Shilling weighed the 20th part of a pound, or more than half an ounce troy. But ſome are of opinion, there were no coins of this denomination, till Henry the 7th, in the year 1504, firſt coined ſilver pieces of 12 pence value, which we call Shillings. Since the reign of Elizabeth, a Shilling weighs the 62nd part of a pound troy, or 3 dwts. $20\frac{8}{11}$ grs. the pound weight of ſilver making 62 Shillings. And hence the ounce of ſilver is worth 5s. 2d. or $5\frac{1}{62}$ Shillings.

SHIVERS, in a ſhip, the ſeamen's term for thoſe little round wheels, in which the rope of a pully or block runs. They turn with the rope, and have pieces of braſs in their centres, into which the pin of the block goes, and on which they turn.

SHORT-SIGHTEDNESS, *myopia*, a defect in the conformation of the eye, when the cryſtalline &c being too convex, the rays that enter the eye are refracted too much, and made to converge too faſt, ſo as to unite before they reach the retina, by which means viſion is rendered dim and confuſed.

It is commonly thought that Short-ſightedneſs wears off in old age, on account of the eye becoming flatter; but Dr. Smith queſtions whether this be matter of fact, or only hypotheſis. It is remarkable that Short-ſighted perſons commonly write a ſmall hand, and love a ſmall print, becauſe they can ſee more of it at one view. That it is cuſtomary with them not to look at the perſon they converſe with, becauſe they cannot well ſee the motion of his eyes and features, and are therefore attentive to his words only. That they ſee more diſtinctly, and ſomewhat farther off, by a ſtrong light, than by a weak one; becauſe a ſtrong light cauſes a contraction of the pupil, and conſequently of the pencils, both here and at the retina, which leſſens their mixture, and conſequently the apparent confuſion; and therefore, to ſee more diſtinctly, they almoſt cloſe their eye-lids, for which reaſon they were anciently called *myopes*. Smith's Optics, vol. 2, Rem. p. 10.

Dr. Jurin obſerves, that perſons who are much and long accuſtomed to view objects at ſmall diſtances, as ſtudents in general, watchmakers, engravers, painters in miniature, &c, ſee better at ſmall diſtances, and worſe at great diſtances, than other people. And he gives the reaſons, from the mechanical effect of habit in the eye. Eſſay on Diſt. and Indiſt. Viſion.

The ordinary remedy for Short-ſightedneſs is a concave lens, held before the eye; for this cauſing the rays to diverge, or at leaſt diminiſhing much of their convergency, it makes a compenſation for the too great convexity of the cryſtalline. Dr. Hook ſuggeſts another remedy; which is to employ a convex glaſs, in a poſition between the object and the eye, by means of which, the object may be made to appear at any diſtance from the eye, and ſo the eye be made to contemplate the picture in the ſame manner as if the object itſelf were in its place. But here unfortunately the image will appear inverted: for this however he has ſome whimſical expedients; viz, in reading to turn the book upſide down, and to learn to write upſide down. As to diſtant objects, the Doctor aſſerts, from his own experience, that with a little practice in contemplating inverted objects, one gets as good an idea of them as if ſeen in their natural poſture.

SHOT, in the Military Art, includes all ſorts of balls or bullets for fire arms, from the cannon to the piſtol. As to thoſe for mortars, they are uſually called ſhells.

Shot are moſtly of a round form, though there are other ſhapes. Thoſe for cannon are of iron; but thoſe for muſkets and piſtols are of lead.

Cannon ſhot and ſhells are uſually ſet up in piles, or heaps, tapering from the baſe towards the top; the baſe being either a triangle, a ſquare, or a rectangle; from

from which the number in the pile is eaſily computed. See PILE.

The weight and dimenſions of balls may be found, the one from the other, whether they are of iron or of lead. Thus,

The weight of an iron ball of 4 inches diameter, is 9lb, and becauſe the weight is as the cube of the diameter, therefore as $4^3 : 9 :: d^3 : \frac{9}{64} d^3 = w$, the weight of the iron ball whoſe diameter is d; that is, $\frac{9}{64}$ of the cube of its diameter. And, converſely, if the weight be given, to find the diameter, it will be $\sqrt[3]{\frac{64}{9} w} = d$; that is, take $\frac{64}{9}$ or $7\frac{1}{9}$ of the weight, and the cube root of that will be the diameter of the iron ball.

For leaden balls; one of $4\frac{1}{4}$ inches diameter weighs 17 pounds; therefore as the cube of $4\frac{1}{4}$ is to 17, or nearly as 9 : 2 : : $d^3 : \frac{2}{9} d^3 = w$, the weight of the leaden ball whoſe diameter is d, that is, $\frac{2}{9}$ of the cube of the diameter. On the contrary, if the weight be given, to find the diameter, it will be $\sqrt[3]{\frac{9}{2} w} = d$; that is, $\frac{9}{2}$ or $4\frac{1}{2}$ of the weight, and the cube root of the product. See my Conic Sections and Select Exerciſes, pa. 141.

SHOULDER *of a Baſtion*, in Fortification, is the angle where the face and the flank meet.

SHOULDERING, in Fortification. See *Epaulement*.

SHWAN-*pan*, a Chineſe inſtrument, compoſed of a number of wires, with beads upon them, which they move backwards and forwards, and which ſerves to aſſiſt them in their computations. See ABACUS.

SIDE, *latus*, in Geometry. The ſide of a figure is a line making part of the periphery of any ſuperficial figure, viz, a part between two ſucceſſive angles.

In triangles, the ſides are alſo called *legs*. In a right-angled triangle, the two ſides that include the right angle, are called *catheti*, or ſometimes the *baſe* and *perpendicular*; and the third ſide, the *hypothenuſe*.

SIDE *of a Polygonal Number*, is the number of terms in the arithmetical progreſſion that are ſummed up to form the number.

SIDE *of a Power*, is what is uſually called the root or radix.

SIDES of *Horn-works*, *Crown-works*, *Double-tenailles*, &c, are the ramparts and parapets which incloſe them on the right and left, from the gorge to the head.

SIDEREAL, or SIDERIAL, ſomething relating to the ſtars. As Sidereal year, day, &c, being thoſe marked out by the ſtars.

SIDEREAL *Year*. See YEAR.

SIDEREAL *Day*, is the time in which any ſtar appears to revolve from the meridian to the meridian again; which is 23 hours 56′ 4″ 6‴ of mean ſolar time; there being 366 Sidereal days in a year, or in the time of 365 diurnal revolutions of the ſun; that is, exactly, if the equinoctial points were at reſt in the heavens. But the equinoctial points go backward, with reſpect to the ſtars, at the rate of 50″ of a degree in a Julian year; which cauſeth the ſtars to have an apparent progreſſive motion eaſtward 50″ in that time. And as the ſun's mean motion in the ecliptic is only 11 ſigns 29° 45′ 40″ 15‴ in 365 days, it follows, that at the end of that time he will be 14′ 19″ 45‴ ſhort of that point of the ecliptic from which he ſet out at the beginning; and the ſtars will be advanced 50″ of a degree with reſpect to that point.

Conſequently, if the ſun's centre be on the meridian with any ſtar on any given day of the year, that ſtar will be 14′ 19″ 45‴ + 50″ or 15′ 9″ 45‴ eaſt of the ſun's centre, on the 365th day afterward, when the ſun's centre is on the meridian; and therefore that ſtar will not come to the meridian on that day till the ſun's centre has paſſed it by 1′ 0″ 38‴ 57‴‴ of mean ſolar time; for the ſun takes ſo much time to go through an arc of 15′ 9″ 45‴; and then, in 365^{da} 0^h 1′ 0″ 38‴ 57‴‴ the ſtar will have juſt completed its 366th revolution to the meridian.

In the following table, of Sidereal revolutions, the firſt column contains the number of revolutions of the ſtars; the others next it ſhew the times in which theſe revolutions are made, as ſhewn by a well regulated clock; and thoſe on the right hand ſhew the daily accelerations of the ſtars, that is, how much any ſtar gains upon the time ſhewn by ſuch a clock, in the correſponding revolutions.

Revol. of the ſtars.	Times in which the revolutions are made.						Accelerations of the ſtars.

This table will not differ the 2799360000000th part of a ſecond of time from the truth in a whole year. It was calculated by Mr. Ferguſon; and it is the only table of the kind in which the receſſion of the equinoctial points has been taken into the calculation.

SIDUS *Georgium*, a new primary planet, diſcovered by Dr. Herſchel at Bath, in the night of March 13, 1781. It is ſometimes alſo called the *Georgian Planet*, and the *New Planet*, from its having been newly or lately diſcovered, alſo *Herſchel's Planet*, from the name of its diſcoverer, and the *Planet Herſchel*, or ſimply *Herſchel*, by which name it is diſtinguiſhed by the aſtronomers of almoſt all foreign nations. The planet is denoted by this character ♅, a Roman H as the initial of the name, the horizontal bar being croſſed by a perpendicular line, forming a kind of croſs, the emblem of Chriſtianity, meaning thereby perhaps that its diſcovery was made by a Chriſtian, or ſince the birth of Chriſt, as all the other planets were diſcovered long before that period.

This planet is the remoteſt of all thoſe that are yet known, though not the largeſt, being in point of magnitude leſs than Saturn and Jupiter. Its light, ſays Dr. Herſchel, is of a blueiſh-white colour, and its brilliancy between that of Venus and the moon. With a teleſcope that magnifies about 300 times, it appears to have a very well defined viſible diſk; but with inſtruments of a ſmall power, it can hardly be diſtinguiſhed from a fixed ſtar of between the 6th and 7th magnitude. In a very fine clear night, when the moon is abſent, a good eye will perceive it without a teleſcope.

From the obſervations and calculations of Dr. Herſchel and other aſtronomers, the elements and dimenſions &c of this planet, have been collected as below.

Place of the node - - - - -	2ˢ	11°	49′	30″
Place of the aphelion in 1795	11	23	33	55
Inclination of the orbit - -	·	·	43	35

Time of the perihelion paſſage Sep. 7, 1799.

Eccentricity of the orbit - -	·8203
Half the greater axis - - - -	19·0818 of Earth's diſt.
Revolution - - - - - - - - -	83¼ ſidereal years
Diameter of the planet - - -	34217 miles
Propor. of diam. to the earth's	4·3177 to 1

Its quantity of matter - - -	17·7406 to 1

And heavy bodies fall on its ſurface 18 feet 8 inches in one ſecond of time.

SIGN, in Algebra, a ſymbol or CHARACTER.

SIGNS, *like*, *poſitive*, *negative*, *radical*, &c. See the adjectives.

SIGN, in Aſtronomy, a 12th part of the ecliptic, or zodiac; or a portion containing 30 degrees of the ſame.

The ancients divided the zodiac into 12 ſegments, called Signs; commencing at the point where the ecliptic and equinoctial interſect, and ſo counting forward from weſt to eaſt, according to the courſe of the ſun; theſe Signs they named from the 12 conſtellations which poſſeſſed thoſe ſegments in the time of Hipparchus. But the conſtellations have ſince ſo changed their places, by the preceſſion of the equinox, that Aries is now found in the ſign called Taurus, and Taurus in that of Gemini, &c.

The names, and characters, of the 12 Signs, and their order, are as follow: Aries ♈, Taurus ♉, Gemini ♊, Cancer ♋, Leo ♌, Virgo ♍, Libra ♎, Scorpio ♏, Sagittarius ♐, Capricornus ♑, Aquarius ♒, Piſces ♓; each of which, with the ſtars in them, ſee under its proper article, ARIES, TAURUS, &c.

The Signs are diſtinguiſhed, with regard to the ſeaſon of the year when the ſun is in them, into vernal, æſtival, autumnal, and brumal.

Vernal or *Spring* SIGNS, are Aries, Taurus, Gemini.

Aeſtival or *Summer* SIGNS, are Cancer, Leo, Virgo.

Autumnal SIGNS, are Libra, Scorpio, Sagittary.

Brumal or *Winter* SIGNS, are Capricorn, Aquarius, Piſces.

The vernal and ſummer Signs are alſo called *northern* Signs, becauſe they are on the north ſide of the equinoctial; and the autumnal and winter Signs are called *ſouthern* ones, becauſe they are on the ſouth ſide of the ſame.

The Signs are alſo diſtinguiſhed into *aſcending* and *deſcending*, according as they are aſcending toward the north, or deſcending toward the ſouth. Thus, the

Aſcending SIGNS, are the winter and ſpring ſigns, or thoſe fix from the winter ſolſtice to the ſummer ſolſtice, viz, the Signs Capricorn, Aquarius, Piſces, Aries, Taurus, Gemini. And the

Deſcending SIGNS are the ſummer and autumn Signs, or the Signs Cancer, Leo, Virgo, Libra, Scorpio, Sagittary.

SIGNS, *Fixed*, *Maſculine*, &c; ſee the adjectives.

SILLON, in Fortification, an elevation of earth, made in the middle of the moat, to fortify it, when too broad. It is more uſually called the Envelope.

SIMILAR, in Arithmetic and Geometry, the ſame with like. Similar things have the ſame diſpoſition or conformation of parts, and differ in nothing but as to their quantity or magnitude; as two ſquares, or two circles, &c.

In Mathematics, Similar parts, as *A*, *a*, have the ſame ratio to their wholes *B*, *b*; and if the wholes have the ſame ratio to the parts, the parts are Similar.

SIMILAR *angles*, are alſo equal angles.

SIMILAR *arcs*, of circles, are ſuch as are like parts of their whole peripheries. And, in general, ſimilar arcs of any like curves, are the like parts of the wholes.

SIMILAR *bodies*, in Natural Philoſophy, are ſuch as have their particles of the ſame kind and nature one with another.

SIMILAR *Curves*. Two ſegments of two curves are ſaid to be Similar when, any right-lined figure being inſcribed within one of them, we can inſcribe always a Similar rectilineal figure in the other.

SIMILAR *Conic Sections*, are ſuch as are of the ſame kind, and have their principal axes and parameters proportional. So, two ellipſes are figures of the ſame kind, but they are not Similar unleſs the axes of the one have the ſame ratio as the axes of the other. And the ſame of two hyperbolas, or two parabolas. And generally, thoſe curves are Similar, that are of the ſame kind, and have their correſponding dimenſions in the ſame ratio.—All circles are Similar figures.

SIMILAR *Diameters of Conic Sections*, are ſuch as make equal angles with their ordinates.

SIMILAR *Figures*, or plane figures, are ſuch as have all their angles equal reſpectively, each to each, and

their

their ſides about the equal angles proportional. And the ſame of Similar polygons.—Similar plane figures have their areas or contents, in the duplicate ratio of their like ſides, or as the ſquares of thoſe ſides.

Similar *Plane Numbers*, are ſuch as may be ranged into the form of Similar rectangles; that is, into rectangles whoſe ſides are proportional. Such are 12 and 48; for the ſides of 12 are 6 and 2, and the ſides of 48 are 12 and 4, which are in the ſame proportion, viz, 6 : 2 :: 12 : 4.

Similar *Polygons*, are polygons of the ſame number of angles, and the angles in the one equal ſeverally to the angles in the other, alſo the ſides about thoſe angles proportional.

Similar *Rectangles*, are thoſe that have their ſides about the like angles proportional.—All ſquares are Similar.

Similar *Segments of circles*, are ſuch as contain equal angles.

Similar *Solids*, are ſuch as are contained under the ſame number of Similar planes, alike ſituated.—Similar ſolids are to each other as the cubes of their like linear dimenſions.

Similar *Solid Numbers*, are thoſe whoſe little cubes may be ſo ranged, as to form Similar parallelopipedons.

Similar *Triangles*, are ſuch as are equiangular ones, or have all their three angles reſpectively equal in each triangle For it is ſufficient for triangles to be ſimilar, that they be equiangular, becauſe that being equiangular, they neceſſarily have their ſides proportional, which is a condition of Similarity in all figures. As to other figures, having more ſides than three, they may be equiangular, without having their ſides proportional, and therefore without being ſimilar.—Similar triangles are as the ſquares of their like ſides.

SIMILITUDE, in Arithmetic and Geometry, denotes the relation of things that are ſimilar to each other.

Euclid and, after him, moſt other authors, demonſtrate every thing in geometry from the principle of congruity. Wolfius, inſtead of it, ſubſtitutes that of Similitude; which, he ſays, was communicated to him by Leibnitz, and which he finds of very conſiderable uſe in geometry, as ſerving to demonſtrate many things directly, which are only demonſtrable from the principle of congruity in a very tedious manner.

SIMPLE, ſomething not mixed, or not compounded; in which ſenſe it ſtands oppoſed to compound.

The elements are Simple bodies, from the compoſition of which there reſult all ſorts of mixed bodies.

Simple *Equation*, *Fraction*, and *Surd*. See the ſubſtantives.

Simple *Quantities*, in Algebra, are thoſe that conſiſt of one term only; as a, or $-ab$, or $3abc$. In oppoſition to compound quantities, which conſiſt of two or more terms; as $a + b$, or $a + 2b - 3ac$.

Simple *Flank*, and *Tenaille*, in Fortification. See the ſubſtantives.

Simple *Machine*, *Motion*, *Pendulum*, and *Wheel*, in Mechanics. See the ſubſtantives.

The ſimpleſt machines are always the moſt eſteemed. And in geometry, the moſt ſimple demonſtrations are the beſt.

Simple *Problem*, in Mathematics. See Linear *Problem*.

Simple *Viſion*, in Optics. See Vision.

SIMPSON (Thomas), F. R. S. a very eminent mathematician, and profeſſor of Mathematics in the Royal Military Academy at Woolwich, was born at Market Boſworth, in the county of Leiceſter, the 20th of Auguſt 1710. His father was a ſtuff-weaver in that town; and though in tolerable circumſtances, yet, intending to bring up his ſon Thomas to his own buſineſs, he took ſo little care of his education, that he was only taught to read Engliſh. But nature had furniſhed him with talents and a genius for far other purſuits; which led him afterwards to the higheſt rank in the mathematical and philoſophical ſciences.

Young Simpſon very ſoon gave indications of his turn for ſtudy in general, by eagerly reading all books he could meet with, teaching himſelf to write, and embracing every opportunity he could find of deriving knowledge from other perſons. His father obſerving him thus to neglect his buſineſs, by ſpending his time in reading what he thought uſeleſs books, and following other ſuch like purſuits, uſed all his endeavours to check ſuch proceedings, and to induce him to follow his profeſſion with ſteadineſs and better effect. But after many ſtruggles for this purpoſe, the differences thus produced between them at length roſe to ſuch a height, that our author quitted his father's houſe entirely.

Upon this occaſion he repaired to Nuneaton, a town at a ſmall diſtance from Boſworth, where he went to lodge at the houſe of a taylor's widow, of the name of Swinfield, who had been left with two children, a daughter and a ſon, by her huſband, of whom the ſon, who was the younger, being but about two years older than Simpſon, had become his intimate friend and companion. And here he continued ſome time, working at his trade, and improving his knowledge by reading ſuch books as he could procure.

Among ſeveral other circumſtances which, long before this, gave occaſion to ſhew our author's early thirſt for knowledge, as well as proving a freſh incitement to acquire it, was that of a large ſolar eclipſe, which took place on the 11th day of May, 1724. This phenomenon, ſo awful to many who are ignorant of the cauſe of it, ſtruck the mind of young Simpſon with a ſtrong curioſity to diſcover the reaſon of it, and to be able to predict the like ſurpriſing events. It was however ſeveral years before he could obtain his deſire, which at length was gratified by the following accident. After he had been ſome time at Mrs. Swinfield's, at Nuneaton, a travelling pedlar came that way, and took a lodging at the ſame houſe, according to his uſual cuſtom. This man, to his profeſſion of an itinerant merchant, had joined the more profitable one of a fortune-teller, which he performed by means of judicial aſtrology. Every one knows with what regard perſons of ſuch a caſt are treated by the inhabitants of country villages; it cannot be ſurpriſing therefore that an untutored lad of nineteen ſhould look upon this man as a prodigy, and, regarding him in this light, ſhould endeavour to ingratiate himſelf into his favour; in which he ſucceeded ſo well, that the ſage was no leſs taken with the quick natural parts and genius of his new acquaintance. The pedlar, intending a journey to Briſtol fair, left in the hands of young Simpſon an old edition of Cocker's Arithmetic, to which was ſubjoined a ſhort Appendix on Algebra, and a book upon Genitures, by Partridge the almanac maker. Theſe books he had peruſed to ſo good purpoſe, during the abſence of his

friend, as to excite his amazement upon his return; in conſequence of which he ſet himſelf about erecting a genethliacal figure, in order to a preſage of Thomas's future fortune.

This poſition of the heavens having been maturely conſidered *ſecundum artem*, the wizard, with great confidence, pronounced, that, "within two years time Simpſon would turn out a greater man than himſelf!"

In fact, our author profited ſo well by the encouragement and aſſiſtance of the pedlar, afforded him from time to time when he occaſionally came to Nuneaton, that, by the advice of his friend, he at length made an open profeſſion of caſting nativities himſelf; from which, together with teaching an evening ſchool, he derived a pretty pittance, ſo that he greatly neglected his weaving, to which indeed he had never manifeſted any great attachment, and ſoon became the oracle of Nuneaton, Boſworth, and the environs. Scarce a courtſhip advanced to a match, or a bargain to a ſale, without previouſly conſulting the infallible Simpſon about the conſequences. But as to helping people to ſtolen goods, he always declared that above his ſkill; and over life and death he declared he had no power: all thoſe called *lawful queſtions* he readily reſolved, provided the perſons were certain as to the horary *data* of the horoſcope: and, he has often declared, with ſuch ſucceſs, that if from very cogent reaſons he had not been thoroughly convinced of the vain foundation and fallaciouſneſs of his art, he never ſhould have dropt it, as he afterwards found himſelf in conſcience bound to do.

About this time he married the widow Swinfield, in whoſe houſe he lodged, though ſhe was then almoſt old enough to be his grandmother, being upwards of fifty years of age. After this the family lived comfortably enough together for ſome ſhort time, Simpſon occaſionally working at his buſineſs of a weaver in the daytime, and teaching an evening ſchool or telling fortunes at night; the family being alſo farther aſſiſted by the labours of young Swinfield, who had been brought up in the profeſſion of his father.

But this tranquillity was ſoon interrupted, and our author driven at once from his home and the profeſſion of aſtrology, by the following accident. A young woman in the neighbourhood had long wiſhed to hear or know ſomething of her lover, who had been gone to ſea; but Simpſon had put her off from time to time, till the girl grew at laſt ſo importunate, that he could deny her no longer. He aſked her if ſhe would be afraid if he ſhould raiſe the devil, thinking to deter her; but ſhe declared ſhe feared neither ghoſt nor devil: ſo he was obliged to comply. The ſcene of action pitched upon was a barn, and young Swinfield was to act the devil or ghoſt; who being concealed under ſome ſtraw in a corner of the barn, was, at a ſignal given, to riſe ſlowly out from among the ſtraw, with his face marked ſo that the girl might not know him. Every thing being in order, the girl came at the time appointed; when Simpſon, after cautioning her not to be afraid, began muttering ſome myſtical words, and chalking round about them, till, on the ſignal given, up riſes the taylor ſlow and ſolemn, to the great terror of the poor girl, who, before ſhe had ſeen half his ſhoulders, fell into violent fits, crying out it was the very image of her lover; and the effect upon her was ſo dreadful, that it was thought either death or madneſs muſt be the conſequence. So that poor Simpſon was obliged immediately to abandon at once both his home and the profeſſion of a conjuror.

Upon this occaſion it would ſeem he fled to Derby, where he remained ſome two or three years, viz, from 1733 till 1735 or 1736; inſtructing pupils in an evening ſchool, and working at his trade by day.

It would ſeem that Simpſon had an early turn for verſifying, both from the circumſtance of a ſong written here in favour of the Cavendiſh family, on occaſion of the parliamentary election at that place, in the year 1733; and from his firſt two mathematical queſtions that were publiſhed in the Ladies Diary, which were both in a ſet of verſes, not ill written for the occaſion. Theſe were printed in the Diary for 1736, and therefore muſt at lateſt have been written in the year 1735. Theſe two queſtions, being at that time pretty difficult ones, ſhew the great progreſs he had even then made in the mathematics; and from an expreſſion in the firſt of them, viz, where he mentions his reſidence as being in latitude 52°, it appears he was not then come up to London, though he muſt have done ſo very ſoon after.

Together with his aſtrology, he had ſoon furniſhed himſelf with arithmetic, algebra, and geometry ſufficient to be qualified for looking into the Ladies Diary (of which he had afterwards for ſeveral years the direction), by which he came to underſtand that there was a ſtill higher branch of the mathematical knowledge than any he had yet been acquainted with; and this was the method of *Fluxions*. But our young analyſt was quite at a loſs to diſcover any Engliſh author who had written on the ſubject, except Mr. Hayes; and his work being a folio, and then pretty ſcarce, exceeded his ability of purchaſing: however an acquaintance lent him Mr. Stone's *Fluxions*, which is a tranſlation of the *Marquis de l'Hoſpital's Analyſe des Infiniment Petits*: by this one book, and his own penetrating talents, he was, as we ſhall ſee preſently, enabled in a very few years to compoſe a much more accurate treatiſe on this ſubject than any that had before appeared in our language.

After he had quitted aſtrology and its emoluments, he was driven to hardſhips for the ſubſiſtence of his family, while at Derby, notwithſtanding his other induſtrious endeavours in his own trade by day, and teaching pupils at evenings. This determined him to repair to London, which he did in 1735 or 1736.

On his firſt coming to London, Mr. Simpſon wrought for ſome time at his buſineſs in Spitalfields, and taught mathematics at evenings, or any ſpare hours. His induſtry turned to ſo good account, that he returned down into the country, and brought up his wife and three children, ſhe having produced her firſt child to him in his abſence. The number of his ſcholars increaſing, and his abilities becoming in ſome meaſure known to the public, he was encouraged to make propoſals for publiſhing by ſubſcription, A new Treatiſe of Fluxions: wherein the Direct and Inverſe Methods are demonſtrated after a new, clear, and conciſe Manner, with their Application to Phyſics and Aſtronomy: alſo the Doctrine of Infinite Series and Reverting Series univerſally, are amply explained, Fluxionary and Exponential Equations ſolved: together with a variety of new and curious Problems.

When

When Mr. Simpſon firſt propoſed his intentions of publiſhing ſuch a work, he did not know of any Engliſh book, founded on the true principles of Fluxions, that contained any thing material, eſpecially the practical part; and though there had been ſome very curious things done by ſeveral learned and ingenious gentlemen, the principles were nevertheleſs left obſcure and defective, and all that had been done by any of them in *infinite ſeries*, very inconſiderable.

The book was publiſhed in 4to, in the year 1737, although the author had been frequently interrupted from furniſhing the preſs ſo faſt as he could have wiſhed, through his unavoidable attention to his pupils for his immediate ſupport. The principles of fluxions treated of in this work, are demonſtrated in a method accurately true and genuine, not eſſentially different from that of their great inventor, being entirely expounded by finite quantities.

In 1740, Mr. Simpſon publiſhed a Treatiſe on The Nature and Laws of Chance, in 4to. To which are annexed, Full and clear Inveſtigations of two important Problems added in the 2d Edition of Mr. De Moivre's Book on Chances, as alſo two New Methods for the Summation of Series.

Our author's next publication was a 4to volume of Eſſays on ſeveral curious and intereſting Subjects in Speculative and Mixed Mathhmatics; printed in the ſame year 1740: dedicated to Francis Blake, Eſq. ſince Fellow of the Royal Society, and our author's good friend and patron.—Soon after the publication of this book, he was choſen a member of the Royal Academy at Stockholm.

Our author's next work was, The Doctrine of Annuities and Reverſions, deduced from general and evident Principles: with uſeful Tables, ſhewing the Values of Single and Joint Lives, &c. in 8vo, 1742. This was followed in 1743, by an Appendix containing ſome Remarks on a late book on the ſame Subject (by Mr. Abr. De Moivre, F. R. S.) with Anſwers to ſome perſonal and malignant Repreſentations in the Preface thereof. To this anſwer Mr. De Moivre never thought fit to reply. A new edition of this work has lately been publiſhed, augmented with the tract upon the ſame ſubject that was printed in our author's Select Exerciſes.

In 1743 alſo was publiſhed his Mathematical Diſſertations on a variety of Phyſical and Analytical Subjects, in 4to; containing, among other particulars,

A Demonſtration of the true Figure which the Earth, or any Planet, muſt acquire from its rotation about an Axis. A general Inveſtigation of the Attraction at the Surfaces of Bodies nearly ſpherical. A Determination of the Meridional Parts, and the Lengths of the ſeveral Degrees of the Meridian, according to the true Figure of the Earth. An Inveſtigation of the Height of the Tides in the Ocean. A new Theory of Aſtronomical Refractions, with exact Tables deduced from the ſame. A new and very exact Method for approximating the Roots of Equations in Numbers; which quintuples the number of Places at each Operation. Several new Methods for the Summation of Series. Some new and very uſeful Improvements in the Inverſe Method of Fluxions. The work being dedicated to Martin Folkes, Eſq. Preſident of the Royal Society.

His next book was A Treatiſe of Algebra, wherein the fundamental Principles are demonſtrated, and applied to the Solution of a variety of Problems. To which he added, The Conſtruction of a great Number of Geometrical Problems, with the Method of reſolving them numerically.

This work, which was deſigned for the uſe of young beginners, was inſcribed to William Jones, Eſq. F. R. S. and printed in 8vo, 1745. And a new edition appeared in 1755, with additions and improvements; among which was a new and general method of reſolving all Biquadratic Equations, that are complete, or having all their terms. This edition was dedicated to James Earl of Morton, F. R. S. Mr. Jones being then dead. The work has gone through ſeveral other editions ſince that time: the 6th, or laſt, was in 1790.

His next work was, "Elements of Geometry, with their Application to the Menſuration of Superficies and Solids, to the Determination of Maxima and Minima, and to the Conſtruction of a great Variety of geometrical Problems:" firſt publiſhed in 1747, in 8vo. And a ſecond edition of the ſame came out in 1760, with great alterations and additions, being in a manner a new work, deſigned for young beginners, particularly for the gentlemen educated at the Royal Military Academy at Woolwich, and dedicated to Charles Frederick, Eſq. Surveyor General of the Ordnance. And other editions have appeared ſince.

Mr. Simpſon met with ſome trouble and vexation in conſequence of the firſt edition of his Geometry. Firſt, from ſome reflections made upon it, as to the accuracy of certain parts of it, by Dr. Robert Simſon, the learned profeſſor of mathematicks in the univerſity of Glaſgow, in the notes ſubjoined to his edition of Euclid's Elements. This brought an anſwer to thoſe remarks from Mr. Simpſon, in the notes added to the 2d edition as above; to ſome parts of which Dr. Simſon again replied in his notes on the next edition of the ſaid Elements of Euclid.

The ſecond was by an illiberal charge of having ſtolen his Elements from Mr. Muller, the profeſſor of fortification and artillery at the ſame academy at Woolwich, where our author was profeſſor of geometry and mathematics. This charge was made at the end of the preface to Mr. Muller's Elements of Mathematics, in two volumes, printed in 1748; which was fully refuted by Mr. Simpſon in the preface to the 2d edition of his Geometry.

In 1748 came out Mr. Simpſon's Trigonometry, Plane and Spherical, with the Conſtruction and Application of Logarithms, 8vo. This little book contains ſeveral things new and uſeful.

In 1750 came out, in two volumes, 8vo, The Doctrine and Application of Fluxions, containing, beſides what is common on the Subject, a Number of new Improvements in the Theory, and the Solution of a Variety of new and very intereſting Problems in different Branches of the Mathematics.—In the preface the author offers this to the world as a new book, rather than a ſecond edition of that which was publiſhed in 1737, in which he acknowledges, that, beſides errors of the preſs, there are ſeveral obſcurities and defects, for want of experience, and the many diſadvantages he then laboured under, in his firſt eſſay.

The

The idea and explanation here given of the firſt principles of Fluxions, are not eſſentially different from what they are in his former treatiſe, though expreſſed in other terms. The conſideration of *time* introduced into the general definition, will, he ſays, perhaps be diſliked by thoſe who would have fluxions to be *mere velocities*: but the advantage of conſidering them otherwiſe, viz, not as the velocities themſelves, but as magnitudes they would uniformly generate in a given time, appears to obviate any objection on that head. By taking fluxions as mere velocities, the imagination is confined as it were to a point, and without proper care inſenſibly involved in metaphyſical difficulties. But according to this other mode of explaining the matter, leſs caution in the learner is neceſſary, and the higher orders of fluxions are rendered much more eaſy and intelligible. Beſides, though Sir Iſaac Newton defines fluxions to be the velocities of motions, yet he has recourſe to the increments or moments generated in equal particles of time, in order to determine thoſe velocities; which he afterwards teaches to expound by finite magnitudes of other kinds. This work was dedicated to George earl of Macclesfield.

In 1752 appeared, in 8vo, the *Select Exerciſes for young Proficients in the Mathematics*. This neat volume contains, A great Variety of algebraical Problems, with their Solutions. A ſelect Number of Geometrical Problems, with their Solutions, both algebraical and geometrical. The Theory of Gunnery, independent of the Conic Sections. A new and very comprehenſive Method for finding the Roots of Equations in Numbers. A ſhort Account of the firſt Principles of Fluxions. Alſo the Valuation of Annuities for ſingle and joint Lives, with a Set of new Tables, far more extenſive than any extant. This laſt part was deſigned as a ſupplement to his Doctrine of Annuities and Reverſions; but being thought too ſmall to be publiſhed alone, it was inſerted here at the end of the Select Exerciſes; from whence however it has been removed in the laſt editions, and referred to its proper place, the end of the Annuities, as before mentioned. The examples that are given to each problem in this laſt piece, are according to the London bills of mortality; but the ſolutions are general, and may be applied with equal facility and advantage to any other table of obſervations. The volume is dedicated to John Bacon, Eſq. F. R. S.

Mr. Simpſon's Miſcellaneous Tracts, printed in 4to, 1757, were his laſt legacy to the public: a moſt valuable bequeſt, whether we conſider the dignity and importance of the ſubjects, or his ſublime and accurate manner of treating them.

The firſt of theſe papers is concerned in determining the Preceſſion of the Equinox, and the different Motions of the Earth's Axis, ariſing from the Attraction of the Sun and Moon. It was drawn up about the year 1752, in conſequence of another on the ſame ſubject, by M. de Sylvabelle, a French gentleman. Though this gentleman had gone through one part of the ſubject with ſucceſs and perſpicuity, and his concluſions were perfectly conformable to Dr. Bradley's obſervations; it nevertheleſs appeared to Mr. Simpſon, that he had greatly failed in a very material part, and that indeed the only very difficult one; that is, in the determination of the momentary alteration of the poſition of the earth's axis, cauſed by the forces of the ſun and moon; of which forces, the quantities, but not the effects, are truly inveſtigated. The ſecond paper contains the Inveſtigation of a very exact Method or Rule for finding the Place of a Planet in its Orbit, from a Correction of Biſhop Ward's circular Hypotheſis, by Means of certain Equations applied to the Motion about the upper Focus of the Ellipſe. By this Method the Reſult, even in the Orbit of Mercury, may be found within a Second of the Truth, and that without repeating the Operation. The third ſhews the Manner of transferring the Motion of a Comet from a parabolic Orbit, to an elliptic one; being of great Uſe, when the obſerved Places of a (new) Comet are found to differ ſenſibly from thoſe computed on the Hypotheſis of a parabolic Orbit. The fourth is an Attempt to ſhew, from mathematical Principles, the Advantage ariſing from taking the Mean of a Number of Obſervations, in practical Aſtronomy; wherein the Odds that the Reſult in this Way, is more exact than from one ſingle Obſervation, is evinced, and the Utility of the Method in Practice clearly made appear. The fifth contains the Determination of certain Fluents, and the Reſolution of ſome very uſeful Equations, in the higher Orders of Fluxions, by Means of the Meaſures of Angles and Ratios, and the right and verſed Sines of circular Arcs. The 6th treats of the Reſolution of algebraical Equations, by the Method of Surd-diviſors; in which the Grounds of that Method, as laid down by Sir Iſaac Newton, are inveſtigated and explained. The 7th exhibits the Inveſtigation of a general Rule for the Reſolution of Hyperimetrical Problems of all Orders, with ſome Examples of the Uſe and Application of the ſaid Rule. The 8th, or laſt part, comprehends the Reſolution of ſome general and very important Problems in Mechanics and Phyſical Aſtronomy; in which, among other Things, the principal Parts of the 3d and 9th Sections of the firſt Book of Newton's Principia are demonſtrated in a new and conciſe Manner. But what may perhaps beſt recommend this excellent tract, is the application of the general equations, thus derived, to the determination of the Lunar Orbit.

According to what Mr. Simpſon had intimated at the concluſion of his Doctrine of Fluxions, the greateſt part of this arduous undertaking was drawn up in the year 1750. About that time M. Clairaut, a very eminent mathematician of the French Academy, had ſtarted an objection againſt Newton's general law of gravitation. This was a motive to induce Mr. Simpſon (among ſome others) to endeavour to diſcover whether the motion of the moon's apogee, on which that objection had its whole weight and foundation, could not be truly accounted for, without ſuppoſing a change in the received law of gravitation, from the inverſe ratio of the ſquares of the diſtances. The ſucceſs anſwered his hopes, and induced him to look farther into other parts of the theory of the moon's motion, than he had at firſt intended: but before he had completed his deſign, M. Clairaut arrived in England, and made Mr. Simpſon a viſit; from whom he learnt, that he had a little before printed a piece on that ſubject, a copy of which Mr. Simpſon afterwards received as a preſent, and found in it the ſame things demonſtrated, to which he himſelf had directed his enquiry, beſides ſeveral others.

The

The facility of the method Mr. Simpſon fell upon, and the extenſiveneſs of it, will in ſome meaſure appear from this, that it not only determines the motion of the apogee, in the ſame manner, and with the ſame eaſe, as the other equations, but utterly excludes all that dangerous kind of terms that had embarraſſed the greateſt mathematicians, and would, after a great number of revolutions, entirely change the figure of the moon's orbit. From whence this important conſequence is derived, that the moon's mean motion, and the greateſt quantities of the ſeveral equations, will remain unchanged, unleſs diſturbed by the intervention of ſome foreign or accidental cauſe. Theſe tracts are inſcribed to the Earl of Macclesfield, Preſident of the Royal Society.

Beſides the foregoing, which are the whole of the regular books or treatiſes that were publiſhed by Mr. Simpſon, he wrote and compoſed ſeveral other papers and fugitive pieces, as follow:

Several papers of his were read at the meetings of the Royal Society, and printed in their Tranſactions: but as moſt, if not all of them, were afterwards inſerted, with alterations or additions, in his printed volumes, it is needleſs to take any farther notice of them here.

He propoſed, and reſolved many queſtions in the Ladies Diaries, &c; ſometimes under his own name, as in the years 1735 and 1736; and ſometimes under feigned or fictitious names; ſuch as, it is thought, Hurlothrumbo, Kubernetes, Patrick O'Cavenah, Marmaduke Hodgſon, Anthony Shallow, Eſq, and probably ſeveral others; ſee the Diaries for the years 1735, 1736, 42, 43, 53, 54, 55, 56, 57, 58, 59, and 60. Mr. Simpſon was alſo the editor or compiler of the Diaries from the year 1754 till the year 1760, both inclusive, during which time he raiſed that work to the higheſt degree of reſpect. He was ſucceeded in the Editorſhip by Mr. Edw. Rollinſon. See my Diarian Miſcellany, vol. 3.

It has alſo been commonly ſuppoſed that he was the real editor of, or had a principal ſhare in, two other periodical works of a miſcellaneous mathematical nature; viz, the Mathematician, and Turner's Mathematical Exerciſes, two volumes, in 8vo, which came out in periodical numbers, in the years 1750 and 1751, &c. The latter of theſe ſeems eſpecially to have been ſet on foot to afford a proper place for expoſing the errors and abſurdities of Mr. Robert Heath, the then conductor of the Ladies Diary and the Palladium; and which controverſy between them ended in the diſgrace of Mr. Heath, and expulſion from his office of editor to the Ladies Diary, and the ſubſtitution of Mr. Simpſon in his ſtead, in the year 1753.

In the year 1760, when the plans propoſed for erecting a new bridge at Blackfriars were in agitation, Mr. Simpſon, among other gentlemen, was conſulted upon the beſt form for the arches, by the New-bridge Committee. Upon this occaſion he gave a preference to the ſemicircular form; and, beſides his report to the Committee, ſome letters alſo appeared, by himſelf and others, on the ſame ſubject, in the public newſpapers, particularly in the Daily Advertiſer, and in Lloyd's Evening Poſt. The ſame were alſo collected in the Gentleman's Magazine for that year, page 143 and 144.

It is probable that this reference to him, gave occaſion to the turning his thoughts more ſeriouſly to this ſubject, ſo as to form the deſign of compoſing a regular treatiſe upon it: for his family have often informed me, that he laboured hard upon this work for ſome time before his death, and was very anxious to have completed it, frequently remarking to them, that this work, when publiſhed, would procure him more credit than any of his former publications. But he lived not to put the finiſhing hand to it. Whatever he wrote upon this ſubject, probably fell, together with all his other remaining papers, into the hands of major Henry Watſon, of the engineers, in the ſervice of the India Company, being in all a large cheſt full of papers. This gentleman had been a pupil of Mr. Simpſon's, and had lodged in his houſe. After Mr. Simpſon's death, Mr. Watſon prevailed upon the widow to let him have the papers, promiſing either to give her a ſum of money for them, or elſe to print and publiſh them for her benefit. But neither of theſe was ever done; this gentleman always declaring, when urged on this point by myſelf and others, that no uſe could be made of any of the papers, owing to the very imperfect ſtate in which he ſaid they were left. And yet he perſiſted in his refuſal to give them up again.

From Mr. Simpſon's writings, I now return to himſelf. Through the intereſt and ſolicitations of the beforementioned William Jones, Eſq, he was, in 1743, appointed profeſſor of mathematics, then vacant by the death of Mr. Derham, in the Royal Academy at Woolwich; his warrant bearing date Auguſt 25th. And in 1745 he was admitted a fellow of the Royal Society, having been propoſed as a candidate by Martin Folkes, Eſq. Preſident, William Jones, Eſq. Mr. George Graham, and Mr. John Machin, Secretary; all very eminent mathematicians. The preſident and council, in conſideration of his very moderate circumſtances, were pleaſed to excuſe his admiſſion fees, and likewiſe his giving bond for the ſettled future payments.

At the academy he exerted his faculties to the utmoſt, in inſtructing the pupils who were the immediate objects of his duty, as well as others, whom the ſuperior officers of the ordnance permitted to be boarded and lodged in his houſe. In his manner of teaching, he had a peculiar and happy addreſs; a certain dignity and perſpicuity, tempered with ſuch a degree of mildneſs, as engaged both the attention, eſteem and friendſhip of his ſcholars; of which the good of the ſervice, as well as of the community, was a neceſſary conſequence.

It muſt be acknowledged however, that his mildneſs and eaſineſs of temper, united with a more inactive ſtate of mind, in the latter years of his life, rendered his ſervices leſs uſeful; and the ſame very eaſy diſpoſition, with an innocent, unſuſpecting ſimplicity, and playfulneſs of mind, rendered him often the dupe of the little tricks of his pupils. Having diſcovered that he was fond of liſtening to little amuſing ſtories, they took care to furniſh themſelves with a ſtock; ſo that, having neglected to learn their leſſons perfect, they would get round him in a crowd, and, inſtead of demonſtrating a propoſition, would amuſe him with ſome comical ſtory, at which he would laugh and ſhake very heartily, eſpecially if it were tinctured with ſomewhat of the ludicrous.

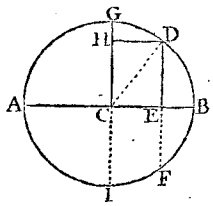
ludicrous or ſmutty; by which device they would contrive imperceptibly to wear out the hours allotted for inſtruction, and ſo avoid the trouble of learning and repeating their leſſon. They tell alſo of various tricks that were practiſed upon him in conſequence of the loſs of his memory in a great degree, in the latter ſtage of his life.

It has been ſaid that Mr. Simpſon frequented low company, with whom he uſed to guzzle porter and gin: but it muſt be obſerved that the miſconduct of his family put it out of his power to keep the company of of gentlemen, as well as to procure better liquor.

In the latter ſtage of his exiſtence, when his life was in danger, exerciſe and a proper regimen were preſcribed him, but to little purpoſe; for he ſunk gradually into ſuch a lowneſs of ſpirits, as often in a manner deprived him of his mental faculties, and at laſt rendered him incapable of performing his duty, or even of reading the letters of his friends; and ſo trifling an accident as the dropping of a tea-cup would flurry him as much as if a houſe had tumbled down.

The phyſicians adviſed his native air for his recovery; and in February, 1761, he ſet out, with much reluctance (believing he ſhould never return) for Boſworth, along with ſome relations. The journey fatigued him to ſuch a degree, that upon his arrival he betook himſelf to his chamber, where he grew continually worſe and worſe, to the day of his death, which happened the 14th of May, in the fifty-firſt year of his age.

SINE, or *Right* SINE, of an arc, in Trigonometry, a right line drawn from one extremity of the arc, perpendicular to the radius drawn to the other extremity of it: Or, it is half the chord of double the arc. Thus the line DE is the ſine of the arc BD; either becauſe it is drawn from one end D of that arc, perpendicular to CB the radius drawn to the other end B of the arc; or alſo becauſe it is half the chord DF of double the arc DBF. For the ſame reaſon alſo DE is the Sine of the arc AD, which is the ſupplement of BD to a ſemicircle or 180 degrees; that is, every Sine is common to two arcs, which are ſupplements to each other, or whoſe ſum make up a ſemicircle, or 180 degrees.



Hence the Sines increaſe always from nothing at B till they become the radius CG, which is the greateſt, being the Sine of the quadrant BG. From hence they decreaſe all the way along the ſecond quadrant from G to A, till they quite vaniſh at the point A, thereby ſhewing that the Sine of the ſemicircle BGA, or 180 degrees, is nothing. After this they are negative all the way along the next ſemicircle, or 3d and 4th quadrants AFB, being drawn on the oppoſite ſide, or downwards from the diameter AB.

Whole SINE, or *Sinus Totus*, is the Sine of the quadrant BG, or of 90 degrees; that is, the Whole Sine is the ſame with the radius CG.

SINE-*Complement*, or *Coſine*, is the ſine of an arc DG, which is the complement of another arc BD, to a quadrant. That is, the line DH is the Coſine of the arc BD; becauſe it is the ſine of DG which is the complement of BD. And for the ſame reaſon DE is the Coſine of DG. Hence the ſine and Coſine and radius, of any arc, form a right-angled triangle CDE or CDH, of which the radius CD is the hypotenuſe; and therefore the ſquare of the radius is equal to the ſum of the ſquares of the ſine and Coſine of any arc, that is, $CD^2 = CE^2 + ED^2$ or $= CH^2 + DH^2$.

It is evident that the Coſine of 0 or nothing, is the whole radius CB. From B, where this Coſine is greateſt, the Coſine decreaſes as the arc increaſes from B along the quadrant BDG, till it become 0 for the complete quadrant BG. After this, the Coſines, decreaſing, become negative more and more all the way to the complete ſemicircle at A. Then the Coſines increaſe again all the way from A through I to B; at I the negation is deſtroyed, and the Coſine is equal to 0 or nothing; from I to B it is poſitive, and at B it is again become equal to the radius. So that, in general, the Coſines in the 1ſt and 4th quadrants are poſitive, but in the 2d and 3d negative.

Verſed-SINE, is the part of the diameter between the ſine and the arc. So BE is the Verſed Sine of the arc BD, and AE the Verſed Sine of AD, alſo GH the Verſed Sine of DG, &c. All Verſed Sines are affirmative. The ſum of the Verſed Sine and coſine, of any arc or angle, is equal to the radius, that is, BE + EC = AC.—The ſine, coſine, and Verſed Sine, of an arc, are alſo the ſame of an angle, or the number of degrees &c, which it meaſures.

The Sines &c, of every degree and minute in a quadrant, are calculated to the radius 1, and ranged in tables for uſe. But becauſe operations with theſe natural Sines require much labour in multiplying and dividing by them, the logarithms of them are taken, and ranged in tables alſo; and theſe logarithmic Sines are commonly uſed in practice, inſtead of the natural ones, as they require only additions and ſubtractions, inſtead of the multiplications and diviſions. For the method of conſtructing the ſcales of Sines &c, ſee the article SCALE.

The Sines were introduced into trigonometry by the Arabians. And for the etymology of the word *Sine* ſee Introduction to my Logarithms, pa. 17 &c. And the various ways of calculating tables of the Sines, may be ſeen in the ſame place, pa. 13 &c.

Theorems for the Sines, Coſines, &c, one from another. From the definitions of them, and the common property of right-angled triangles, with that of the circle, viz, that $DE^2 = CD^2 - CE^2 = AE \times EB$, are eaſily deduced theſe following values of the Sines, &c, viz, putting

s = the ſine DE,
c = the coſine CE,
v = verſed ſine BE,
v = ſuppl. verſed ſine AE,
r = radius AC or CB,
a = arc BD; then

$$s = \sqrt{r^2 - c^2} = \sqrt{vv} = \sqrt{2rv - vv} = \sqrt{2r\mathrm{v} - \mathrm{vv}}$$

$$c = \sqrt{r^2 - s^2} = r - v = \mathrm{v} - r = \tfrac{1}{2}\mathrm{v} - \tfrac{1}{2}v.$$

$$v = r - c = 2r - \mathrm{v} = r - \sqrt{r^2 - s^2} = \mathrm{v} - 2c.$$

$$\mathrm{v} = r + c = 2r - v = r + \sqrt{r^2 - s^2} = v + 2c.$$

The

The tangent $= \frac{rs}{\sqrt{r^2 - s^2}}$. And Cotang. $= \frac{r\sqrt{r^2 - s^2}}{s}$.

The Secant $= \frac{rr}{\sqrt{r^2 - s^2}}$. And Cofec. $= \frac{rr}{s}$.

$$s = a - \frac{a^3}{2.3r^2} + \frac{a^5}{2.3.4.5r^4} - \frac{a^7}{2.3.4.5.6.7r^6} \text{ &c.}$$

$$a = s + \frac{s^3}{2.3r^2} + \frac{1.3s^5}{2.4.5r^4} + \frac{1.3.5s^7}{2.4.6.7r^6} \text{ &c.}$$

$$\text{Log. } s = \log. a - M\left(\frac{a^2}{6} + \frac{a^4}{180} + \frac{a^6}{2835} + \frac{a^8}{37800} \text{ &c}\right)$$

$$\text{or Log. } s = -\tfrac{1}{2}M\left(c^2 + \tfrac{1}{3}c^4 + \tfrac{1}{5}c^6 + \tfrac{1}{7}c^8 \text{ &c}\right)$$

$$\text{or Log. } s = -2M\left(z + \tfrac{1}{3}z^3 + \tfrac{1}{5}z^5 + \tfrac{1}{7}z^7 \text{ &c.}\right)$$

when $z = \frac{1-s}{1+s}$, radius 1, and M = ·43429448 &c.

If A be any other arc, S its fine, and C its cofine. Then

$$\text{Sin. } \overline{A+a} = \frac{Sc + sC}{r}. \quad \text{Cof. } \overline{A+a} = \frac{Cc - Ss}{r}.$$

$$\text{Sin. } \overline{A-a} = \frac{Sc - sC}{r}. \quad \text{Cof. } \overline{A-a} = \frac{Cc + Ss}{r}.$$

$$\text{Sin. A} \times \text{cof. } a = \tfrac{1}{2}\text{fin. } \overline{A-a} + \tfrac{1}{2}\text{fin. } \overline{A+a}.$$

$$\text{Sin. A} \times \text{fin. } a = \tfrac{1}{2}\text{cof. } \overline{A-a} - \tfrac{1}{2}\text{cof. } \overline{A+a}.$$

$$\text{Cof. A} \times \text{cof. } a = \text{cof. } \frac{A-a}{2} + \text{cof. } \frac{A+a}{2}.$$

If $h = 2{\cdot}718281828$ &c, the number whofe hyp. log. is 1; then

$$\text{Sin. } a = s = \frac{h^{a\sqrt{-1}} - h^{-a\sqrt{-1}}}{2\sqrt{-1}}.$$

$$\text{Cof. } a = c = \frac{h^{a\sqrt{-1}} + h^{-a\sqrt{-1}}}{2}.$$

See many other curious expreffions of this kind in Bougainville's Calcul Integral, and in Bertrand's Mathematics.

From fome of the foregoing theorems the Sines of a great variety of angles, or number of degrees, may be computed. Ex. gr. as below.

Angles.	*Sines.*
90°	r
75	$\frac{1}{2}r\sqrt{2+\sqrt{3}} = r \times \frac{\sqrt{6}+\sqrt{2}}{4}$
72	$\frac{1}{2}r\sqrt{\frac{5+\sqrt{5}}{2}}$
67½	$\frac{1}{2}r\sqrt{2+\sqrt{2}}$
60	$\frac{1}{2}r\sqrt{3}$
54	$\frac{1}{2}r\sqrt{\frac{3+\sqrt{5}}{2}} = r \times \frac{\sqrt{5}+1}{4}$
45	$\frac{1}{2}r\sqrt{2}$
36	$\frac{1}{2}r\sqrt{\frac{5-\sqrt{5}}{2}}$
30	$\frac{1}{2}r$
22½	$\frac{1}{2}r\sqrt{2-\sqrt{2}}$
18	$\frac{1}{2}r\sqrt{\frac{3-\sqrt{5}}{2}} = r \times \frac{\sqrt{5}-1}{4}$
15	$\frac{1}{2}r\sqrt{2-\sqrt{3}} = r \times \frac{\sqrt{6}-\sqrt{2}}{4}$

Radius being 1. Then for multiple arcs:

the Sin. $\overline{n+1}.a = 2c \times \text{fin. } na - \text{fin. } \overline{n-1}.a$,

and Cof. $\overline{n+1}.a = 2c \times \text{cof. } na - \text{cof. } \overline{n-1}.a$;

That is, multiplying any Sine or cofine by $2c$, and the next preceding Sine or cofine fubtracted from it, it gives the next following Sine or cofine. Hence

fin. $0a = 0$.	cof. $0a = 1$ or radius.
fin. $a = s$.	cof. $a = c$.
fin. $2a = 2sc$.	cof. $2a = c^2 - s^2$.
fin. $3a = 3sc^2 - s^3$.	cof. $3a = c^3 - 3cs^2$.
fin. $4a = 4sc^3 - 4s^3c$.	cof. $4a = c^4 - 6c^2s^2 + s^4$.
fin. $5a = 5sc^4 - 10s^3c^2 + s^5$.	cof. $5a = c^5 - 10c^3s^2 + 5cs^4$.
&c.	&c.

And, in general,

$$\text{Sin. } na = nsc^{n-1} - \frac{n.n-1.n-2}{1.2.3}s^3c^{n-3} + \frac{n.n-1.n-2.n-3.n-4}{1.2.3.4.5}s^5c^{n-5} \text{ &c.}$$

$$\text{or Sin. } na = ns - \frac{n.n^2-1^2}{2.3}s^3 + \frac{n.n^2-1^2.n^2-3^2}{2.3.4.5}s^5 \text{ &c.}$$

$$\text{Cof. } na = c^n - \frac{n.n-1}{2}s^2c^{n-2} + \frac{n.n-1.n-2.n-3}{2.3.4}s^4c^{n-4} \text{ &c.}$$

$$\text{or Cof. } na = 1 - \frac{n^2}{2}s^2 + \frac{n.n^2-2^2}{2.3.4}s^4 - \frac{n^2.n^2-2^2.n^2-4^2}{2.3.4.5.6}s^6 \text{ &c.}$$

$$\text{Sin. } \tfrac{1}{2}a = r\sqrt{\frac{r-c}{2r}}. \quad \text{And cof. } \tfrac{1}{2}a = r\sqrt{\frac{r+c}{2r}}. \quad \text{Radius being } r.$$

Of the Tables of Sines, &c.

In eſtimating the quantity of the Sines &c, we aſſume radius for unity; and then compute the quantity of the Sines, tangents, and ſecants, in fractions of it. From Ptolomy's Almageſt we learn, that the ancients divided the radius into 60 parts, which they called degrees, and thence determined the chords in minutes,

nutes, ſeconds, and thirds; that is, in ſexageſimal fractions of the radius, which they likewiſe uſed in the reſolution of triangles. As to the Sines, tangents and ſecants, they are modern inventions; the Sines being introduced by the Moors or Saracens, and the tangents and ſecants afterwards by the Europeans. See Introd. to my Logs. pa. 1 to 19.

Regiomontanus, at firſt, with the ancients, divided the radius into 60 degrees; and determined the Sines of the ſeveral degrees in decimal fractions of it. But he afterwards found it would be more convenient to aſſume 1 for radius, or 1 with any number of cyphers, and take the Sines in decimal parts of it; and thus he introduced the preſent method in trigonometry. In this way, different authors have divided the radius into more or fewer decimal parts; but in the common tables of Sines and tangents, the radius is conceived as divided into 10000000 parts; by which all the Sines are eſtimated.

An idea of ſome of the modes of conſtructing the tables of Sines, may be conceived from what here follows: Firſt, by common geometry the ſides of ſome of the regular polygons inſcribed in the circle are computed, from the given radius, which will be the chords of certain portions of the circumference, denoted by the number of the ſides; viz, the ſide of the triangle the chord of the 3d part, or 120 degrees; the ſide of the pentagon the chord of the 5th part, or 72 degrees; the ſide of the hexagon the chord of the 6th part, or 60 degrees; the ſide of the octagon the chord of the 8th part, or 45 degrees; and ſo on. By this means there are obtained the chords of ſeveral of ſuch arcs; and the halves of theſe chords will be the Sines of the halves of the ſame arcs. Then the theorem $c = \sqrt{1 - s^2}$ will give the coſines of the ſame half arcs. Next, by biſecting theſe arcs continually, there will be found the Sines and coſines of a continued ſeries as far as we pleaſe by theſe two theorems,

$$\text{Sin. } \tfrac{1}{2}a = \sqrt{\frac{1-c}{2}}; \text{ and cof. } \tfrac{1}{2}a = \sqrt{\frac{1+c}{2}}.$$

Then, by the theorems for the ſums and differences of arcs, from the foregoing ſeries, will be derived the Sines and coſines of various other arcs, till we arrive at length at the arc of 1′, or 1″, &c, whoſe Sine and coſine thus become known.

Or, rather, the ſine of 1 minute will be much more eaſily found from the ſeries

$$s = a - \frac{a^3}{6} + \frac{a^5}{120} \text{ &c,}$$

becauſe the arc is equal to its Sine in ſmall arcs; whence $s = a$ only in ſuch ſmall arcs. But the length of the arc of 180° or 10800′ is known to be 3·14159265, &c; therefore, by proportion, as 10800′ : 1′ :: 3·14159265 : 0·0002908882 = a the arc or s the ſine of 1′, which number is true to the laſt place of decimals. Then, for the coſine of 1′, it is $c = \sqrt{1 - s^2}$ = 0·9999999577 the coſine of the ſame 1′.

Hence we ſhall readily obtain the Sines and coſines of all the multiples of 1′, as of 2′, 3′ 4′ 5′, &c, by the application of theſe two theorems,

$$\text{Sin. } \overline{n+1}.\, a = 2c \times \text{ſin. } na - \text{ſin. } \overline{n-1}.\, a,$$
$$\text{Cof. } \overline{n+1}.\, a = 2c \times \text{cof. } na - \text{cof. } \overline{n-1}.\, a;$$

for ſuppoſing a = the arc of 1, then c = 0·9999999577, and taking n ſucceſſively equal to 1, 2, 3, 4, &c, the theorems for the Sines and coſines give ſeverally the Sines and coſines of 1′, 2′, 3′, 4′, &c; viz, the Sines thus:

ſin. 1′ = s - - - - - - - - - - = ·0002908882
ſin. 2′ = 2c × ſin. 1′ — ſin. 0′ = ·0005817764
ſin. 3′ = 2c × ſin. 2′ — ſin. 1′ = ·0008726645
ſin. 4′ = 2c × ſin. 3′ — ſin. 2′ = ·0011635526
ſin. 5′ = 2c × ſin. 4′ — ſin. 3′ = ·0014544406
&c.

And the Coſines thus,

cof. 1′ = c - - - - - - - - - - = ·9999999577
cof. 2′ = 2c × cof. 1′ — cof. 0′ = ·9999998308
cof. 3′ = 2c × cof. 2′ — cof. 1′ = ·9999996192
cof. 4′ = 2c × cof. 3′ — cof. 2′ = ·9999993231
cof. 5′ = 2c × cof. 4′ — cof. 3′ = ·9999989423
&c.

In this manner then all the Sines and coſines are made, by only one conſtant multiplication and a ſubtraction, up to 30 degrees, forming thus the Sines of the firſt and laſt 30 degrees of the quadrant, or from 0 to 30° and from 60° to 90°; or, which will be much the ſame thing, the Sines only may be thus computed all the way up to 60°.

Then the Sines of the remaining 30°, from 60 to 90, will be found by one addition only for each of them, by means of this theorem, viz,

$$\text{Sin. } \overline{60+a} = \text{ſin. } \overline{60-a} + \text{ſin. } a;$$

that is, to the ſine of any arc below 60°, add the Sine of its defect below 60, and the ſum will be the Sine of another arc which is juſt as much above 60.

The Sines of all arcs being thus found, they give alſo very eaſily the verſed ſines, the tangents, and the ſecants. The verſed ſines are only the arithmetical complements to 1, that is, each coſine taken from the radius 1.

The tangents are found by theſe three theorems:

1. As coſine to ſine, ſo is radius to tangent.

2. Radius is a mean proportional between the tangent and cotangent.

3. Half the difference between the tangent and cotangent, is equal to the tangent of the difference between the arc and its complement. Or, the ſum ariſing from the addition of double the tangent of an arc with the tangent of half its complement, is equal to the tangent of the ſum of that arc and the ſaid half complement.

By the 1ſt and 2d of theſe theorems, the tangents are to be found for one half of the quadrant: then the other half of them will be found by one ſingle addition, or ſubtraction, for each, by the 3d theorem.

This done, the ſecants will be all found by addition or ſubtraction only, by theſe two theorems: 1ſt. The ſecant of an arc, is equal to the ſum of its tangent and the tangent of half its complement. 2nd. The ſecant

of

of an arc, is equal to the difference between the tangent of that arc and the tangent of the arc added to half its complement.

Artificial SINES, are the logarithmic Sines, or the logarithms of the Sines.

Curve or *Figure of the* SINES. See FIGURE *of the Sines, &c.* To what is there ſaid of the figure of the Sines, may be here added as follows, from a property juſt given above, viz, if x denote the abſciſs of this curve, or the correſponding circular arc, and y its ordinate, or the Sine of that arc; then the equation of the curve will be this,

$$y = \text{ſin. } x = \frac{h^{x\sqrt{-1}} - h^{-x\sqrt{-1}}}{2\sqrt{-1}};$$

where $h = 2{\cdot}718281828$, &c, the number whoſe hyp. log. is 1.

Line of SINES, is a line on the ſector, or Gunter's ſcale, &c, divided according to the Sines, or expreſſing the Sines. See thoſe articles.

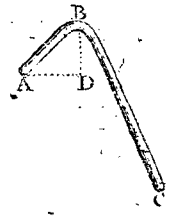
SINE *of Incidence*, or *of Reflection*, or *of Refraction*, is uſed for the Sine of the *angle* of incidence, &c.

SINICAL *Quadrant*, is a quadrant, made of wood or metal, with lines drawn from each ſide interſecting one another, with an index, divided by ſines, alſo with 90 degrees on the limb, and two ſights at the edge. Its uſe is to take the altitude of the ſun. Inſtead of the ſines, it is ſometimes divided all into equal parts; and then it is uſed by ſeamen to reſolve, by inſpection, any problem of plane ſailing.

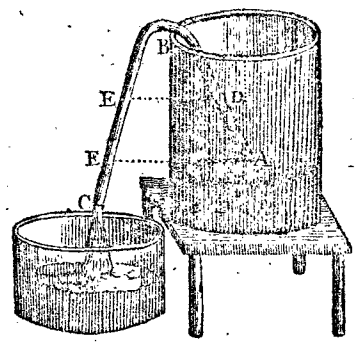
SIPHON, or SYPHON, in Hydraulics, a crooked pipe or tube uſed in the raiſing of fluids, emptying of veſſels, and in various hydroſtatical experiments. It is otherwiſe called a crane.

Wolfius deſcribes two veſſels under the name of Siphons; the one cylindrical in the middle and conical at the two extremes; the other globular in the middle, with two narrow tubes fitted to it axis-wiſe; both ſerving to take up a quantity of liquid, and to retain it when up.

But the moſt uſual Syphon is that which is here repreſented; where ABC is any crooked tube, having two legs of unequal lengths; but ſuch however that, in any poſition, the perpendicular altitude BD, of B above A, when AB is filled with any fluid, the weight of that fluid may not be more than about 15lb. upon every ſquare inch of the baſe, or equal to the preſſure of the atmoſphere, becauſe the preſſure of the atmoſphere will raiſe or ſuſpend the fluid ſo high, when the tube is exhauſted of air. This height is about 30 inches when the fluid is quickſilver, and about 34 feet when it is water; and ſo on for other fluids, according to the rarity of them.



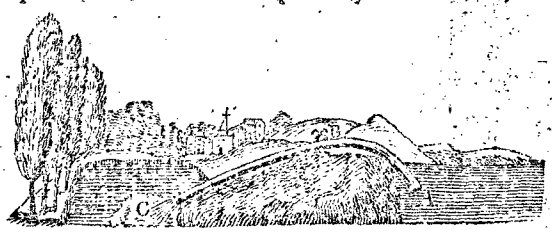
To uſe the Siphon, in drawing off any fluid; immerſe the ſhorter end A into the fluid, then ſuck or draw the air out by the other or lower end C, and the fluid will preſently follow, and run out by the Siphon, from the veſſel at A to the veſſel at C; till ſuch time as the ſurface of the fluid ſink as low as the orifice at A,



when the decanting will ceaſe, and the Siphon will empty itſelf of the fluid, the whole of that which is in it running out at C. The principle upon which the Siphon acts, is this: when the tube is exhauſted of air, the preſſure of the atmoſphere upon the ſurface of the fluid at D, forces it into the tube by the orifice at A, as in the barometer tube, and down the leg BC, if B is not above the ſurface at D more than 34 feet for water, or 30 inches for quickſilver, &c. Here, if the external leg of the Siphon terminate at E, on a horizontal level with the immerſed end at A, or rather on a level with the water at D, the perpendicular preſſures of the fluid in each leg, and of the external air, againſt each orifice, being alike in both, the fluid will be at reſt in the Siphon, completely filling it, but without running or preponderating either way. But if the external end be the lower, terminating at C, then the fluid in this end being the heavier, or having more preſſure, will preponderate and run out by the orifice at C; this would leave a vacuum at B but for the continual preſſure of the atmoſphere at D, which forces the fluid up by A to B, and ſo producing a continued motion of it through the tube, and a diſcharge or ſtream at C.

Inſtead of ſucking out the air at C, another method is, firſt to fill the tube completely with the fluid, in an inverted poſition with the angle B downward; and, ſtopping the two orifices with the fingers, revert the tube again, and immerge the end A in the fluid; then take off the fingers, and immediately the ſtream commences from the end C.

Either of the two foregoing methods can be conveniently practiſed when the Siphon is ſmall, and eaſily managed by the hand; as in decanting off liquors from caſks, &c. But when the Siphon is very large, and many feet in height, as in exhauſting water from a valley or pit, the following method is then recommended: Stop the orifice C, and, by means of an opening made in the top at B, fill the tube completely with water; then ſtop the opening at B with a plug, and open that at C; upon which the water will preſently flow out at C, and



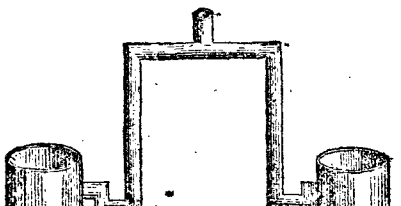
ſo continue till that at A is exhauſted. And this method of conveying water over a hill, from one valley to another, is deſcribed by Hero, the chief author of any conſequence upon this ſubject among the Ancients. But in this experiment it muſt be noted, that the effect will not be produced when the hill at B is more than 33 or 34 feet above the ſurface of the water at A.

In an experiment of this kind, it is even ſaid the water in the legs, unleſs it be purged of its air, will not reſt at a height of quite 30 feet above the water in the veſſels; becauſe air will extricate itſelf out of the water, and getting above the water in the legs, preſs it downward, ſo that its height will be leſs to balance the preſſure of the atmoſphere. But with very fine, or capillary tubes, the experiment will ſucceed to a height ſomewhat greater; becauſe the attraction of the matter of the very fine tube will attract the fluid, and ſupport it at ſome certain height, independent of the preſſure of the atmoſphere. For which reaſon alſo it is, that the experiment ſucceeds for ſmall heights in the exhauſted receiver; as has been tried both with water and mercury, by Deſaguliers and many other philoſophers. Exper. Philoſ. vol. 2, pa. 168.

The figure of the veſſel may be varied at pleaſure, provided the orifice C be but below the level of the ſurface of the water to be drawn up, but ſtill the farther it is below it, the quicker will the fluid run off. And if, in the courſe of the efflux, the orifice A be drawn out of the fluid; all the liquor in the Siphon will iſſue out at the lower orifice C; that in the leg BC dragging, as it were, that in the ſhorter leg AB after it.

But if a filled Siphon be ſo diſpoſed, as that both orifices, A and C, be in the ſame horizontal line; the fluid will remain pendant in each leg, how unequal ſoever the length of the legs may be. So that fluids in Siphons ſeem, as it were, to form one continued body; the heavier part deſcending like a chain, and drawing the lighter after it.

The *Wirtemberg* SIPHON, is a very extraordinary



machine, performing ſeveral things which the common Siphon will not reach. This Siphon was projected by Jordan Pelletier, and executed at the expence of prince Frederic Charles, adminiſtrator of Wirtemberg, by his mathematician Shabackard, who made each branch 20 feet long, and ſet them 18 feet apart; and the deſcription of it was publiſhed by Reiſelius, the duke's phyſician. This gave occaſion to Papin to invent another, which performed the ſame things, and is deſcribed in the Philoſ. Tranſ. vol. 14, & Abr. vol. 1. Reiſelius, in another paper in the ſame volume, ingenuouſly owns that this is the ſame with the Wirtemberg Siphon.

In this engine, though the legs be on the ſame level, yet the water riſes up the one, and deſcends through the other: The water riſes even through the aperture if the leſs leg be only half immerged in water. The Siphon has its effect after continuing dry a long time: Either of the apertures being opened, the other remaining ſhut for a whole day, and then opened, the water flows out as uſual: Laſtly, the water riſes and falls indifferently through either leg.

Muſſchenbroek, in accounting for the operation of this Siphon, obſerves that no diſcharge could be made by it, unleſs the water applied to either leg cauſe the one to be ſhorter, and the other longer by its own weight. Introd. ad Phil. Nat. tom. 2, pa. 853, ed. 4to. 1762.

SIRIUS, the *Dog-ſtar*, a very bright ſtar of the firſt magnitude, in the mouth of the conſtellation *Canis Major*, or the Great Dog.

This is the brighteſt of all the ſtars in our firmanent, and therefore probably, ſays Dr. Maſkelyne, the aſtronomer royal, the neareſt to us of them all, in a paper recommending the diſcovery of its parallax, Philoſ. Tranſ. vol. 2, pa. 889. Some however ſuppoſe Arcturus to be the neareſt.

The Arabs call it *Aſchere*, *Elſchecre*, *Scera*; the Greeks, *Sirius*; and the Latins, *Canicula*, or *Canis candens*. See CANICULA.

This is one of the earlieſt named ſtars in the whole heavens. Heſiod and Homer mention only four or five conſtellations, or ſtars, and this is one of them. Sirius and Orion, the Hyades, Pleiades, and Arcturus are almoſt the whole of the old poetical aſtronomy. The three laſt the Greeks formed of their own obſervation, as appears by the names; the two others were Egyptian. Sirius was ſo called from the Nile, one of the names of that river being Siris; and the Egyptians, ſeeing that river begin to ſwell at the time of a particular riſing of this ſtar, paid divine honours to the ſtar, and called it by a name derived from that of the river, expreſſing the ſtar of the Nile.

SITUS, in Algebra and Geometry, denotes the ſituation of lines, ſurfaces, &c. Wolfius delivers ſome things in geometry, which are not deduced from the common analyſis, particularly matters depending on the *Situs* of lines and figures. Leibnitz has even founded a particular kind of analyſis upon it, called *Calculus Situs*.

SKY, the blue expanſe of the air or atmoſphere.

The azure colour of the ſky is attributed, by Newton, to vapours beginning to condenſe, having attained conſiſtence enough to reflect the moſt reflexible rays, viz, the violet ones; but not enough to reflect any of the leſs reflexible ones.

De la Hire attributes it to our viewing a black object, viz the dark ſpace beyond the regions of the atmoſphere, through a white or lucid one, viz the air illuminated by the ſun; a mixture of black and white always appearing blue. But this hypotheſis is not originally his; being as old as Leonardo da Vinci.

SLIDING, in Mechanics, is when the ſame point of a body, moving along a ſurface, deſcribes a line on

that

that ſurface. Such is the motion of a parallelopipedon moved along a plane.

From Sliding ariſes friction.

SLIDING *Rule*, a mathematical inſtrument ſerving to perform computations in gauging, meaſuring, &c, without the uſe of compaſſes; merely by the ſliding of the parts of the inſtrument one by another, the lines and diviſions of which give the anſwer or amount by inſpection.

This inſtrument is variouſly contrived and applied by different authors, particularly Gunter, Partridge, Hunt, Everard, and Coggeſhall; but the moſt uſual and uſeful ones are thoſe of the two latter.

Everard's SLIDING *Rule* is chiefly uſed in caſk gauging. It is commonly made of box, 12 inches long, 1 inch broad, and $\frac{6}{10}$ of an inch thick. It conſiſts of three parts; viz, the ſtock juſt mentioned, and two thin ſlips, of the ſame length, ſliding in ſmall grooves in two oppoſite ſides of the ſtock: conſequently, when both theſe pieces are drawn out to their full extent, the inſtrument is 3 feet long.

On the firſt broad face of the inſtrument are four logarithmic lines of numbers; for the properties &c, of which, ſee GUNTER'S *Line*. The firſt, marked A, conſiſting of two radii numbered 1, 2, 3, 4, 5, 6, 7, 8, 9, 1; and then 2, 3, 4, 5, &c, to 10. On this line are four braſs centre-pins, two in each radius; one in each of them being marked MB, for malt-buſhel, is ſet at 2150·42 the number of cubic inches in a malt-buſhel; the other two are marked with A, for ale-gallon, at 282, the number of cubic inches in an ale gallon. The 2d and 3d lines of numbers are on the ſliding pieces, and are exactly the ſame with the firſt; but they are diſtinguiſhed by the letter B. In the firſt radius is a dot, marked *Si*, at ·707, the ſide of a ſquare inſcribed in a circle whoſe diameter is 1. Another dot, marked *Se*. ſtands at ·886, the ſide of a ſquare equal to the area of the ſame circle. A third dot, marked W, is at 231, the cubic inches in a wine gallon. And a fourth, marked C, at 3·14, the circumference of the ſame circle whoſe diameter is 1. The fourth line of numbers, marked MD, to ſignify malt-depth, is a broken line of two radii, numbered 2, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1, 9, 8, 7, &c; the number 1 being ſet directly againſt MB on the firſt radius.

On the ſecond broad face, marked *cd*, are ſeveral lines: as 1ſt, a line marked D, and numbered 1, 2, 3, &c, to 10. On this line are four centre pins: the firſt, marked WG, for wine-gauge, is at 17·15, the gauge-point for wine gallons, being the diameter of a cylinder whoſe height is one inch, and content 231 cubic inches, or a wine gallon: the ſecond centre-pin, marked AG, for ale-gauge, is at 18·95, the like diameter for an ale gallon: the 3d, marked MS, for malt ſquare, is at 46·3, the ſquare root of 2150·42, or the ſide of a ſquare whoſe content is equal to the number of inches in a ſolid buſhel: and the fourth, marked MR, for malt-round, is at 52·32, the diameter of a cylinder, or buſhel, the area of whoſe baſe is the ſame 2150·42, the inches in a buſhel. 2dly, Two lines of numbers on the ſliding piece, on the other ſide, marked C. On theſe are two dots; the one, marked *c*, at ·0795, the area of a circle whoſe circumference is 1; and the other, marked *d*, at ·785, the area of the circle whoſe diameter is 1. 3dly, Two lines of ſegments, each numbered 1, 2, 3, to 100; the firſt for finding the ullage of a caſk, taken as the middle fruſtum of a ſpheroid, lying with its axis parallel to the horizon; and the other for finding the ullage of a caſk ſtanding.

Again, on one of the narrow ſides, noted *c*, are, 1ſt, a line of inches, numbered 1, 2, 3, &c to 12, each ſubdivided into 10 equal parts. 2dly, A line by which, with that of inches, we find a mean diameter for a caſk, in the figure of the middle fruſtum of a ſpheroid: it is marked *Spheroid*, and numbered 1, 2, 3, &c to 7. 3dly, A line for finding the mean diameter of a caſk, in the form of the middle fruſtum of a parabolic ſpindle, which gaugers call the ſecond variety of caſks; it is therefore marked *Second Variety*, and is numbered 1, 2, 3, &c.

4thly, A line by which is found the mean diameter of a caſk of the third variety, conſiſting of the fruſtums of two parabolic conoids, abutting on a common baſe; it is therefore marked *Third Variety*, and is numbered 1, 2, 3, &c.

On the other narrow face, marked *f*, are 1ſt, a line of a foot divided into 100 equal parts, marked FM. 2dly, A line of inches, like that before mentioned, marked IM. 3dly, A line for finding the mean diameter of the fourth variety of caſks, which is formed of the fruſtums of two cones, abutting on a common baſe. It is numbered 1, 2, 3, &c; and marked FC, for fruſtum of a cone.

On the backſide of the two ſliding pieces is a line of inches, from 12 to 36, for the whole extent of the 3 feet, when the pieces are put endwiſe; and againſt that, the correſpondent gallons, and 100th parts, that any ſmall tub, or the like open veſſel, will contain at 1 inch deep.

For the various uſes of this inſtrument, ſee the authors mentioned above, and moſt other writers on Gauging.

Coggeſhall's SLIDING *Rule* is chiefly uſed in meaſuring the ſuperficies and ſolidity of timber, maſonry, brick-work, &c.

This conſiſts of two rulers, each a foot long, which are united together in various ways. Sometimes they are made to ſlide by one another, like glaziers' rules: ſometimes a groove is made in the ſide of a common two-foot joint rule, and a thin ſliding piece in one ſide, and Coggeſhall's lines added on that ſide; thus forming the common or Carpenter's rule: and ſometimes one of the two rulers is made to ſlide in a groove made in the ſide of the other.

On the Sliding ſide of the rule are four lines of numbers, three of which are double, that is, are lines to two radii, and the fourth is a ſingle broken line of numbers. The firſt three, marked A, B, C, are figured 1, 2, 3, &c to 9; then 1, 2, 3, &c to 10; the conſtruction and uſe of them being the ſame as thoſe on Everard's Sliding rule. The ſingle line, called the *girt line*, and marked D, whoſe radius is equal to the two radii of any of the other lines, is broken for the eaſier meaſuring of timber, and figured 4, 5, 6, 7, 8, 9, 10, 20, 30, &c. From 4 to 5 it is divided into 10 parts, and each 10th ſubdivided into 2; and ſo on from 5 to 10, &c.

On the backſide of the rule are, 1ſt, a line of inch meaſure, from 1 to 12; each inch being divided and ſubdivided. 2dly, A line of foot meaſure, conſiſting of

of one foot divided into 100 equal parts, and figured 10, 20, 30, &c.

The backside of the sliding piece is divided into inches, halves, &c, and figured from 12 to 24; so that when the side is out, there may be a measure of 2 feet.

In the Carpenter's rule, the inch measure is on one side, continued all the way from 1 to 24, when the rule is unfolded, and subdivided into 8ths or half-quarters: on this side are also some diagonal scales of equal parts. And upon the edge, the whole length of 2 feet is divided into 200 equal parts, or 100ths of a foot.

SLING, a string instrument, serving for the casting of stones &c with the greater violence.

Pliny, lib. 76, chap. 5, attributes the invention of the Sling to the Phœnicians; but Vegetius ascribes it to the inhabitants of the Balearic islands, who were celebrated in antiquity for the dextrous management of it. Florus and Strabo say, those people bore three kinds of Slings; some longer, others shorter, which they used according as their enemies were more remote or nearer hand. Diodorus adds, that the first served them for a head-band, the 2d for a girdle, and that the third they constantly carried with them in the hand. But it must be impossible to tell who were the first inventors of the Sling, as the instrument is so simple, and has been in general use by almost all nations. The instrument is much spoken of in the wars and history of the Israelites. David was so expert a slinger, that he ventured to go out, with one in his hand, against the giant and champion Goliath, and at a distance struck him on the forehead with the stone. And there were a number of left-handed men of one of the tribes of Israel, who it is said could Sling a stone at an hair's breadth.

The motion of a stone discharged from a Sling arises from its centrifugal force, when whirled round in a circle. The velocity with which it is discharged, is the same as that which it had in the circle, and is much greater than what can be given to it by the hand alone. And the direction in which it is discharged, is that of the tangent to the circle at the point of discharge. Whence its motion and effect may be computed as a projectile.

SLUSE, or Slusius (*René Francis Walter*) of Vise, a small town in the county of Liege, where he enjoyed honours and preferment. He then became abbé of Amas, canon, councellor and chancellor of Liege, and made his name famous for his knowledge in theology, physics, and mathematics. The Royal Society of London elected him one of their members, and inserted several of his compositions in their Transactions. This very ingenious and learned man died at Liege in 1683, at 63 years of age.

Of Slusius's works there have been published, some learned letters, and a work intitled, *Mesolabium et Problemata solida*; beside the following pieces in the Philosophical Transactions, viz,

1. Short and Easy Method of drawing Tangents to all Geometrical Curves; vol. 7, pa. 5143.

2. Demonstration of the same; vol. 8, pa. 6059, 6119.

3. On the Optic Angle of Alhazen; vol. 8, pa. 6139.

SMEATON (John), F. R. S. and a very celebrated civil engineer, was born the 28th of May 1724, at Austhorpe, near Leeds, in a house built by his grandfather, where the family have resided ever since, and where our author died the 28th of October 1792, in the 68th year of his age.

Mr. Smeaton seems to have been born an engineer. The originality of his genius and the strength of his understanding appeared at a very early age. His playthings were not those of children, but the tools men work with; and he had always more amusement in observing artificers work, and asking them questions, than in any thing else. Having watched some mill-wrights at work, he was one day, soon after, seen (to the distress of his family) on the top of his father's barn, fixing up something like a windmill. Another time, attending some men who were fixing a pump at a neighbouring village, and observing them cut off a piece of bored pipe, he contrived to procure it, of which he made a working pump that actually raised water. These anecdotes refer to circumstances that happened when he was hardly out of petticoats, and probably before he had reached the 6th year of his age. About his 14th or 15th year, he had made for himself an engine to turn rose-work; and he made several presents to his friends of boxes in ivory and wood, turned by him in that way.

His friend and partner in the Deptford Waterworks, Mr. John Holmes, an eminent clock and watch maker in the Strand, says, he visited Mr. Smeaton and spent a month with him at his father's house, in the year 1742, when consequently our author was about 18 years of age. Mr. Holmes could not but view young Smeaton's works with astonishment: he forged his own iron and steel, and melted his own metals; he had tools of every sort, for working in wood, ivory, and metals: he had made a lathe, by which he had cut a perpetual screw in brass, a thing very little known at that day.

Thus had Mr. Smeaton, by the strength of his genius, and indefatigable industry, acquired, at 18 years of age, an extensive set of tools, and the art of working in most of the mechanical trades, without the assistance of any master, and which he continued to do a part of every day when at the place where his tools were: and few men could work better.

Mr. Smeaton's father was an attorney, and was desirous of bringing him up to the same profession. He therefore came up to London in 1742, and for some time attended the courts in Westminster Hall. But finding that the profession of the law did not suit *the bent of his genius*, as his usual expression was, he wrote a strong memorial to his father on the subject, whose good sense from that moment left Mr. Smeaton to pursue the bent of his genius in his own way.

Mr. Smeaton after this continued to reside in London, and about 1750 he commenced philosophical instrument maker, which he continued for some time, and became acquainted with most of the ingenious men of that time; and this same year he made his first communication to the Royal Society, being an account of Dr. Knight's improvements of the mariner's compass. Continuing his very useful labours, and making experiments, he communicated to that learned body, the two following years, a number of other ingenious improve-

ments, as will be enumerated in the list of his writings, at the end of this account of him.

In 1751 he began a courſe of experiments, to try a machine of his invention, for meaſuring a ſhip's way at ſea; and alſo made two voyages in company with Dr. Knight to try it, as well as a compaſs of his own invention.

In 1753 he was elected a member of the Royal Society; and in 1759 he was honoured with their gold medal, for his paper concerning the natural powers of water and wind to turn mills, and other machines depending on a circular motion. This paper, he ſays, was the reſult of experiments made on working models in the years 1752 and 1753, but not communicated to the Society till 1759, having in the interval found opportunities of putting the reſult of theſe experiments into real practice, in a variety of caſes, and for various purpoſes, ſo as to aſſure the Society he had found them to anſwer.

In 1754 his great thirſt after experimental knowledge led him to undertake a voyage to Holland and the Low Countries, where he made himſelf acquainted with moſt of the curious works of art ſo frequent in thoſe places.

In December 1755, the Edyſtone lighthouſe was burnt down, and the proprietors, being deſirous of rebuilding it in the moſt ſubſtantial manner, enquired of the earl of Macclesfield, then preſident of the Royal Society, who he thought might be the fitteſt perſon to rebuild it, when he immediately recommended our author. Mr. Smeaton accordingly undertook the work, which he completed with ſtone in the ſummer of 1759. Of this work he gives an ample deſcription in a folio volume, with plates, publiſhed in 1791. A work which contains, in a great meaſure, the hiſtory of four years of his life, in which the originality of his genius is fully diſplayed, as well as his activity, induſtry, and perſeverance.

Though Mr. Smeaton completed the building of the Edyſtone lighthouſe in 1759, yet it ſeems he did not ſoon get into full buſineſs as a civil engineer; for in 1764, while in Yorkſhire, he offered himſelf a candidate for one of the receivers of the Derwentwater eſtate; in which he ſucceeded, though two other perſons, ſtrongly recommended and powerfully ſupported, were candidates for the employment. In this appointment he was very happy, by the aſſiſtance and abilities of his partner Mr. Walton the younger, of Farnacres near Newcaſtle, one of the preſent receivers, who, taking upon himſelf the management and the accounts, left Mr. Smeaton leiſure and opportunity to exert his abilities on public works, as well as to make many improvements in the mills, and in the eſtates of Greenwich hoſpital.

By the year 1775, he had ſo much buſineſs, as a civil engineer, that he was deſirous of reſigning the appointment for that hoſpital, and would have done it then, had not his friends prevailed upon him to continue in the office about two years longer.

Mr. Smeaton having thus got into full buſineſs as a civil engineer, it would be an endleſs taſk to enumerate all the variety of concerns he was engaged in. A very few of them however may be juſt mentioned in this place. —He made the river Calder navigable: a work that required great ſkill and judgment; owing to the very impetuous floods in that river.—He planned and attended the execution of the great canal in Scotland, for conveying the trade of the country, either to the Atlantic or German ocean; and having brought it to a concluſion, he declined a handſome yearly ſalary, that he might not be prevented from attending to the multiplicity of his other buſineſs.

On opening the great arch at London bridge, the excavation around and under the ſterlings was ſo conſiderable, that it was thought the bridge was in great danger of falling; the apprehenſions of the people on this head being ſo great, that few would paſs over or under it. He was then in Yorkſhire, where he was ſent for by expreſs, and he arrived in town with the greateſt expedition. He applied himſelf immediately to examine it, and to ſound about the ſterlings as minutely as he could. The committee being called together, adopted his advice, which was, to repurchaſe the ſtones that had been taken from the middle pier, then lying in Moorfields, and to throw them into the river to guard the ſterlings, a practice he had before adopted on other occaſions. Nothing ſhews the apprehenſions of the bridge falling, more than the alacrity with which his advice was purſued: the ſtones were repurchaſed that day; horſes, carts, and barges were got ready, and the work inſtantly begun though it was Sunday morning. Thus Mr. Smeaton, in all human probability, ſaved London bridge from falling, and ſecured it till more effectual methods could be taken.

In 1771, he became, jointly with his friend Mr. Holmes above mentioned, proprietor of the works for ſupplying Deptford and Greenwich with water; which by their united endeavours they brought to be of general uſe to thoſe they were made for, and moderately beneficial to themſelves.

About the year 1785, Mr. Smeaton's health began to decline; in conſequence he then took the reſolution to endeavour to avoid any new undertakings in buſineſs as much as he could, that he might thereby alſo have the more leiſure to publiſh ſome account of his inventions and works. Of this plan however he got no more executed than the account of the Edyſtone lighthouſe, and ſome preparations for his intended treatiſe on mills; for he could not reſiſt the ſolicitations of his friends in various works; and Mr. Aubert, whom he greatly loved and reſpected, being choſen chairman of Ramſgate harbour, prevailed upon him to accept the office of engineer to that harbour; and to their joint efforts the public are chiefly indebted for the improvements that have been made there within theſe few years; which fully appears in a report that Mr. Smeaton gave in to the board of truſtees in 1791, which they immediately publiſhed.

It had for many years been the practice of Mr. Smeaton to ſpend part of the year in town, and the remainder in the country, at his houſe at Auſthorpe; on one of theſe excurſions in the country, while walking in his garden, on the 16th of September 1792, he was ſtruck with the palſy, which put an end to his uſeful life the 28th of October following, to the great regret of a numerous ſet of friends and acquaintances.

The great variety of mills conſtructed by Mr. Smeaton, ſo much to the ſatisfaction and advantage of the owners, will ſhew the great uſe he made of his experiments

ments in 1752 and 1753. Indeed he ſcarcely truſted to theory in any caſe where he could have an opportunity to inveſtigate it by experiment; and for this purpoſe he built a ſteam-engine at Auſthorpe, that he might make experiments expreſsly to aſcertain the power of Newcomen's ſteam-engine, which he improved and brought to a much greater degree of certainty, both in its conſtruction and powers, than it was before.

During many years of his life, Mr Smeaton was a conſtant attendant on parliament, his opinion being continually called for. And here his natural ſtrength of judgment and perſpicuity of expreſſion had their full diſplay. It was his conſtant practice, when applied to, to plan or ſupport any meaſure, to make himſelf fully acquainted with it, and be convinced of its merits, before he would be concerned in it. By this caution, joined to the clearneſs of his deſcription, and the integrity of his heart, he ſeldom failed having the bill he ſupported carried into an act of parliament. No perſon was heard with more attention, nor had any one ever more confidence placed in his teſtimony. In the courts of law he had ſeveral compliments paid to him from the bench, by the late lord Mansfield and others, on account of the new light he threw upon difficult ſubjects.

As a civil engineer, he was perhaps unrivalled, certainly not excelled by any one, either of the preſent or former times. His building the Edyſtone light-houſe, were there no other monument of his fame, would eſtabliſh his character. The Edyſtone rocks have obtained their name from the great variety of contrary *ſets* of the tide or current in their vicinity. They are ſituated nearly S. S. W. from the middle of Plymouth Sound. Their diſtance from the port of Plymouth is about 14 miles. They are almoſt in the line which joins the Start and the Lizard points; and as they lie nearly in the direction of veſſels coaſting up and down the channel, they were unavoidably, before the eſtabliſhment of a light-houſe there, very dangerous, and often fatal to ſhips. Their ſituation with regard to the Bay of Biſcay and the Atlantic is ſuch, that they lie open to the ſwells of the bay and ocean, from all the ſouth-weſtern points of the compaſs; ſo that all the heavy ſeas from the ſouth-weſt quarter come uncontroled upon the Edyſtone rocks, and break upon them with the utmoſt fury. Sometimes, when the ſea is to all appearance ſmooth and even, and its ſurface unruffled by the ſlighteſt breeze, the *ground ſwell* meeting the ſlope of the rocks, the ſea beats upon them in a frightful manner, ſo as not only to obſtruct any work being done on the rock, or even landing upon it, when, figuratively ſpeaking, you might go to ſea in a walnut-ſhell. That circumſtances fraught with danger ſurrounding it ſhould lead mariners to wiſh for a light-houſe, is not wonderful; but the danger attending the erection leads us to wonder that any one could be found hardy enough to undertake it. Such a man was firſt found in the perſon of Mr. H. Winſtanley, who, in the year 1696, was furniſhed by the Trinity-houſe with the neceſſary powers. In 1700 it was finiſhed; but in the great ſtorm of November 1703, it was deſtroyed, and the projector periſhed in the ruins. In 1709 another, upon a different conſtruction, was erected by a Mr. Rudyerd, which, in 1755, was unfortunately conſumed by fire. The next building was under the direction of Mr. Smeaton, who, having conſidered the errors of the former conſtructions, has judiciouſly guarded againſt them, and erected a building, the demolition of which ſeems little to be dreaded, unleſs the rock on which it is erected ſhould periſh with it.—Of his works, in conſtructing bridges, harbours, mills, engines, &c. &c. it were endleſs to ſpeak. Of his inventions and improvements of philoſophical inſtruments, as of the air-pump, the pyrometer, hygrometer, &c, &c, ſome idea may be formed from the liſt of his writings inſerted below.

In his perſon, Mr. Smeaton was of a middle ſtature, but broad and ſtrong made, and poſſeſſed of an excellent conſtitution. He had a great ſimplicity and plainneſs in his manners: he had a warmth of expreſſion that might appear, to thoſe who did not know him well, to border on harſhneſs; but ſuch as were more cloſely acquainted with him, knew it aroſe from the intenſe application of his mind, which was always in the purſuit of truth, or engaged in the inveſtigation of difficult ſubjects. He would ſometimes break out haſtily, when any thing was ſaid that was contrary to his ideas of the ſubject; and he would not give up any thing he argued for, till his mind was convinced by ſound reaſoning.

In all the ſocial duties of life, Mr. Smeaton was exemplary; he was a moſt affectionate huſband, a good father, a warm, zealous and ſincere friend, always ready to aſſiſt thoſe he reſpected, and often before it was pointed out to him in what way he could ſerve them. He was a lover and an encourager of merit wherever he found it; and many perſons now living are in a great meaſure indebted for their preſent ſituation to his aſſiſtance and advice. As a companion, he was always entertaining and inſtructive, and none could ſpend their time in his company without improvement.

As to the liſt of his writings; beſide the large work abovementioned, being the Hiſtory of Edyſtone Light-houſe, and numbers of reports and memorials, many of which were printed, his communications to the Royal Society, and inſerted in their Tranſactions, are as follow:

1. An Account of Dr. Knight's Improvements of the Mariner's Compaſs; an. 1750, pa. 513.

2. Some improvements in the Air-pump; an. 1752, pa. 413.

3. An Engine for raiſing Water by Fire; being an improvement on Savary's conſtruction, to render it capable of working itſelf: invented by M. de Moura, of Portugal. Ib. pa. 436.

4. Deſcription of a new Tackle, or Combination of Pulleys. Ib. 494.

5. Experiments upon a machine for meaſuring the Way of a Ship at Sea. An. 1754, pa. 532.

6. Deſcription of a new Pyrometer. Ib. pa. 598.

7. Effects of Lightning on the Steeple and Church of Leſtwithial in Cornwall. An. 1757, pa. 198.

8. Remarks on the different Temperature of the Air at Edyſtone Light-houſe, and at Plymouth. An. 1758, pa. 488.

9. Experimental enquiry concerning the natural powers of Water and Wind to turn mills and other machines depending on a circular motion. An. 1759, pa. 100.

10. On the Menſtrual Parallax ariſing from the mutual gravitation of the earth and moon, its influence on the obſervation of the ſun and planets, with a method of obſerving it. An. 1768, pa. 156.

11. Deſcription of a new method of Obſerving the heavenly bodies out of the meridian. An. 1768, pa. 170.

12. Obſervations of a Solar Eclipſe. An. 1769, pa. 286.

13. Deſcription of a new Hygrometer. An. 1771, pa. 198.

14. An Experimental Examination of the quantity and proportion of Mechanical Power, neceſſary to be employed in giving different degrees of velocity to heavy bodies from a ſtate of reſt. An. 1776, pa. 450.

SMOKE, or *Smoak*, a humid matter exhaled in form of vapour by the action of heat, either external or internal; or Smoke conſiſts of palpable particles, elevated by means of the rarefying heat, or by the force of the aſcending current of air, from certain bodies expoſed to heat; which particles vary much in their properties, according to the ſubſtances from which they are produced.

Sir Iſaac Newton obſerves, that Smoke aſcends in the chimney by the impulſe of the air it floats in: for that air, being rarefied by the heat of the fire underneath, has its ſpecific gravity diminiſhed; and thus, being diſpoſed to aſcend itſelf, it carries up the Smoke along with it. The tail of a comet, the ſame author ſuppoſes, aſcends from the nucleus after the ſame manner.

Smoke of fat unctuous woods, as fir, beech, &c, makes what is called lamp-black.

There are various inventions for preventing and curing ſmoky chimneys: as the æolipiles of Vitruvius, the ventiducts of Cardan, the windmills of Bernard, the capitals of Serlio, the little drums of Paduanus, and ſeveral artifices of De Lorme. See alſo the philoſophical works of Dr. Franklin. Pans, reſembling ſugar pans, placed over the tops of chimneys, are uſeful to make them draw better; and the fire-grates called regiſter-ſtoves, are always a ſure remedy.

In the Philoſophical Tranſactions is the deſcription of an engine, invented by M. Daleſme, which conſumes the Smoke of all ſorts of wood ſo effectually, that the eye cannot diſcover it in the room, nor the noſe diſtinguiſh the ſmell of it, though the fire be made in the middle of the room It conſiſts of ſeveral iron hoops, 4 or 5 inches in diameter, which ſhut into one another, and is placed on a trevet.

The late invention called Argand's lamp, alſo conſumes the Smoke, and gives a very ſtrong light. Its principle is a thin broad cotton wick, rolled into the form of a hollow cylinder; the air paſſes up the hollow of it, and the Smoke is almoſt all conſumed.

SMOKE *Jack*, is a jack for turning a ſpit, turned by the Smoke of the kitchen fire, by means of thin iron ſails ſet obliquely on an axis in the flue of the chimney. See JACK.

SNELL (RODOLPH), a reſpectable Dutch philoſopher, was born at Oudenwater in 1546. He was ſome time profeſſor of Hebrew and mathematics at Leyden, where he died in 1613, at 67 years of age. He was author of ſeveral works on geometry, and on all parts of the philoſophy of his time; but I have not obtained a particular liſt of them.

SNELL *(Willebrord)*, ſon of Rodolph above mentioned, an excellent mathematician, was born at Leyden in 1591, where he ſucceeded his father in the mathematical chair in 1613, and where he died in 1626, at only 35 years of age.

Willebrord Snell was author of ſeveral ingenious works and diſcoveries. Thus, it was he who firſt diſcovered the true law of the refraction of the rays of light; a diſcovery which he made before it was announced by Des Cartes, as Huygens aſſures us. Though the work which Snell prepared upon this ſubject, and upon optics in general, was never publiſhed, yet the diſcovery was very well known to belong to him, by ſeveral authors about his time, who had ſeen it in his manuſcripts.——He undertook alſo to meaſure the earth. This he effected by meaſuring a ſpace between Alcmaer and Bergen-op-zoom, the difference of latitude between theſe places being 1° 11′ 30″. He alſo meaſured another diſtance between the parallels of Alcmaer and Leyden; and from the mean of both theſe meaſurements, he made a degree to conſiſt of 55021 French toiſes or fathoms. Theſe meaſures were afterwards repeated and corrected by Muſſchenbroek, who found the degree to contain 57033 toiſes.—He was author of a great many learned mathematical works, the principal of which are,

1. *Apollonius Batavus*; being the reſtoration of ſome loſt pieces of Apollonius, concerning Determinate Section, with the Section of a Ratio and Space: in 4to, 1608, publiſhed in his 17th year.

2. *Eratoſthenes Batavus*; in 4to, 1617. Being the work in which he gives an account of his operations in meaſuring the earth.

3. A tranſlation out of the Dutch language, into Latin, of Ludolph van Collen's book *De Circulo & Adſcriptis*, &c; in 4to, 1619.

4. *Cyclometricus, De Circuli Dimenſione* &c; 4to, 1621. In this work, the author gives ſeveral ingenious approximations to the meaſure of the circle, both arithmetical and geometrical.

5. *Typhis Batavus*; being a treatiſe on Navigation and Naval Affairs; in 4to, 1624.

6. A poſthumous treatiſe, being four books *Doctrinæ Triangulorum Canonicæ*; in 8vo, 1627. In which are contained the canon of ſecants; and in which the conſtruction of lines, tangents, and ſecants, with the dimenſion or calculation of triangles, both plane and ſpherical, are briefly and clearly treated.

7. Heſſian and Bohemian Obſervations; with his own notes.

8. *Libra Aſtronomica & Philoſophica*; in which he undertakes the examination of the principles of Galileo concerning comets.

9. Concerning the Comet which appeared in 1618, &c.

SNOW, a well known meteor, formed by the freezing of the vapours in the atmoſphere. It differs from hail and hoar-froſt in being as it were cryſtallized, which they are not. This appears on examination of a flake of Snow by a magnifying glaſs; when the whole of it appears to be compoſed of fine ſhining ſpicula diverging like rays from a centre. As the flakes deſcend

through the atmosphere, they are continually joined by more of these radiated spicula, and thus increase in bulk like the drops of rain or hailstones; so that it seems as if the whole body of Snow were an infinite mass of icicles irregularly figured.

The lightness of Snow, although it is firm ice, is owing to the excess of its surface, in comparison to the matter contained under it; as even gold itself may be extended in surface, till it will float upon the least breath of air.

According to Beccaria, clouds of Snow differ in nothing from clouds of rain, but in the circumstance of cold that freezes them. Both the regular diffusion of the Snow, and the regularity of the structure of its parts, shew that clouds of Snow are acted upon by some uniform cause like electricity; and he endeavours to shew how electricity is capable of forming these figures. He was confirmed in his conjectures by observing, that his apparatus for shewing the electricity of the atmosphere, never failed to be electrified by Snow as well as by rain. Professor Wintrop sometimes found his apparatus electrified by Snow when driven about by the wind, though it had not been affected by it when the Snow itself was falling. A more intense electricity, according to Beccaria, unites the particles of hail more closely than the more moderate electricity does those of Snow, in the same manner as we see that the drops of rain which fall from the thunder-clouds, are larger than those which fall from others, though the former descend through a less space.

In the northern countries, the ground is covered with snow for several months; which proves exceedingly favourable for vegetation, by preserving the plants from those intense frosts which are common in such countries, and which would certainly destroy them. Bartholin ascribes great virtues to Snow-water, but experience does not seem to warrant his assertions. Snow-water, or ice-water, is always deprived of its fixed air: and those nations who live among the Alps, and use it for their constant drink, are subject to affections of the throat, which it is thought are occasioned by it.

From some late experiments on the quantity of water yielded by Snow, it appears that the latter gives only about one-tenth of its bulk in water.

SOCIETY, an assemblage or union of several learned persons, for their mutual assistance, improvement, or information, and for the promotion of philosophical or other knowledge. There are various philosophical Societies instituted in different parts of the world. See ROYAL *Society*.

American Philosophical SOCIETY, was established at Philadelphia in the year 1769, for promoting useful knowledge, under the direction of a patron, a president, three vice-presidents, a treasurer, four secretaries, and three curators. The first volume of their Transactions comprehends a period of two years, viz, from Jan. 1, 1769, to Jan. 1, 1771. Their labours seem to have been interrupted during the troubles in America, which commenced soon after; but since their termination, some more volumes have been published, containing a number of very ingenious and useful memoirs.

American Academy of Arts and Sciences, was established by a law of the Commonwealth of Massachusetts in North America, in the year 1780.

Boston Academy of Arts and Sciences. This is a Society similar to the former, which has lately been established at Boston in New England, under the title of the Academy of Arts and Sciences &c.

Berlin SOCIETY. The Society of Natural Historians at Berlin, was founded by Dr. [illegible]. There is also a Philosophical Society in the same place.

Brussels SOCIETY. The [illegible] Royal Academy of Sciences and Belles [illegible] Brussels was founded in 1773. Several volumes [illegible] Transactions have now been published.

Dublin SOCIETY. This is an Experimental Society for promoting natural knowledge, which was instituted in 1777: the members meet once a week, and distribute three honorary gold medals annually for the most approved discovery, invention, or essay on any mathematical or philosophical subject. The Society is under the direction of a president, two vice-presidents, and a secretary.

Edinburgh Philosophical SOCIETY, succeeded the Medical Society, and was formed upon the plan of including all the different branches of natural knowledge and the antiquities of Scotland. The meetings of this Society, interrupted in 1745, were revived in 1752; and in 1754 the first volume of their collection was published, under the title of Essays or Observations Physical and Literary, which has been succeeded by other volumes. This Society has been lately incorporated by royal charter, under the name of the Royal Society of Scotland, instituted for the advancement of learning and useful knowledge. The members are divided into two classes, physical and literary; and those who are near enough to *Edinburgh* to attend the meetings, pay a guinea on admission, and the same sum annually. The first meeting was held on the first Monday of August 1783; when there were chosen, a president, two vice-presidents, a secretary, treasurer, and a council of 12 persons. Three of the volumes of their Transactions have been published, which are very respectable both for their magnitude and contents.

In *France* there have been several institutions of this kind for the improvement of science, besides those recounted under the word ACADEMY: As, the Royal Academy at Soissons, founded in 1674; at Villefranche, Beaujolois, in 1679; at Nismes, in 1682; at Angers, in 1685; the Royal Society at Montpelier, in 1706, which is so intimately connected with the Royal Academy of Sciences of Paris, as to form with it, in some respects, one body; the literary productions of this Society are published in the memoirs of the academy: the Royal Academy of Sciences and Belles Lettres at Lyons, in 1700; at Bourdeaux, in 1703; at Marseilles, in 1726; at Rochelle, in 1734; at Dijon, in 1740; at Pau in Bern, in 1721; at Beziers, in 1723; at Montauban, in 1744; at Rouen, in 1744; at Amiens, in 1750; at Toulouse, in 1750; at Besançon, in 1752; at Metz, in 1760; at Arras, in 1773; and at Chalons sur Maine, in 1775. For other institutions of a similar nature, and their literary productions, see the articles ACADEMY, JOURNAL, and TRANSACTIONS.

Manchester Literary and Philosophical SOCIETY, is of considerable reputation, and has been lately established there, under the direction of two presidents, four vice-presidents, and two secretaries. The number of

of members is limited to 50; beſides theſe there are ſeveral honorary members all of whom are elected by ballot; and the officers are choſen annually in April. Several valuable eſſays have been already read at the meetings of this Society.

Newcaſtle-upon-Tyne Literary and Philoſophical Society. This Society was inſtituted the 7th of February 1793, under the direction of a preſident, four vice-preſidents, two ſecretaries, a treaſurer, which together with four of the ordinary members form a committee, annually elected at a general meeting. The objects propoſed for the conſideration and improvement of this Society, comprehend the mathematics, natural philoſophy and hiſtory, chemiſtry, polite literature, antiquities, civil hiſtory, biography, queſtions of general law and policy, commerce, and the arts. From ſuch ample ſcope in the objects of the Society, with the known reſpectability, zeal, and talents of the members, the greateſt improvements and diſcoveries may be expected to be made in thoſe important branches of uſeful knowledge.

SOCRATES, the chief of the ancient philoſophers, was born at Alopece, a ſmall village of Attica, in the 4th year of the 77th olympiad, or about 467 years before Chriſt. Sophroniſcus, his father, being a ſtatuary or carver of images in ſtone, our author followed the ſame profeſſion for ſome time, for a ſubſiſtence. But being naturally averſe to this profeſſion, he only followed it when neceſſity compelled him; and upon getting a little before-hand, would for a while lay it aſide. Theſe intermiſſions of his trade were beſtowed upon philoſophy, to which he was naturally addicted; and this being obſerved by Crito, a rich philoſopher of Athens, Socrates was at length taken from his ſhop, and put into a condition of philoſophiſing at his eaſe and leiſure.

He had various inſtructors in the ſciences, as Anaxagoras, Archylaus, Damon, Prodicus, to whom may be added the two learned women Diotyma and Aſpaſia, of the laſt of whom he learned rhetoric: of Eunus he learned poetry; of Ichomachus, huſbandry; and of Theodorus, geometry.

At length he began himſelf to teach; and was ſo eloquent, that he could lead the mind to approve or diſapprove whatever he pleaſed; but never uſed this talent for any other purpoſe than to conduct his fellow citizens into the path of virtue. The academy of the Lycæum, and a pleaſant meadow without the city on the ſide of the river Ilyſſus, were places where he chiefly delivered his inſtructions, though it ſeems he was never out of his way in that reſpect; as he made uſe of all times and places for that purpoſe.

He is repreſented by Xenophon as excellent in all kinds of learning, and particularly inſtances arithmetic, geometry, and aſtrology or aſtronomy: Plato mentions natural philoſophy; Idomeneus, rhetoric; Laertius, medicine. Cicero affirms, that by the teſtimony of all the learned, and the judgment of all Greece, he was, as well in wiſdom, acuteneſs, politeneſs, and ſubtlety, as in eloquence, variety, and richneſs, in whatever he applied himſelf to, without exception, the prince of all.

It has been obſerved by many, that Socrates little affected travel; his life being wholly ſpent at home, excepting when he went out upon military ſervices. In the Peloponneſian war he was thrice perſonally engaged: upon which occaſions it is ſaid he outwent all the ſoldiers in hardineſs: and if at any time, ſaith Alcibiades, as it often happens in war, the proviſions failed, there were none who could bear the want of meat and drink like Socrates; yet, on the other hand, in times of feaſting, he alone ſeemed to enjoy them; and though of himſelf he would not drink, yet being invited, he far outdrank every one, though he was never ſeen intoxicated.

To this great philoſopher Greece was principally indebted for her glory and ſplendor. He formed the manners of the moſt celebrated perſons of Greece, as Alcibiades, Xenophon, Plato, &c. But his great ſervices and the excellent qualities of his mind could not ſecure him from envy, perſecution, and calumny. The thirty tyrants forbad his inſtructing youth; and as he derided the plurality of the Pagan deities, he was accuſed of impiety. The day of trial being come, Socrates made his own defence, without procuring an advocate, as the cuſtom was, to plead for him. He did not defend himſelf with the tone and language of a ſuppliant or guilty perſon, but, as if he were maſter of the judges themſelves, with freedom, firmneſs, and ſome degree of contumacy. Many of his friends alſo ſpoke in his behalf; and laſtly, Plato went up into the chair, and began a ſpeech in theſe words: "Though I, Athenians, am the youngeſt of thoſe that come up into this place"—but they ſtopped him, crying out, "of thoſe that go down," which he was thereupon conſtrained to do; and then proceeding to vote, they condemned Socrates to death, which was effected by means of poiſon, when he was 70 years of age. Plato gives an affecting account of his impriſonment and death, and concludes, "This was the end of the beſt, the wiſeſt, and the juſteſt of men." And that account of it by Plato, Tully profeſſes, he could never read without tears.

As to the perſon of Socrates, he is repreſented as very homely; he was bald, had a dark complexion, a flat noſe, eyes ſticking out, and a ſevere downcaſt look. But the defects of his perſon were amply compenſated by the virtues and accompliſhments of his mind. Socrates was indeed a man of all virtues; and ſo remarkably frugal, that how little ſoever he had, it was always enough. When he was amidſt a great variety of rich and expenſive objects, he would often ſay to himſelf, "How many things are there which I do not want!"

Socrates had two wives, one of which was the noted Xantippe; whom Aulus Gellius deſcribes as an accurſed froward woman, always chiding and ſcolding, by day and by night, and whom it was ſaid he made choice of as a trial and exerciſe of his temper. Several inſtances are recorded of her impatience and his forbearance. One day, before ſome of his friends, ſhe fell into the uſual extravagances of her paſſion; when he, without anſwering a word, went abroad with them: but on his going out of the door, ſhe ran up into the chamber, and threw down water upon his head; upon which, turning to his friends, "Did not I tell you

(ſays he), that after ſo much thunder we ſhould have rain?" Another time ſhe pulled his cloak from his ſhoulders in the open forum; and ſome of his friends adviſing him to beat her, "Yes (ſays he), that while we two fight, you may all ſtand by, and cry, Well done, Socrates; to him, Xantippe."

They who affirm that Socrates wrote nothing, mean only in reſpect to his philoſophy; for it is atteſted and allowed, that he aſſiſted Euripides in compoſing tragedies, and was the author of ſome pieces of poetry. Dialogues alſo and epiſtles are aſcribed to him: but his philoſophical diſputations were committed to writing only by his ſcholars; and that chiefly by Plato and Xenophon. The latter ſet the example to the reſt in doing it firſt, and alſo with the greateſt punctuality; as Plato did it with the moſt liberty, intermixing ſo much of his own, that it is hardly poſſible to know what part belongs to each. Hence Socrates, hearing him recite his Lyſis, cried out, "How many things doth this young man feign of me!" Accordingly, the greateſt part of his philoſophy is to be found in the writings of Plato. To Socrates is aſcribed the firſt introduction of moral philoſophy. Man having a twofold relation to things divine and human, his doctrines were with regard to the former metaphyſical, to the latter moral. His metaphyſical opinions were chiefly, that, There are three principles of all things, God, matter, and idea. God is the univerſal intellect; matter the ſubject of generation and corruption; idea, an incorporeal ſubſtance, the intellect of God; God the intellect of the world. God is one, perfect in himſelf, giving the being and well-being of every creature.—That God, not chance, made the world and all creatures, is demonſtrable from the reaſonable diſpoſition of their parts, as well for uſe as defence; from their care to preſerve themſelves, and continue their ſpecies.—That he particularly regards man in his body, appears from his noble upright form, and from the gift of ſpeech; in his ſoul, from the excellency of it above others.—That God takes care of all creatures, is demonſtrable from the benefit he gives them of light, water, fire, and fruits of the earth in due ſeaſon. That he hath a particular regard of man, from the deſtination of all plants and creatures for his ſervice; from their ſubjection to man, though they may exceed him ever ſo much in ſtrength; from the variety of man's ſenſe, accommodated to the variety of objects, for neceſſity, uſe, and pleaſure; from reaſon, by which he diſcourſeth through reminiſcence from ſenſible objects; from ſpeech, by which he communicates all he knows, gives laws, and governs ſtates. Finally, that God, though inviſible himſelf, at once ſees all, hears all, is every where, and orders all.

As to the other great object of metaphyſical research, the ſoul, Socrates taught, that it is pre-exiſtent to the body, endued with the knowledge of eternal ideas, which in its union to the body it loſeth, as ſtupefied, until awakened by diſcourſe from ſenſible objects; on which account, all its learning is only reminiſcence, a recovery of its firſt knowledge. That the body, being compounded, is diſſolved by death; but that the ſoul, being ſimple, paſſeth into another life, incapable of corruption. That the ſouls of men are divine. That the ſouls of the good after death are in a happy ſtate, united to God in a bleſſed inacceſſible place; that the bad in convenient places ſuffer condign puniſhment.

All the Grecian ſects of philoſophers refer their origin to the diſcipline of Socrates; particularly the Platonics, Peripatetics, Academics, Cyrenaics, Stoics, &c.

SOL, in Aſtrology, &c, ſignifies the ſun.

SOLAR, ſomething relating to the ſun. Thus, we ſay Solar fire in contradiſtinction to culinary fire.

Solar *Civil Month*. See Month.

Solar *Cycle*. See Cycle.

Solar *Comet*. See Discus.

Solar *Eclipſe*, is a privation of the light of the ſun, by the interpoſition of the opake body of the moon. See Eclipse.

Solar *Month*, *Riſing*, *Spots*. See the ſubſtantives.

Solar *Syſtem*, the order and diſpoſition of the ſeveral heavenly bodies, which revolve round the ſun as the centre of their motion; viz, the planets, primary and ſecondary, and the comets. See System.

Solar *Year*. See Year.

SOLID, in Phyſics, a body whoſe minute parts are connected together, ſo as not to give way, or ſlip from each other, on the ſmalleſt impreſſion. The word is uſed in this ſenſe, in contradiſtinction to fluid.

Solid, in Geometry, is a magnitude extended in every poſſible direction, quite around. Though it is commonly ſaid to be endued with three dimenſions only, length, breadth, and depth or thickneſs.

Hence, as all bodies have theſe three dimenſions, and nothing but bodies, *Solid* and *body* are often uſed indiſcriminately.

The extremes of Solids are ſurfaces. That is, Solids are terminated either by one ſurface, as a globe, or by ſeveral, either plane or curved. And from the circumſtances of theſe, Solids are diſtinguiſhed into regular and irregular.

Regular Solids, are thoſe that are terminated by regular and equal planes. Theſe are the tetraedron, hexaedron, or cube, octaedron, dodecaedron, and icoſaedron; nor can there poſſibly be more than theſe five regular Solids or bodies, unleſs perhaps the ſphere or globe be conſidered as one of an infinite number of ſides. See theſe articles ſeverally, alſo the article *Regular* Body.

Irregular Solids, are all ſuch as do not come under the definition of regular ones: ſuch as cylinder, cone, priſm, pyramid, &c.

Similar Solids are to one another in the triplicate ratio of their like ſides, or as the cubes of the ſame. And all ſorts of priſms, as alſo pyramids, are to one another in the compound ratio of their baſes and altitudes.

Solid *Angle*, is that formed by three or more plane angles meeting in a point; like an angle of a die, or the point of a diamond well cut.

The ſum of all the plane angles forming a Solid angle, is always leſs than 360°; otherwiſe they would conſtitute the plane of a circle, and not a Solid.

Atmoſphere of Solids. See Atmosphere.

Solid *Baſtion*. See Bastion.

Cubature of Solids. See Cubature and Solidity.

Meaſure

Meaſure of a SOLID. See MEASURE.

SOLID *Foot.* See FOOT.

SOLID *Numbers*, are thoſe which ariſe from the multiplication of a plane number, by any other number whatever. Thus, 18 is a Solid number, produced from the plane number 6 and 3, or from 9 and 2.

SOLID *Place.* See LOCUS.

SOLID *Problem*, is one which cannot be conſtructed geometrically; but by the interſection of a circle and a conic ſection, or by the interſection of two conic ſections. Thus, to deſcribe an iſoſceles triangle on a given baſe, ſo that either angle at the baſe ſhall be triple of that at the vertex, is a Solid problem, reſolved by the interſection of a parabola and circle, and it ſerves to inſcribe a regular heptagon in a given circle.

In like manner, to deſcribe an iſoſceles triangle having its angles at the baſe each equal to 4 times that at the vertex, is a Solid problem, effected by the interſection of an hyperbola and a parabola, and ſerves to inſcribe a regular nonagon in a given circle.

And ſuch a problem as this has four ſolutions, and no more; becauſe two conic ſections can interſect but in 4 points.

How all ſuch problems are conſtructed, is ſhewn by Dr. Halley, in the Philoſ. Tranſ. num. 188.

SOLID *of Leaſt Reſiſtance.* See RESISTANCE.

Surfaces of SOLIDS. See AREA and SUPERFICIES.

SOLID *Theorem.* See THEOREM.

SOLIDITY, in Phyſics, a property of matter or body, by which it excludes every other body from that place which is poſſeſſed by itſelf.

Solidity in this ſenſe is a property common to all bodies, whether ſolid or fluid. It is uſually called *impenetrability*; but Solidity expreſſes it better, as carrying with it ſomewhat more of poſitive than the other, which is a negative idea.

The idea of Solidity, Mr. Locke obſerves, ariſes from the reſiſtance we find one body makes to the entrance of another into its own place. Solidity, he adds, ſeems the moſt extenſive property of body, as being that by which we conceive it to fill ſpace; it is diſtinguiſhed from mere ſpace, by this latter not being capable of reſiſtance or motion.

It is diſtinguiſhed from hardneſs, which is only a firm coheſion of the ſolid parts.

The difficulty of changing ſituation gives no more Solidity to the hardeſt body than to the ſofteſt; nor is the hardeſt diamond properly a jot more ſolid than water. By this we diſtinguiſh the idea of the extenſion of body, from that of the extenſion of ſpace: that of body is the continuity or coheſion of ſolid, ſeparable, moveable parts; that of ſpace the continuity of unſolid, inſeparable, immoveable parts.

The Carteſians however will, by all means, deduce Solidity, or as they call it impenetrability, from the nature of extenſion; they contend, that the idea of the former is contained in that of the latter; and hence they argue againſt a vacuum. Thus, ſay they, one cubic foot of extenſion cannot be added to another without having two cubic feet of extenſion; for each has in itſelf all that is required to conſtitute that magnitude. And hence they conclude, that every part of ſpace is ſolid, or impenetrable, as of its own nature it excludes all others. But the concluſion is falſe, and the inſtance they give follows from this, that the parts of ſpace are immoveable, not from their being impenetrable or ſolid. See MATTER.

SOLIDITY is alſo uſed for hardneſs, or firmneſs; as oppoſed to fluidity; viz, when body is conſidered either as fluid or ſolid, or hard or firm.

SOLIDITY, in Geometry, denotes the quantity of ſpace contained in a ſolid body, or occupied by it; called alſo the *ſolid content*, or the *cubical content*; for all ſolids are meaſured by cubes, whoſe ſides are inches, or feet, or yards, &c; and hence the Solidity of a body is ſaid to be ſo many cubic inches, feet, yards, &c, as will fill its capacity or ſpace, or another of an equal magnitude.

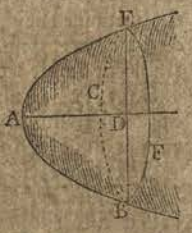
The Solidity of a cube, parallelopipedon, cylinder, or any other priſmatic body, i. e. one whoſe parallel ſections are all equal and ſimilar throughout, is found by multiplying the baſe by the height or perpendicular altitude. And of any cone or other pyramid, the Solidity is equal to one-third part of the ſame priſm, becauſe any pyramid is equal to the 3d part of its circumſcribing priſm. Alſo, becauſe a ſphere or globe may be conſidered as made up of an infinite number of pyramids, whoſe baſes form the ſurface of the globe, and their vertices all meet in the centre, or having their common altitude equal to the radius of the globe; therefore the ſolid content of it is equal to one-third part of the product of its radius and ſurface. For the Solidity of other figures, ſee each figure ſeparately.

The foregoing rules are ſuch as are derived from common geometry. But there are in nature numberleſs other forms, which require the aid of other methods and principles, as follows.

Of the SOLIDITY *of Bodies formed by a Plane revolving about any Axis, either within or without the Body.*—Concerning ſuch bodies, there is a remarkable property or relation between their Solidity and the path or line deſcribed by the centre of gravity of the revolving plane; viz, the Solidity of the body generated, whether by a whole revolution, or only a part of one, is always equal to the product ariſing from the generating plane drawn into the path or line deſcribed by its centre of gravity, during its motion in deſcribing the body. And this rule holds true for figures generated by all ſorts of motion whatever, whether rotatory, or direct or parallel, or irregularly zigzag, &c, provided the generating plane vary not, but continue the ſame throughout. And the ſame law holds true alſo for all ſurfaces any how generated by the motion of a right line. This is called the Centrobaric method. See my Menſuration, ſect. 3, part 4, pa. 501, 2d edit.

Of the SOLIDITY *of Bodies by the Method of Fluxions.*—This method applies very advantageouſly in all caſes alſo in which a body is conceived to be generated by the revolution of a plane figure about an axis, or, which is much the ſame thing, by the parallel motion of a circle, gradually expanding and contracting itſelf, according to the nature of the generating plane. And this method is particularly uſeful for the ſolids generated by any curvilineal plane figures. Thus, let the plane AED revolve about the axis AD; then it will generate the ſolid ABFEC. But as every ordinate DE, perpendicular

pendicular to the axis AD, describes a circle BCEF in the revolution, therefore the same solid may be conceived as generated by a circle BCEF, gradually expanding itself larger and larger, and moving perpendicularly along the axis AD. Consequently the area of that circle being drawn into the fluxion of the axis, will produce the fluxion of the solid; and therefore the fluent, when taken, will give the Solidity of that body. That is, AD × circle BCF, (whose radius is DE, or diameter BE) is the fluxion of the Solidity.



Hence then, putting AD $= x$, DE $= y$, $c = 3.1416$; because cy^2 is equal to the area of the circle BCF; therefore $cy^2\dot{x}$ is the fluxion of the solid. Consequently if the value of either y^2 or $\dot{x}$ be found in terms of each other, from the given equation expressing the nature of the curve, and that value be substituted for it in the fluxional expression $cy^2\dot{x}$, the fluent of the resulting quantity, being taken, will be the required Solidity of the body.

For Ex. Suppose the figure of a parabolic conoid, generated by the rotation of the common parabola ADE about its axis AD. In this case, the equation of the curve of the parabola is $px = y^2$, where p denotes the parameter of the axis. Substituting therefore px instead of y^2, in the fluxion $cy^2\dot{x}$, it becomes $cpx\dot{x}$; and the fluent of this is $\frac{1}{2}cpx^2 = \frac{1}{2}cxy^2$ for the Solidity; that is, half the product of the base of the solid drawn into its altitude; for cy^2 is the area of the circular base BCF, and x is the altitude. And so on for other such figures. See the content of each solid under its proper article.

For the SOLIDITY *of Irregular Solids*, or such as cannot be considered as generated by some regular motion or description; they must either be considered as cut or divided into several parts of known forms, as prisms, or pyramids, or wedges, &c, and the contents of these parts found separately. Or, in the case of the smaller bodies, of forms so irregular as not to be easily divided in that way, put them into some hollow regular vessel, as a hollow cylinder or parallelopipedon, &c; then pour in water or sand so as it may fill the vessel just up to the top of the inclosed irregular body, noting the height it rises to; then take out the body, and note the height the fluid again stands at; the difference of these two heights is to be considered as the altitude of a prism of the same base and form as the hollow vessel; and consequently the product of that altitude and base will be the accurate Solidity of the immerged body, be it ever so irregular.

SOLSTICE, in Astronomy, is the time when the sun is in one of the solstitial points, that is, when he is at the greatest distance from the equator, which is now nearly 23° 28′ on either side of it. It is so called, because the sun then seems to stand still, and not to change his place, as to declination, either way.

There are two Solstices, in each year, when the sun is at the greatest distance on the north and south sides of the ecliptic; viz, the *æstival* or *summer solstice*, and the *hyemal* or *winter solstice*.

The *Summer Solstice* is when the sun is in the tropic of Cancer; which is about the 21st of June, when he makes the longest day. And

The *Winter Solstice* is when he enters the first degree of Capricorn; which is about the 22d day of December, when he makes the shortest day.

This is to be understood, as to our northern hemisphere; for in the southern, the sun's entrance into Capricorn makes their summer solstice, and that in Cancer the winter one. So that it is more precise and determinate, to say the northern and southern solstice.

SOLSTITIAL *Points*, are those two points of the ecliptic the sun is in at the times of the two Solstices, being the first points of Cancer and Capricorn, which are diametrically opposite to each other.

SOLSTITIAL *Colure*, is that which passes through the Solstitial points.

SOLUTION, in Mathematics, is the answering or resolving of a question or problem that is proposed. See RESOLUTION, and REDUCTION *of Equations*.

SOLUTION, in Physics, is the reduction of a solid or firm body, into a fluid state, by means of some menstruum.—Solution is often confounded with what is called dissolution, though there is a difference.

SOSIGENES, was an Egyptian mathematician, whose principal studies were chronology and the mathematics in general, and who flourished in the time of Julius Cæsar. He is represented as well versed in the mathematics and astronomy of the Ancients; particularly of those celebrated mathematicians, Thales, Archimedes, Hipparchus, Calippus, and many others, who had undertaken to determine the quantity of the solar year; which they had ascertained much nearer the truth than one can well imagine they should, with instruments so very imperfect; as may appear by reference to Ptolomy's Almagest.

It seems Sosigenes made great improvements, and gave proofs of his being able to demonstrate the certainty of his discoveries; by which means he became popular, and obtained repute with those who had a genius to understand and relish such enquiries. Hence he was sent for by Julius Cæsar, who being convinced of his capacity, employed him in reforming the calendar; and it was he who formed the Julian year which begins 45 years before the birth of Christ. His other works are lost since that period.

SOUND, in Geography, denotes a strait or inlet of the sea, between two capes or head-lands.

The SOUND is used, by way of eminence, for that celebrated strait which connects the German sea to the Baltic. It is situated between the island of Zealand and the coast of Schonen. It is about 16 leagues in length, and in general about 5 in breadth, except near the castle of Cronenberg, where it is but one; so that there is no passage for vessels but under the cannon of the fortress.

SOUND, in Physics, a perception of the mind, communicated by means of the ear; being an effect of the collision of bodies, and their consequent tremulous motion, communicated to the ambient fluid, and so propagated through it to the organs of hearing.

To illustrate the cause of Sound, it is to be observed, 1st, That a motion is necessary in the sonorous body for the production of sound. 2dly, That this motion exists first in the small and insensible parts of the sonorous bodies

bodies, and is excited in them by their mutual collision againſt each other, which produces the tremulous motion ſo obſervable in bodies that have a clear ſound, as bells, muſical chords, &c. 3dly, That this motion is communicated to, or produces a like motion in the air, or ſuch parts of it as are fit to receive and propagate it. Laſtly, That this motion muſt be communicated to thoſe parts that are the proper and immediate inſtruments of hearing.

Now that motion of a ſonorous body, which is the immediate cauſe of Sound, may be owing to two different cauſes; either the percuſſion between it and other hard bodies, as in drums, bells, chords, &c; or the beating and daſhing of the ſonorous body and the air immediately againſt each other, as in flutes, trumpets, &c.

But in both theſe caſes, the motion, which is the conſequence of the mutual action, as well as the immediate cauſe of the ſonorous motion which the air conveys to the ear, is ſuppoſed to be an inviſible, tremulous or undulating motion, in the ſmall and inſenſible parts of the body. Perrault adds, that the viſible motion of the groſſer parts contributes no otherwiſe to Sound, than as it cauſes the inviſible motion of the ſmaller parts, which he calls particles, to diſtinguiſh them from the ſenſible ones, which he calls parts, and from the ſmalleſt of all, which are called corpuſcles.

The ſonorous body having made its impreſſion on the contiguous air, that impreſſion is propagated from one particle to another, according to the laws of pneumatics.

A few particles, for inſtance, driven from the ſurface of the body, puſh or preſs their adjacent particles into a leſs ſpace; and the medium, as it is thus rarefied in one place, becomes condenſed in the other; but the air thus compreſſed in the ſecond place, is, by its elaſticity, returned back again, both to its former place and its former ſtate; and the air contiguous to that is compreſſed; and the like obtains when the air leſs compreſſed, expanding itſelf, a new compreſſion is generated. Therefore from each agitation of the air there ariſes a motion in it, analogous to the motion of a wave on the ſurface of the water; which is called a *wave* or *undulation* of air.

In each wave, the particles go and return back again, through very ſhort equal ſpaces; the motion of each particle being analogous to the motion of a vibrating pendulum while it performs two oſcillations; and moſt of the laws of the pendulum, with very little alteration, being applicable to the former.

Sounds are as various as are the means that concur in producing them. The chief varieties reſult from the figure, conſtitution, quantity, &c, of the ſonorous body; the manner of percuſſion, with the velocity &c, of the conſequent vibrations; the ſtate and conſtitution of the medium; the diſpoſition, diſtance, &c, of the organ; the obſtacles between the organ and the ſonorous object and the adjacent bodies. The moſt notable diſtinction of Sounds, ariſing from the various degrees and combinations of the conditions above mentioned, are into *loud* and *low* (or ſtrong and weak); into *grave* and *acute* (or ſharp and flat, or high and low); and into *long* and *ſhort*. The management of which is the office of muſic.

Euler is of opinion, that no Sound making fewer vibrations than 30 in a ſecond, or more than 7520, is diſtinguiſhable by the human ear. According to this doctrine, the limit of our hearing, as to acute and grave, is an interval of 8 octaves. Tentam. Nov. Theor. Muſ. cap. 1, ſect. 13.

The velocity of Sound is the ſame with that of the aerial waves, and does not vary much, whether it go with the wind or againſt it. By the wind indeed a certain quantity of air is carried from one place to another; and the Sound is accelerated while its waves move through that part of the air, if their direction be the ſame as that of the wind. But as Sound moves vaſtly ſwifter than the wind, the acceleration it will hereby receive is but inconſiderable; and the chief effect we can perceive from the wind is, that it increaſes and diminiſhes the ſpace of the waves, ſo that by help of it the Sound may be heard to a greater diſtance than otherwiſe it would.

That the air is the uſual medium of Sound, appears from various experiments in rarefied and condenſed air. In an unexhauſted receiver, a ſmall bell may be heard to ſome diſtance; but when exhauſted, it can ſcarce be heard at the ſmalleſt diſtance. When the air is condenſed, the Sound is louder in proportion to the condenſation, or quantity of air crowded in; of which there are many inſtances in Haukſbee's experiments, in Dr. Prieſtley's, and others.

Beſides, ſounding bodies communicate tremors to diſtant bodies; for example, the vibrating motion of a muſical ſtring puts others in motion, whoſe tenſion and quantity of matter diſpoſe their vibrations to keep time with the pulſes of air, propagated from the ſtring that was ſtruck. Galileo explains this phenomenon by obſerving, that a heavy pendulum may be put in motion by the leaſt breath of the mouth, provided the blaſts be often repeated, and keep time exactly with the vibrations of the pendulum; and alſo by the like art in raiſing a large bell.

It is not air alone that is capable of the impreſſions of Sound, but water alſo; as is manifeſt by ſtriking a bell under water, the Sound of which may plainly enough be heard, only not ſo loud, and alſo a fourth deeper, according to good judges in muſical notes. And Merſenne ſays, a Sound made under water is of the ſame tone or note, as if made in air, and heard under the water.

The velocity of Sound, or the ſpace through which it is propagated in a given time, has been very differently eſtimated by authors who have written concerning this ſubject. Roberval ſtates it at the rate of 560 feet in a ſecond; Gaſſendus at 1473; Merſenne at 1474; Duhamel, in the Hiſtory of the Academy of Sciences at Paris, at 1338; Newton at 968; Derham, in whoſe meaſure Flamſteed and Halley acquieſce, at 1142.

The reaſon of this variety is aſcribed by Derham, partly to ſome of thoſe gentlemen uſing ſtrings and plummets inſtead of regular pendulums; and partly to the too ſmall diſtance between the ſonorous body and the place of obſervation; and partly to no regard being had to the winds.

But by the accounts ſince publiſhed by M. Caſſini de Thury, in the Memoirs of the Royal Acad. of Scien-

ces at Paris, 1738, where cannon were fired at various as well as great diſtances, under many varieties of weather, wind, and other circumſtances, and where the meaſures of the different places had been ſettled with the utmoſt exactneſs, it was found that Sound was propagated, on a medium, at the rate of 1038 French feet in a ſecond of time. But the French foot is in proportion to the Engliſh as 15 to 16; and conſequently 1038 French feet are equal to 1107 Engliſh feet. Therefore the difference of the meaſures of Derham and Caſſini is 35 Engliſh feet, or 33 French feet, in a ſecond. The medium velocity of Sound therefore is nearly at the rate of a mile, or 5280 feet, in 4¾ ſeconds, or a league in 14 ſeconds, or 13 miles in a minute. But ſea miles are to land miles nearly as 7 to 6; and therefore Sound moves over a ſea mile in 5⅓ ſeconds nearly, or a ſea league in 16 ſeconds.

Farther, it is a common obſervation, that perſons in good health have about 75 pulſations, or beats of the artery at the wriſt, in a minute; conſequently in 75 pulſations, Sound flies about 13 land miles, or 11¼ ſea miles, which is about 1 land mile in 6 pulſes, or one ſea mile in 7 pulſes, or a league in 20 pulſes.

And hence the diſtance of objects may be found, by knowing the time employed by Sound in moving from thoſe objects to an obſerver. For Ex. On ſeeing the flaſh of a gun at ſea, if 54 beats of the pulſe at the wriſt were counted before the report was heard; the diſtance of the gun will eaſily be found by dividing 54 by 20, which gives 2·7 leagues, or about 8 miles.

Upon the nature, production, and propagation of Sound, ſee the article PHONICS and ECHO; alſo the Memoirs of the Acad. and the Philoſ. Tranſ. in many places; Newton, Principia; Kircher, Meſurgia Univerſalis; Merſenne; Borelli, Del Suono; Prieſtley, Exper. and Obſerv. vol. 5; Hales, Sonorum Doctrina rationalis et experimentalis; 4to 1778. See alſo an ingenious treatiſe publiſhed 1790, by Mr. Geo. Saunders, on Theatres; in which he relates many experiments made by himſelf, on the nature and propagation of Sound. In this work, he ſhews the great effect of water, and ſome other bodies, in conducting of Sound, probably by rendering the air more denſe near them. Some of his concluſions and obſervations are as follow:

Earth may be ſuppoſed to have a twofold property with reſpect to Sound. Being very porous, it abſorbs Sound, which is counteracted by its property of conducting Sound, and occaſions it to paſs on a plane, in an equal proportion to its progreſs in air, unencumbered by any body.

If a Sound be ſufficiently intenſe to impreſs the earth in its tremulous quality, it will be carried to a conſiderable diſtance, as when the earth is ſtruck with any thing hard, as by the motion of a carriage, horſes feet, &c.

Plaſter is proportionally better than looſe earth for conducting Sound, as it is more compact.

Clothes of every kind, particularly woollen cloths, are very prejudicial to Sound: their abſorption of Sound, may be compared to that of water, which they greedily imbibe.

A number of people ſeated before others, as in the pit or gallery of a theatre, do conſiderably prevent the voice reaching thoſe behind; and hence it is, that we hear ſo much better in the front of the galleries, or of any ſituation, than behind others, though we may be nearer to the ſpeaker. Our ſeats, riſing ſo little above each other, occaſion this defect, which would be remedied, could we have the ſeats to riſe their whole height above each other, as in the ancient theatres.

Paint has generally been thought unfavourable to Sound, from its being ſo to muſical inſtruments, whoſe effects it quite deſtroys.

Muſical inſtruments moſtly depend on the vibrative or tremulous property of the materials. Such a body of colour hardened in oil muſt very much alter; but we ſhould diſtinguiſh that this regards the formation of Sound, which may not altogether be the caſe in the progreſs of it.

Water has been little noticed, with reſpect to its conducting Sound; but it will be found to be of the greateſt conſequence. I had often perceived in newly-finiſhed houſes, that while they were yet damp, they produced echoes; but that the echoing abated as they dried.

Exp. When I made the following experiment there was a gentle wind; conſequently the water was proportionally agitated. I choſe a quiet part of the river Thames, near Chelſea Hoſpital, and with two boats tried the diſtance the voice would reach. On the water we could diſtinctly hear a perſon read at the diſtance of 140 feet, on land at that of 76. It ſhould be obſerved, that on land no noiſe intervened; but on the river ſome noiſe was occaſioned by the flowing of the water againſt the boats; ſo that the difference on land and on water muſt be much more.

Watermen obſerve, that when the water is ſtill, and the weather quite calm, if no noiſe intervene, a whiſper may be heard acroſs the river; and that with the current it will be carried to a much greater diſtance, and vice verſa againſt the current.

Mariners well know the difference of Sound on ſea and land.

When a canal of water was laid under the pit floor of the theatre of Argentino, at Rome, a ſurpriſing difference was obſerved; the voice has ſince been heard at the end very diſtinctly, where it was before ſcarce diſtinguiſhable. It is obſervable that, in this part, the canal is covered with a brick arch, over which there is a quantity of earth, and the timber floor over all.

The villa Simonetta near Milan, ſo remarkable for its echoes, is entirely over arcades of water.

Another villa near Rouen, remarkable for its echo, is built over ſubterraneous cavities of water.

A reſervoir of water domed over, near Stanmore, has a ſtrong echo.

I do not remember ever being under the arches of a ſtone bridge that did not echo; which is not always the caſe with ſimilar ſtructures on land.

A houſe in Lambeth Marſh, inhabited by Mr. Turtle, is very damp during winter, when it yields an echo which abates as the houſe becomes dry in ſummer.

Kircher obſerves, that echoes repeat more by night than during the day: he makes the difference to be double.

Dr. Plott ſays, the echo in Woodſtock park repeated 17 times by day, and 20 by night. And Addiſon's

experiment at the Villa Simonetta was in a fog, when it produced 56 repetitions.

After all theſe inſtances, I think little doubt can remain of the influence water has on Sound; and I conclude that it conducts Sound more than any other body whatever.

After water, ſtone may be reckoned the beſt conductor of Sound. To what cauſe it may be attributed, I leave to future enquiries: I have confined myſelf to ſpeak of facts only as they appear.

Stone is ſonorous, but gives a harſh diſagreeable tone, unfavourable to muſic.

Brick, in reſpect to Sound, has nearly the ſame properties as ſtone. Part of the garden wall of the late W. Pitt, Eſq. of Kingſton in Dorſetſhire, conveys a whiſper to the diſtance of near 200 feet.

Wood is ſonorous, conductive, and vibrative; of all materials it produces a tone the moſt agreeable and melodious; and it is therefore the fitteſt for muſical inſtruments, and for lining of rooms and theatres.

The common notion that whiſpering at one end of a long piece of timber would be heard at the other end, I found by experiment to be erroneous. A ſtick of timber 65 feet long being ſlightly ſtruck at one end, a ſound was heard at the other, and the tremor very perceptible: which is eaſily accounted for, when we conſider the number or length of the fibres that compoſe it, each of which may be compared to a ſtring of catgut.

For the Reflection, Refraction, &c. of SOUND; ſee ECHO, and PHONICS.

Articulate SOUND. See ARTICULATE.

SOUND, in Muſic, denotes a quality in the ſeveral agitations of the air, ſo as to make muſic or harmony.

Sound is the object of muſic; which is nothing but the art of applying Sounds, under ſuch circumſtances of tone and time, as to raiſe agreeable ſenſations. The principal affection of Sound, by which it becomes fitted to have this end, is that by which it is diſtinguiſhed into acute and grave. This difference depends on the nature of the ſonorous body; the particular figure and quantity of it; and even in ſome caſes, on the part of the body where it is ſtruck: and it is this that conſtitutes what are called *different tones*.

The cauſe of this difference appears to be no other than the different velocities of the vibrations of the ſounding body. Indeed the tone of a Sound is found, by numerous experiments, to depend on the nature of thoſe vibrations, whoſe differences we can conceive no otherwiſe than as having different velocities: and ſince it is proved that the ſmall vibrations of the ſame chord are all performed in equal times, and that the tone of a Sound, which continues for ſome time after the ſtroke, is the ſame from firſt to laſt, it follows, that the tone is neceſſarily connected with a certain quantity of time in making each vibration, or each wave; or that a certain number of vibrations or waves, made in a given time, conſtitute a certain and determinate tone. From this principle are all the phænomena of tune deduced.

If the vibrations be iſochronous, or performed in the ſame time, the Sound is called muſical, and is ſaid to continue at the ſame pitch; and it is alſo accounted acuter, ſharper, or higher than any other Sound, whoſe vibrations are ſlower, and therefore graver, flatter, or lower, than any other whoſe vibrations are quicker. See UNISON.

From the ſame principle ariſe what are called *concords*, &c; which reſult from the frequent unions and coincidences of the vibrations of two ſonorous bodies, and conſequently of the pulſes or the waves of the air occaſioned by them.

On the contrary, the reſult of leſs frequent coincidences of thoſe vibrations, is what is called *diſcord*.

Another conſiderable diſtinction of muſical Sounds, is that by which they are called *long* and *ſhort*, owing to the continuation of the impulſe of the efficient cauſe on the ſonorous body for a longer or ſhorter time, as in the notes of a violin &c, which are made longer or ſhorter by ſtrokes of different length or quickneſs. This continuity is properly a ſucceſſion of ſeveral Sounds, or the effect of ſeveral diſtinct ſtrokes, or repeated impulſes, on the ſonorous body, ſo quick, that we judge it one continued Sound, eſpecially where it is continued in the ſame degree of ſtrength; and hence ariſes the doctrine of *meaſure* and *time*.

Muſical Sounds are alſo divided into *ſimple* and *compound*; and that in two different ways. In the firſt, a Sound is ſaid to be compound, when a number of ſucceſſive vibrations of the ſonorous body, and the air, come ſo faſt upon the ear, that we judge them the ſame continued Sound; like as in the phenomenon of the circle of fire, cauſed by putting the fired end of a ſtick in a quick circular motion; where ſuppoſing the end of the ſtick in any point of the circle, the idea we receive of it there continues till the impreſſion is renewed by a ſudden return.

A *Simple* SOUND then, with regard to this compoſition, ſhould be the effect of a ſingle vibration, or of as many vibrations as are neceſſary to raiſe in us the idea of Sound.

In the ſecond ſenſe of compoſition, a ſimple Sound is the product of one voice, or one inſtrument, &c.

A *Compound* SOUND conſiſts of the Sounds of ſeveral diſtinct voices or inſtruments all united in the ſame individual time, and meaſure of duration, that is, all ſtriking the ear together, whatever their other differences may be. But in this ſenſe again, there is a twofold compoſition; a natural and an artificial one.

The natural compoſition is that proceeding from the manifold reflections of the firſt Sound from adjacent bodies, where the reflections are not ſo ſudden as to occaſion echoes, but are all in the ſame tune with the firſt note.

The artificial compoſition, which alone comes under the muſician's province, is that mixture of ſeveral Sounds, which being made by art, the ingredient Sounds are ſeparable, and diſtinguiſhable from one another. In this ſenſe the diſtinct Sounds of ſeveral voices or inſtruments, or ſeveral notes of the ſame inſtrument, are called ſimple Sounds, in contradiſtinction to the compound ones, in which, to anſwer the end

of muſic, the ſimples muſt have ſuch an agreement in all relations, chiefly as to acuteneſs and gravity, as that the ear may receive the mixture with pleaſure.

Another diſtinction of Sounds, with regard to muſic, is that by which they are ſaid to be *ſmooth* or *even*, and *rough* or *harſh*, alſo *clear* and *hoarſe*: the cauſe of which difference depends on the diſpoſition and ſtate of the ſonorous body, or the circumſtances of the place; but the ideas of the differences muſt be ſought from obſervation.

Smooth and *Rough* Sounds depend chiefly on the ſounding body; of which we have a notable inſtance in ſtrings that are uneven, and not of the ſame dimenſion and conſtitution throughout.

As to *clear* and *hoarſe* Sounds, they depend on circumſtances that are accidental to the ſonorous body. Thus, a voice or inſtrument will be hollow and hoarſe if ſounded within an empty hogſhead, that yet is clear and bright out of it: the effect is owing to the mixture of different Sounds, raiſed by reflections, which corrupt and change the ſpecies of the primitive Sound.

For Sounds to be fit to obtain the end of muſic, they ought to be ſmooth and clear, eſpecially the firſt; ſince, without this, they cannot have one certain and diſcernible tone, capable of being compared to others, in a certain relation of acuteneſs, which the ear may judge of. So that, with Malcolm, we call that an harmonic or muſical Sound which, being clear and even, is agreeable to the ear, and gives a certain and diſcernible tune (hence called tunable Sound), which is the ſubject of the whole theory of harmony.

Wood has a particular vibrating quality, owing to its elaſticity; and all muſical inſtruments made of this matter, are of a thickneſs proportioned to the ſuperficies of the wood, and the tone they are to produce.

Metals are ſonorous and vibrative, producing a harſh tone, very ſerviceable to ſome parts of muſic. Moſt wind inſtruments are made of metal, which is acted upon in its elaſtic and tremulous quality, being capable of being reduced very thin for that purpoſe. Inſtruments of this kind are ſuch as horns, trumpets, &c. Some inſtruments however depend more on the form than the material; as flutes, for inſtance, which, if their lengths and bore be the ſame, have very little difference in their Sounds, whatever the matter of them may be. See HARMONICAL.

SOUND-BOARD, the principal part of an organ, and that which makes the whole machine play. This Sound-board, or ſummer, is a reſervoir into which the wind, drawn in by the bellows, is conducted by a portvent, and thence diſtributed into the pipes placed over the holes of its upper part. This wind enters them by valves, which open by preſſing upon the ſtops or keys, after drawing the regiſters, which prevent the air from going into any of the other pipes beſide thoſe it is required in.

SOUND-*board* denotes alſo a thin broad board placed over the head of a public ſpeaker, to enlarge and extend or ſtrengthen his voice.

Sound-boards, in theatres, are found by experience to be of no ſervice; their diſtance from the ſpeaker being too great, to be impreſſed with ſufficient force. But Sound-boards immediately over a pulpit have often a good effect, when the caſe is made of a juſt thickneſs, and according to certain principles.

SOUND-*Poſt*, is a poſt placed within-ſide of a violin, &c, as a prop between the back and the belly of the inſtrument, and nearly under the bridge.

SOUNDING, in Navigation, the act of trying the depth of the water, and the quality of the bottom, by a line and plummet, or other artifice.

At ſea, there are two plummets uſed for this purpoſe, both ſhaped like the fruſtum of a cone or pyramid. One of theſe is called the hand-lead, weighing about 8 or 9lb; and the other the deep-ſea-lead, weighing from 25 to 30lb. The former is uſed in ſhallow waters, and the latter at a great diſtance from the ſhore. The line of the hand-lead, is about 25 fathoms in length, and marked at every 2 or 3 fathoms, in this manner, viz, at 2 and 3 fathoms from the lead there are marks of black leather; at 5 fathoms a white rag, at 7 a red rag, at 10 and at 13 black leather, at 15 a white rag, and at 17 a red one.

Sounding with the hand-lead, which the ſeamen call heaving the lead, is generally performed by a man who ſtands in the main-chains to windward. Having the line all ready to run out, without interruption, he holds it nearly at the diſtance of a fathom from the plummet, and having ſwung the latter backwards and forwards three or four times, in order to acquire the greater velocity, he ſwings it round his head, and thence as far forward as is neceſſary; ſo that, by the lead's ſinking whilſt the ſhip advances, the line may be almoſt perpendicular when it reaches the bottom. The perſon ſounding then proclaims the depth of the water in a kind of ſong reſembling the cries of hawkers in a city; thus, if the mark of 5 be cloſe to the ſurface of the water, he calls, 'by the mark 5,' and as there is no mark at 4, 6, 8, &c, he eſtimates thoſe numbers, and calls, 'by the dip four, &c.' If he judges it to be a quarter or a half more than any particular number, he calls, 'and a quarter 5,' 'and a half 4' &c. If he conceives the depth to be three quarters more than a particular number, he calls it a quarter leſs than the next: thus, at 4 fathom ¾, he calls, 'a quarter leſs 5,' and ſo on.

The deep-ſea-lead line is marked with 2 knots at 20 fathom, 3 at 30, 4 at 40, &c to the end. It is alſo marked with a ſingle knot at the middle of each interval, as at 25, 35, 45 fathoms, &c. To uſe this lead more effectually at ſea, or in deep water on the ſea-coaſt, it is uſual previouſly to bring-to the ſhip, in order to retard her courſe: the lead is then thrown as far as poſſible from the ſhip on the line of her drift, ſo that, as it ſinks, the ſhip drives more perpendicularly over it. The pilot feeling the lead ſtrike the bottom, readily diſcovers the depth of the water by the mark on the line neareſt its ſurface. The bottom of the lead, which is a little hollowed there for the purpoſe, being alſo well rubbed over with tallow, retains the diſtinguiſhing marks of the bottom, as ſhells, ooze, gravel, &c, which naturally adhere to it.

The depth of the water, and the nature of the ground, which are called the Soundings, are carefully marked in the log-book, as well to determine the diſtance of

the place from the ſhore, as to correct the obſervations of former pilots. Falconer.

For a machine to meaſure unfathomable depths of the ſea, ſee ALTITUDE.

SOUNDING *the pump*, at ſea, is done by letting fall a ſmall line, with ſome weight at the end, down into the pump, to know what depth of water there is in it.

SOUTH, one of the four cardinal points of the wind, or compaſs, being that which is directly oppoſite to the north.

SOUTH *Direct Dials*. See PRIME *Verticals*.

SOUTHERN *Hemiſphere, Signs, &c*, thoſe in the ſouth ſide of the equator.

SOUTHING, in Navigation, the difference of latitude made by a ſhip in ſailing to the ſouthward.

SPACE, denotes room, place, diſtance, capacity, extenſion, duration, &c.

When Space is conſidered barely in length between any two bodies, it gives the ſame idea as that of diſtance. When it is conſidered in length, breadth, and thickneſs, it is properly called capacity. And when conſidered between the extremities of matter, which fills the capacity of Space with ſomething ſolid, tangible, and moveable, it is then called extenſion.

So that extenſion is an idea belonging to body only; but Space may be conſidered without it. Therefore Space, in the general ſignification, is the ſame thing with diſtance conſidered every way, whether there be any matter in it or not.

Space is uſually divided into *abſolute* and *relative*.

Abſolute SPACE is that which is conſidered in its own nature, without regard to any thing external, which always remains the ſame, and is infinite and immoveable.

Relative SPACE is that moveable dimenſion, or meaſure of the former, which our ſenſes define by its poſitions to bodies within it; and this the vulgar uſe for immoveable Space.

Relative Space, in magnitude and figure, is always the ſame with abſolute; but it is not neceſſary it ſhould be ſo numerically. Thus, when a ſhip is perfectly at reſt, then the places of all things within her are the ſame both abſolutely and relatively, and nothing changes its place: but, on the contrary, when the ſhip is under ſail, or in motion, ſhe continually paſſes through new parts of abſolute Space; though all things on board, conſidered relatively, in reſpect to the ſhip, may yet be in the ſame places, or have the ſame ſituation and poſition, in regard to one another.

The Carteſians, who make extenſion the eſſence of matter, aſſert, that the Space any body takes up, is the ſame thing with the body itſelf; and that there is no ſuch thing in the univerſe as mere Space, void of all matter; thus making Space or extenſion a ſubſtance. See this diſproved under VACUUM.

Among thoſe too who admit a vacuum, and conſequently an eſſential difference between Space and matter, there are ſome who aſſert that Space is a ſubſtance. Among theſe we find Graveſande, Introd. ad Philoſ. ſect. 19.

Others again put Space into the ſame claſs of beings as time and number; thus making it to be no more than a notion of the mind. So that according to theſe authors, abſolute Space, of which the Newtonians ſpeak, is a mere chimera. See the writings of the late biſhop Berkley.

Space and time, according to Dr. Clarke, are attributes of the Deity; and the impoſſibility of annihilating theſe, even in idea, is the ſame with that of the neceſſary exiſtence of the Deity.

SPACE, in Geometry, denotes the area of any figure; or that which fills the interval or diſtance between the lines that terminate or bound it. Thus,

The Parabolic Space is that included in the whole parabola. The conchoidal Space, or the ciſſoidal Space, is what is included within the cavity of the conchoid or ciſſoid. And the aſymptotic Space, is what is included between an hyperbolic curve and its aſymptote. By the new methods now introduced, of applying algebra to geometry, it is demonſtrated that the conchoidal and ciſſoidal Spaces, though infinitely extended in length, are yet only finite magnitudes or Spaces.

SPACE, in Mechanics, is the line a moveable body, conſidered as a point, is conceived to deſcribe by its motion.

SPANDREL, with Builders, is the ſpace included between the curve of an arch and the ſtraight or right lines which incloſe it; as the ſpace *a*, or *b*.

SPEAKING *Trumpet*. See *Speaking* TRUMPET.

SPECIES, in Algebra, are the letters, ſymbols, marks, or characters, which repreſent the quantities in any operation or equation.

This ſhort and advantageous way of notation was chiefly introduced by Vieta, about the year 1590; and by means of which he made many diſcoveries in algebra, not before taken notice of.

The reaſon why Vieta gave this name of Species to the letters of the alphabet uſed in algebra, and hence called Arithmetica Specioſa, ſeems to have been in imitation of the Civilians, who call caſes in law that are put abſtractedly, between John a Nokes and Tom a Stiles, between A and B; ſuppoſing thoſe letters to ſtand for any perſons indefinitely. Such caſes they call Species: whence, as the letters of the alphabet will alſo as well repreſent quantities, as perſons, and that alſo indefinitely, one quantity as well as another, they are properly enough called Species; that is general ſymbols, marks, or characters. From whence the literal algebra hath ſince been often called Specious Arithmetic, or Algebra in Species.

SPECIES, in Optics, the image painted on the retina by the rays of light reflected from the ſeveral points of the ſurface of an object, received in by the pupil, and collected in their paſſage through the cryſtalline, &c.

Philoſophers have been in great doubt, whether the Species of objects, which give the ſoul an occaſion of ſeeing, are an effuſion of the ſubſtance of the body; or a mere impreſſion which they make on all ambient bodies, and which theſe all reflect, when in a proper diſpoſition and diſtance; or laſtly, whether they are not ſome other more ſubtile body, as light, which receives all theſe impreſſions from bodies, and is continually ſent and returning from one to another, with the different impreſſions and figures it has taken. But the moderns have decided this point by their invention of

artificial eyes, inwhich the Species of objects are received on a paper, in the same manner as they are received in the natural eye.

SPECIFIC, in Philosophy, that which is proper and peculiar to any thing; or that characterises it, and distinguishes it from every other thing. Thus, the attracting of iron is Specific to the loadstone, or is a Specific property of it.

A just definition should contain the Specific notion of the thing defined, or that which specifies and distinguishes it from every thing else.

SPECIFIC *Gravity*, in Hydrostatics, is the relative proportion of the weight of bodies of the same bulk. See *Specific* GRAVITY.

SPECIFIC *Gravity of living men.* Mr. John Robertson, late librarian to the Royal Society, in order to determine the Specific gravity of men, prepared a cistern 78 inches long, 30 inches wide, 30 inches deep; and having procured 10 men for his purpose, the height of each was taken and his weight; and afterwards they plunged successively into the cistern. A ruler or scale, graduated to inches and decimal parts, was fixed to one end of the cistern, and the height of the water shown by it was noted before each man went in, and to what height it rose when he immersed himself under its surface. The following table contains the several results of his experiments:

No. of men.	Height. Ft. In.	Weight. lbs.	Water raised. Inches.	Solidity. Feet.	Wt. of water. lbs.	Specific gravity. (Wat. 1)
1	6 2	161	1·90	2·573	160·8	1·001
2	5 10 3/8	147	1·91	2·586	161·6	0·901
3	5 9 1/2	156	1·85	2·505	156·6	0·991
4	5 6 3/4	140	2·04	2·763	172·6	0·801
5	5 5 7/8	158	2·08	2·817	176·0	0·900
6	5 5 1/2	158	2·17	2·939	183·7	0·849
7	5 4 3/8	140	2·01	2·722	170·1	0 823
8	5 4 1/8	121	1·79	2·424	151·5	0·890
9	5 3 1/4	146	1·73	2·343	146·4	0·997
10	5 3 1/8	132	1·85	2·505	156·6	0·843
medium of all.	5 6 2/3	146	1·933	2·618	163·6	0·891

One of the reasons, Mr. Robertson says, that induced him to make these experiments, was a desire of knowing what quantity of timber would be sufficient to keep a man afloat in water, thinking that most men were specifically heavier than river or common fresh water; but the contrary appears from the trials above recited; for, except the first, every man was lighter than an equal bulk of fresh water, and much more so than that of sea-water. So that, if persons who fall into water had presence of mind enough to avoid the fright usual on such occasions, many might be preserved from drowning; and a piece of wood not larger than an oar, would buoy a man partly above water as long as he had strength or spirits to keep his hold. Philos. Trans. vol. 50, art. 5.

From the last line of the table appears the medium of all the circumstances of height, weight, &c; particularly the mean Specific Gravity, 0·891, which is about 1/9 less than common water.

SPECTACLES, an optical machine, consisting of two lenses set in a frame, and applied on the nose, to assist in defects of the organ of sight.

Old people, and all presbytæ, use Spectacles of convex lenses, to make amends for the flatness of the eye, which does not make the rays converge enough to have them meet in the retina.

Short-sighted people, or myopes, use concave lenses, to prevent the rays from converging so fast, on account of the greater roundness of the eye, or smallness of the sphere, which is such as to make them meet before they reach the retina.

F. Cherubin, a capuchin, describes a kind of Spectacle telescopes, for viewing remote objects with both eyes; and hence called *binoculi*. Though F. Rheita had mentioned the same before him, in his Oculus Enoch et Eliæ. See BINOCLE. The same author invented a kind of Spectacles, with three or four glasses, which performed very well.

The invention of Spectacles has been much disputed. They were certainly not known to the ancients. Francisco Redi, in a learned treatise on Spectacles, contends that they were first invented between the years 1280 and 1311, probably about 1290; and adds, that Alexander de Spina, a monk of the order of Predicants of St. Catharine, at Pisa, first communicated the secret, which was of his own invention, upon learning that another person had it as well as himself.

The author tells us, that in an old manuscript still preserved in his library, composed in 1299, Spectacles are mentioned as a thing invented about that time: and that a celebrated Jacobin, one Jourdon de Rivalto, in a treatise composed in 1305, says expressly, that it was not yet 20 years since the invention of Spectacles. He likewise quotes Bernard Gordon in his Lilium Medicinæ, written the same year, where he speaks of a collyrium, good to enable an old man to read without Spectacles.

Musschenbroek observes, (Introd. vol. 2, pa. 786) that it is inscribed on the tomb of Salvinus Armatus, a nobleman of Florence, who died in 1317, that he was the inventor of Spectacles.

Du-Cange, however, carries the invention of Spectacles farther back; assuring us, that there is a Greek poem in manuscript in the French king's library, which shews that Spectacles were in use in the year 1150: however the dictionary of the Academy Della Crusca, under the word *occhiale*, inclines to Redi's side; and quotes a passage from Jourdon's sermons, which says that Spectacles had not been 20 years in use; and Salvati has observed that those sermons were composed between the years 1330 and 1336.

It is probable that the first hint of the construction and use of Spectacles, was derived from the writings either of Alhazen, who lived in the 12th century, or of our own countryman Roger Bacon, who was born in 1214, and died in 1292, or 1294. The following remarkable passage occurs in Bacon's Opus Majus by Jebb, p. 352. Si vero homo aspiciat literas et alias res minutas per medium crystalli, vel vitri, vel alterius perspicui suppositi literis, et sit portio minor sphæræ, cujus convexitas sit versus oculum et oculus sit in aëre, longe

longe melius videbit literas, et apparebunt ei majores.—Et ideo hoc inſtrumentum eſt utile ſenibus et habentibus oculos debiles: nam literam quantumcunque parvam poſſunt videre in ſufficienti magnitudine. Hence, and from other paſſages in his writings, much to the ſame purpoſe, Molyneux, Plott, and others, have attributed to him the invention of reading-glaſſes. Dr. Smith indeed, obſerving that there are ſome miſtakes in his reaſoning on this ſubject, has diſputed his claim. See Molyneux's Dioptr. p. 256. Smith's Optics, Rem. 86—89.

SPECULATIVE *Geometry*, *Mathematics*, *Muſic*, and *Philoſophy*. See the SUBSTANTIVES.

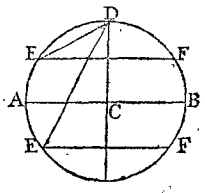
SPECULUM, or *Mirror*, in Optics, any poliſhed body, impervious to the rays of light: ſuch as poliſhed metals, and glaſſes lined with quickſilver, or any other opake matter, popularly called Looking-glaſſes; or even the ſurface of mercury or of water, &c.

For the ſeveral kinds and forms of Specula, plane, concave, and convex, with their theory and phenomena, ſee MIRROR. And for their laws and effects, ſee REFLECTION and BURNING-*Glaſs*.

As for the Specula of reflecting teleſcopes, it may here be obſerved, that the perfection of the metal of which they ſhould be made, conſiſts in its hardneſs, whiteneſs, and compactneſs; for upon theſe properties the reflective powers and durability of the Specula depend. There are various compoſitions recommended for theſe Specula, in Smith's Optics, book 3, ch. 2, ſect. 787; alſo by Mr. Mudge in the Philoſ. Tranſ. vol. 67; and in various other places, as by Mr. Edwards, in the Naut. Alm. for 1787, whoſe metal is the whiteſt and beſt of any that I have ſeen.—For the method of grinding, ſee GRINDING.

Mr. Hearne's method of cleaning a tarniſhed Speculum was this: Get a little of the ſtrongeſt ſoap ley from the ſoap-makers, and having laid the Speculum on a table with its face upwards, put on as much of the ley as it will hold, and let it remain about an hour: then rub it ſoftly with a ſilk or muſlin, till the ley is all gone; then put on ſome ſpirit of wine, and rub it dry with another part of the ſilk or muſlin. If the Speculum will not perform well after this, it muſt be new poliſhed. A few faint ſpots of tarniſh may be rubbed off with ſpirit of wine only, without the ley. Smith's Optics, Rem. p. 107.

SPHERE, in Geometry, a ſolid body contained under one ſingle uniform ſurface, every point of which is equally diſtant from a certain point in the middle called its centre.



The Sphere may be ſuppoſed to be generated by the revolution of a ſemicircle ABD about its diameter AB, which is alſo called the *axis* of the Sphere, and the extreme points of the axis, A and B, the *poles* of the Sphere; alſo the middle of the axis C is the *centre*, and half the axis, AC, the *radius*.

Properties of the SPHERE, are as follow.

1. A Sphere may be conſidered as made up of an infinite number of pyramids, whoſe common altitude is equal to the radius of the Sphere, and all their baſes form the ſurface of the Sphere. And therefore the ſolid content of the Sphere is equal to that of a pyramid whoſe altitude is the radius, and its baſe is equal to the ſurface of the Sphere, that is, the ſolid content is equal to $\frac{1}{3}$ of the product of its radius and ſurface.

2. A Sphere is equal to $\frac{2}{3}$ of its circumſcribing cylinder, or of the cylinder of the ſame height and diameter, and therefore equal to the cube of the diameter multiplied by ·5236, or $\frac{2}{3}$ of ·7854; or equal to double a cone of the ſame baſe and height. Hence alſo different Spheres are to one another as the cubes of their diameters. And their ſurfaces as the ſquares of the ſame diameters.

3. The ſurface or ſuperficies of any Sphere, is equal to 4 times the area of its great circle, or of a circle of the ſame diameter as the Sphere. Or

4. The ſurface of the whole Sphere is equal to the area of a circle whoſe radius is equal to the diameter of the Sphere. And, in like manner, the curve ſurface of any ſegment EDF, whether greater or leſs than a hemiſphere, is equal to a circle whoſe radius is the chord line DE, drawn from the vertex D of the ſegment to the circumference of its baſe, or the chord of half its arc.

5. The curve ſurface of any ſegment or zone of a Sphere, is alſo equal to the curve ſurface of a cylinder of the ſame height with that portion, and of the ſame diameter with the Sphere. Alſo the ſurface of the whole Sphere, or of an hemiſphere, is equal to the curve ſurface of its circumſcribing cylinder. And the curve ſurfaces of their correſponding parts are equal, that are contained between any two places parallel to the baſe. And conſequently the ſurface of any ſegment or zone of a Sphere, is as its height or altitude.

Moſt of theſe properties are contained in Archimedes's treatiſe on the Sphere and cylinder. And many other rules for the ſurfaces and ſolidities of Spheres, their ſegments, zones, fruſtums, &c, may be ſeen in my Menſuration, part 3, ſect. 1, prob. 10, &c.

Hence, if d denote the diameter or axis of a Sphere, s its curve ſurface, c its ſolid content, and $a = ·7854$ the area of a circle whoſe diam. is 1; then we ſhall, from the foregoing properties, have theſe following general values or equations, viz,

$$s = 4ad^2 = \frac{6c}{d} = 6\sqrt[3]{\tfrac{2}{3}ac^2}.$$

$$c = \tfrac{1}{6}ds = \tfrac{2}{3}ad^3 = \tfrac{1}{12}\sqrt{\frac{s^3}{a}}.$$

$$d = \frac{6c}{s} = \sqrt{\frac{s}{4a}} = \sqrt[3]{\frac{3c}{2a}}.$$

Doctrine of the SPHERE. See SPHERICS.

Projection of the SPHERE. See PROJECTION.

SPHERE *of Activity*, of any body, is that determinate ſpace or extent all around it, to which, and no farther, the effluvia or the virtue of that body reaches, and in which it operates according to the nature of the body. See ACTIVITY.

SPHERE, in Aſtronomy, that concave orb or expanſe which inveſts our globe, and in which the heavenly

venly bodies, the ſun, moon, ſtars, planets, and comets, appear to be fixed at an equal diſtance from the eye. This is alſo called the Sphere of the world; and it is the ſubject of ſpherical aſtronomy.

This Sphere, as it includes the fixed ſtars, from whence it is ſometimes called the *Sphere of the fixed ſtars*, is immenſely great. So much ſo, that the diameter of the earth's orbit is vaſtly ſmall in reſpect of it; and conſequently the centre of the Sphere is not ſenſibly changed by any alteration of the ſpectator's place in the ſeveral parts of the orbit: but ſtill in all points of the earth's ſurface, and at all times, the inhabitants have the ſame appearance of the Sphere; that is, the fixed ſtars ſeem to poſſeſs the ſame points in the ſurface of the Sphere. For, our way of judging of the places &c of the ſtars, is to conceive right lines drawn from the eye, or from the centre of the earth, through the centres of the ſtars, and thence continued till they cut the Sphere; and the points where theſe lines ſo meet the Sphere, are the apparent places of thoſe ſtars.

The better to determine the places of the heavenly bodies in the Sphere, ſeveral circles are conceived to be drawn in the ſurface of it, which are called circles of the Sphere.

SPHERE, in Geography, &c, denotes a certain diſpoſition of the circles on the ſurface of the earth, with regard to one another, which varies in the different parts of it.

The circles originally conceived on the ſurface of the Sphere of the world, are almoſt all transferred, by analogy, to the ſurface of the earth, where they are conceived to be drawn directly underneath thoſe of the Sphere, or in the ſame poſitions with them; ſo that, if the planes of thoſe of the earth were continued to the Sphere of the ſtars, they would coincide with the reſpective circles on it. Thus, we have an horizon, meridian, equator, &c, on the earth. And as the equinoctial, or equator, in the heavens, divides the Sphere into two equal parts, the one north and the other ſouth, ſo does the equator on the ſurface of the earth divide its globe in the ſame manner. And as the meridians in the heavens paſs through the poles of the equinoctial, ſo do thoſe on the earth, &c. With regard then to the poſition of ſome of theſe circles in reſpect of others, we have a *right*, an *oblique*, and a *parallel* Sphere.

A Right or Direct SPHERE, (fig. 4, plate 26), is that which has the poles of the world PS in its horizon, and the equator FQ in the zenith and nadir. The inhabitants of this Sphere live exactly at the equator of the earth, or under the line. They have therefore no latitude, nor no elevation of the pole. They can ſee both poles of the world; all the ſtars do riſe, culminate, and ſet to them; and the ſun always riſes at right-angles to their horizon, making their days and nights always of equal length, becauſe the horizon biſects the circle of the diurnal revolution.

An Oblique SPHERE, (fig. 5, plate 26), is that in which the equator EQ, as alſo the axis PS, cuts the horizon HO obliquely. In this Sphere, one pole P is above the horizon, and the other below it; and therefore the inhabitants of it ſee always the former pole, but never the latter; the ſun and ſtars &c all riſe and ſet obliquely; and the days and nights are always varying, and growing alternately longer and ſhorter.

A Parallel SPHERE, (fig. 6, plate 26), is that which has the equator in or parallel to the horizon, as well as all the ſun's parallels of declination. Hence, the poles are in the zenith and nadir; the ſun and ſtars move always quite around parallel to the horizon, the inhabitants, if any, being juſt at the two poles, having 6 months continual day, and 6 months night, in each year; and the greateſt height to which the ſun riſes to them, is 23° 28′, or equal to his greateſt declination.

Armillary or Artificial SPHERE, is an aſtronomical inſtrument, repreſenting the ſeveral circles of the Sphere in their natural order; ſerving to give an idea of the office and poſition of each of them, and to reſolve various problems relating to them.

It is thus called, as conſiſting of a number of rings of braſs, or other matter, called by the Latins *armillæ*, from their reſembling of bracelets or rings for the arm.

By this, it is diſtinguiſhed from the globe, which, though it has all the circles of the Sphere on its ſurface; yet is not cut into armillæ or rings, to repreſent the circles ſimply and alone; but exhibits alſo the intermediate ſpaces between the circles.

Armillary Spheres are of different kinds, with regard to the poſition of the earth in them; whence they become diſtinguiſhed into Ptolomaic and Copernican Spheres: in the firſt of which, the earth is in the centre, and in the latter near the circumference, according to the poſition which that planet obtains in thoſe ſyſtems.

The Ptolomaic SPHERE, is that commonly in uſe, and is repreſented in fig. 6, plate 2, vol. 1, with the names of the ſeveral circles, lines, &c of the Sphere inſcribed upon it. In the middle, upon the axis of the Sphere, is a ball T, repreſenting the earth, on the ſurface of which are the circles &c of the earth. The Sphere is made to revolve about the ſaid axis, which remains at reſt; by which means the ſun's diurnal and annual courſes about the earth are repreſented according to the Ptolomaic hypotheſis: and even by means of this, all problems relating to the phenomena of the ſun and earth are reſolved, as upon the celeſtial globe, and after the ſame manner; which ſee deſcribed under GLOBE.

Copernican SPHERE, fig. 7, plate 26, is very different from the Ptolomaic, both in its conſtitution and uſe; and is more intricate in both. Indeed the inſtrument is in the hands of ſo few people, and its uſe ſo inconſiderable, except what we have in the other more common inſtruments, particularly the globe and the Ptolomaic Sphere, that any farther account of it is unneceſſary.

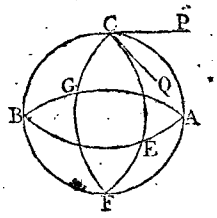
Dr. Long had an Armillary Sphere of glaſs, of a very large ſize, which is deſcribed and repreſented in his Aſtronomy. And Mr. Ferguſon conſtructed a ſimilar one of braſs, which is exhibited in his Lectures, p. 194 &c.

SPHERICAL, ſomething relating to the ſphere. As,

SPHERICAL *Angle*, is the angle formed on the ſurface of a Sphere or globe by the circumferences of

two

two great circles. This angle, formed by the circumferences, is equal to that formed by the planes of the ſame circles, or equal to the inclination of thoſe two planes; or equal to the angle made by their tangents at the angular point. Thus, the inclination of the two planes CAF, CEF, forms the Spherical Angle ACE, equal to the tangential angle PCQ.



The meaſure of a Spherical Angle, ACE, is an arc of a great circle AE, deſcribed from the vertex C, as from a pole, and intercepted between the legs CA and CE.

Hence, 1ſt, Since the inclination of the plane CEF to the plane CAF, is every where the ſame, the angles in the oppoſite interſections, C and F, are equal.—2d, Hence the meaſure of a Spherical Angle ACE, is an arc deſcribed at the interval of a quadrant CA or CE, from the vertex C between the legs CA, CE.—3d, If a circle of the ſphere CEFG cut another AEBG, the adjacent angles AEC and BEC are together equal to two right angles; and the vertical angles AEC, BEF are equal to one another. Alſo all the angles formed at the ſame point, on the ſame ſide of a circle, are equal to two right angles, and all thoſe quite around any point equal to four right angles.

SPHERICAL *Triangle*, is a triangle formed upon the ſurface of a ſphere, by the interſecting arcs of three great circles; as the triangle ACE.

Spherical Triangles are either *right-angled*, *oblique*, *equilateral*, *iſoſceles*, or *ſcalene*, in the ſame manner as plane triangles. They are alſo ſaid to be *quadrantal*, when they have one ſide a quadrant. Two ſides or two angles are ſaid to be of the *ſame affection*, when they are at the ſame time either both greater, or both leſs than a quadrant or a right angle or 90°; and of *different affections*, when one is greater and the other leſs than 90 degrees.

Properties of SPHERICAL *Triangles.*

1. Spherical Triangles have many properties in common with plane ones: Such as, That, in a triangle, equal ſides ſubtend equal angles, and equal angles are ſubtended by equal ſides: That the greater angles are ſubtended by the greater ſides, and the leſs angles by the leſs ſides.

2. In every Spherical Triangle, each ſide is leſs than a ſemicircle: any two ſides taken together are greater than the third ſide: and all the three ſides taken together are leſs than the whole circumference of a circle.

3. In every Spherical Triangle, any angle is leſs than 2 right angles; and the ſum of all the three angles taken together, is greater than 2, but leſs than 6, right angles.

4. In an oblique Spherical Triangle, if the angles at the baſe be of the ſame affection, the perpendicular from the other angle falls within the triangle; but if they be of different affections, the perpendicular falls without the triangle.

Dr. Maſkelyne's remarks on the properties of Spherical Triangles, are as follow: (See the Introd. to my Logs. pa. 160, 2d edition.).

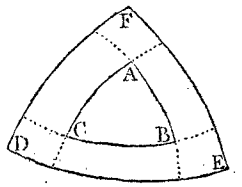
5. "A Spherical Triangle is equilateral, iſoſcelar, or ſcalene, according as it has its three angles all equal, or two of them equal, or all three unequal; and vice verſa.

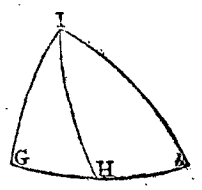
6. The greateſt ſide is always oppoſite the greateſt angle, and the ſmalleſt ſide oppoſite the ſmalleſt angle.

7. Any two ſides taken together are greater than the third.

8. If the three angles are all acute, or all right, or all obtuſe; the three ſides will be, accordingly, all leſs than 90°, or equal to 90°, or greater than 90°; and vice verſa.

9. If from the three angles A, B, C, of a triangle ABC, as poles, there be deſcribed, upon the ſurface of the ſphere, three arches of a great circle DE, DF, FE, forming by their interſections a new Spherical Triangle DEF; each ſide of the new triangle will be the ſupplement of the angle at its pole; and each angle of the ſame triangle, will be the ſupplement of the ſide oppoſite to it in the triangle ABC.





10. In any triangle GHI or GbI, right angled in G, 1ſt, The angles at the hypotenuſe are always of the ſame kind as their oppoſite ſides; 2dly, The hypotenuſe is leſs or greater than a quadrant, according as the ſides including the right angle, are of the ſame or different kinds; that is to ſay, according as theſe ſame ſides are either both acute, or both obtuſe, or as one is acute and the other obtuſe. And, vice verſa, 1ſt, The ſides including the right angle, are always of the ſame kind as their oppoſite angles; 2dly, The ſides including the right angle will be of the ſame or different kinds, according as the hypotenuſe is leſs or more than 90°; but one at leaſt of them will be of 90°, if the hypotenuſe is ſo."

Of the Area of a SPHERICAL *Triangle.* The menſuration of Spherical Triangles and polygons was firſt found out by Albert Girard, about the year 1600, and is given at large in his *Invention Nouvelle en l'Algebre*, pa. 50, &c; 4to, Amſt. 1629. In any Spherical Triangle, the area, or ſurface incloſed by its three ſides upon the ſurface of the globe, will be found by this proportion:

As 8 right angles or 720°,
Is to the whole ſurface of the ſphere;
Or, as 2 right angles or 180°,
To one great circle of the ſphere;
So is the exceſs of the 3 angles above 2 right angles,
To the area of the Spherical Triangle.

Hence, if *a* denote ·7854,

d = diam. of the globe, and
s = ſum of the 3 angles of the triangle;

then

then $add \times \frac{s-180}{180}$ = area of the Spherical Triangle.

Hence alſo, if r denote the radius of the ſphere, and c its circumference;
then the area of the triangle will thus be variouſly expreſſed; viz, Area =

$$ad^2 \times \frac{s-180}{180} = cd \times \frac{s-180}{720} = cr \times \frac{s-180}{360};$$

or barely $= r \times \overline{s-180^\circ}$, in ſquare degrees, when the radius r is eſtimated in degrees; for then the circumference c is $= 360^\circ$.

Farther, becauſe the radius r, of any circle, when eſtimated in degrees, is, $= \frac{180}{3{\cdot}14159 \text{ &c.}} = 57{\cdot}2957795$, the laſt rule $r \times \overline{s-180}$, for expreſſing the area A of the Spherical Triangle, in ſquare degrees, will be barely

$$A = 57{\cdot}2957795\, s - 10313{\cdot}24 =$$
$$= 57\tfrac{5}{17}\tfrac{0}{9}s - 10313\tfrac{1}{4} \text{ very nearly.}$$

Hence may be found the ſums of the three angles in any Spherical Triangle, having its area A known; for the laſt equation gives the ſum

$$s = \frac{A}{r} + 180 = \frac{A}{57{\cdot}29 \text{ &c.}} + 180 = \frac{169A}{9683} + 180.$$

So that, for a Triangle on the ſurface of the earth, whoſe three ſides are known; if it be but ſmall, as of a few miles extent, its area may be found from the known lengths of its ſides, conſidering it as a plane Triangle, which gives the value of the quantity A; and then the laſt rule above will give the value of s, the ſum of the three angles; which will ſerve to prove whether thoſe angles are nearly exact, that have been taken with a very nice inſtrument, as in large and extenſive meaſurements on the ſurface of the earth.

Reſolution of SPHERICAL *Triangles.* See TRIANGLE, and TRIGONOMETRY.

SPHERICAL *Polygon*, is a figure of more than three ſides, formed on the ſurface of a globe by the interſecting arcs of great circles.

The area of any Spherical Polygon will be found by the following proportion; viz,

As 8 right-angles or 720°,
To the whole ſurface of the ſphere;
Or, as 2 right angles or 180°,
To a great circle of the ſphere;
So is the exceſs of all the angles above the product of 180 and 2 leſs than the number of angles,
To the area of the ſpherical polygon.

That is, putting n = the number of angles,
s = ſum of all the angles,
d = diam. of the ſphere,
$a = 78539$ &c,

Then $A = ad^2 \times \frac{s-(n-2)180}{180}$ = the area of the Spherical Polygon.

Hence other rules might be found, ſimilar to thoſe for the area of the Spherical Triangle.

Hence alſo, the ſum s of all the angles of any Spherical Polygon, is always leſs than $180n$, but greater than $180\,(n-2)$, that is leſs than n times 2 right angles, but greater than $n-2$ times 2 right angles.

SPHERICAL *Aſtronomy*, that part of aſtronomy which conſiders the univerſe ſuch as it appears to the eye. See ASTRONOMY.

Under Spherical Aſtronomy, then, come all the phenomena and appearances of the heavens and heavenly bodies, ſuch as we perceive them, without any enquiry into the reaſon, the theory, or truth of them. By which it is diſtinguiſhed from theorical aſtronomy, which conſiders the real ſtructure of the univerſe, and the cauſes of thoſe phenomena.

In the Spherical Aſtronomy, the world is conceived to be a concave Spherical ſurface, in whoſe centre is the earth, or rather the eye, about which the viſible frame revolves, with ſtars and planets fixed in the circumference of it. And on this ſuppoſition all the other phenomena are determined.

The theorical aſtronomy teaches us, from the laws of optics, &c, to correct this Scheme and reduce the whole to a juſter ſyſtem.

SPHERICAL *Compaſſes.* See COMPASSES.

SPHERICAL *Geometry*, the doctrine of the ſphere; particularly of the circles deſcribed on its ſurface, with the method of projecting the ſame on a plane; and meaſuring their arches and angles when projected.

SPHERICAL *Numbers.* See CIRCULAR *Numbers.*

SPHERICAL *Trigonometry.* See *Spherical* TRIGONOMETRY.

SPHERICITY, the quality of a ſphere; or that by which a thing becomes ſpherical or round.

SPHERICS, the Doctrine of the ſphere, particularly of the ſeveral circles deſcribed on its ſurface; with the method of projecting the ſame on a plane. See PROJECTION *of the Sphere.*

A circle of the ſphere is that which is made by a plane cutting it. If the plane paſs through the centre, it is a *great* circle: if not, it is a *little* circle.

The *pole* of a circle, is a point on the ſurface of the ſphere equidiſtant from every point of the circumference of the circle. Hence every circle has two poles, which are diametrically oppoſite to each other; and all circles that are parallel to each other have the ſame poles.

Properties of the Circles of the Sphere.

1. If a ſphere be cut in any manner by a plane, the ſection will be a circle. And a great circle when the ſection paſſes through the centre, otherwiſe it is a *little* circle. Hence, all great circles are equal to each other: and the line of ſection of two great circles of the ſphere, is a diameter of the ſphere: and therefore two great circles interſect each other in points diametrically oppoſite; and make equal angles at thoſe points; and divide each other into two equal parts; alſo any great circle divides the whole ſphere into two equal parts.

2. If a great circle be perpendicular to any other circle, it paſſes through its poles. And if a great circle

paſs

paſs through the pole of any other circle, it cuts it at right angles, and into two equal parts.

3. The diſtance between the poles of two circles, is equal to the angle of their inclination.

4. Two great circles paſſing through the poles of another great circle, cut all the parallels to this latter into ſimilar arcs. Hence, an angle made by two great circles of the ſphere, is equal to the angle of inclination of the planes of theſe great circles. And hence alſo the lengths of thoſe parallels are to one another as the ſines of their diſtances from their common pole, or as the coſines of their diſtances from their parallel great circle. Conſequently, as radius is to the coſine of the latitude of any point on the globe, ſo is the length of a degree at the equator, to the length of a degree in that latitude.

5. If a great circle paſs through the poles of another; this latter alſo paſſes through the poles of the former; and the two cut each other perpendicularly.

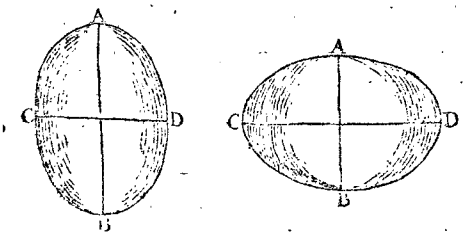
6. If two or more great circles interſect each other in the poles of another great circle; this latter will paſs through the poles of all the former.

7. All circles of the ſphere that are equally diſtant from the centre, are equal; and the farther they are diſtant from the centre, the leſs they are.

8. The ſhorteſt diſtance on the ſurface of a ſphere, between any two points on that ſurface, is the arc of a great circle paſſing through thoſe points. And the ſmaller the circle is that paſſes through the ſame points, the longer is the arc of diſtance between them. Hence the proper meaſure, or diſtance, of two places on the ſurface of the globe, is an arc of a great circle intercepted between the ſame. See Theodoſius and other writers on Spherics.

SPHEROID, a ſolid body approaching to the figure of a ſphere, though not exactly round, but having one of its diameters longer than the other.

This ſolid is uſually conſidered as generated by the rotation of an oval plane figure about one of its axes. If that be the longer or tranſverſe axis, the ſolid ſo generated is called an *oblong* Spheroid, and ſometimes *prolate*, which reſembles an egg, or a lemon; but if the oval revolve about its ſhorter axis, the ſolid will be an *oblate* Spheroid, which reſembles an orange, and in this ſhape alſo is the figure of the earth, and the other planets.



The axis about which the oval revolves, is called the *fixed* axis, as AB; and the other CD is the *revolving* axis: whichever of them happens to be the longer.

When the revolving oval is a perfect ellipſe, the ſolid generated by the revolution is properly called an *ellipſoid*, as diſtinguiſhed from the Spheroid, which is generated from the revolution of any oval whatever, whether it be an ellipſe or not. But generally ſpeaking, in common acceptation, the term Spheroid is uſed for an ellipſoid; and therefore, in what follows, they are conſidered as one and the ſame thing.

Any ſection of a Spheroid, by a plane, is an ellipſe (except the ſections perpendicular to the fixed axe, which are circles); and all parallel ſections are ſimilar ellipſes, or having their tranſverſe and conjugate axes in the ſame conſtant ratio; and the ſections parallel to the fixed axe are ſimilar to the ellipſe from which the ſolid was generated. See my Menſuration pa. 267 &c, 2d edit.

For the Surface of a Spheroid, whether it be oblong or oblate. Let f denote the fixed axe,

r the revolving axe,

$$a = \cdot 7854, \text{ and } q = \frac{ff \sim rr}{ff + rr};$$

then will the ſurface s be expreſſed by the following ſeries, uſing the upper ſigns for the oblong ſpheroid, and the under ſigns for the oblate one; viz,

$$s = 4arf \times \left(1 \mp \frac{1}{2.3}q - \frac{1}{2.4.5}q^2 \mp \frac{3}{2.4.6.7}q^3 \&c\right);$$

where the ſigns of the terms, after the firſt, are all negative for the oblong Spheroid, but alternately poſitive and negative for the oblate one.

Hence, becauſe the factor $4arf$ is equal to 4 times the area of the generating ellipſe, it appears that the ſurface of the oblong Spheroid is leſs than 4 times the generating ellipſe, but the ſurface of the oblate Spheroid is greater than 4 times the ſame: while the ſurface of the ſphere falls in between the two, being juſt equal to 4 times its generating circle.

Huygens, in his Horolog. Oſcillat. prop. 9, has given two elegant conſtructions for deſcribing a circle equal to the ſuperficies of an oblong and an oblate Spheroid, which he ſays he found out towards the latter end of the year 1657. As he gave no demonſtrations of theſe, I have demonſtrated them, and alſo rendered them more general, by extending and adapting them to the ſurface of any ſegment or zone of the Spheroid. See my Menſuration, pa. 308 &c, 2d ed. where alſo are ſeveral other rules and conſtructions for the ſurfaces of Spheroids, beſides thoſe of their ſegments, and fruſtums.

Of the Solidity of a Spheroid. Every Spheroid, whether oblong or oblate, is, like a ſphere, exactly equal to two-thirds of its circumſcribing cylinder. So that if f denote the fixed axe, r the revolving axe, and $a = \cdot 7854$; then $\frac{2}{3}afr^2$ denotes the ſolid content of either Spheroid. Or, which comes to the ſame thing, if t denote the tranſverſe, and c the conjugate axe of the generating ellipſe;

then $\frac{2}{3}ac^2t$ is the content of the oblong Spheroid,
and $\frac{2}{3}act^2$ is the content of the oblate Spheroid.

Conſequently, the proportion of the former ſolid to the latter, is as c to t, or as the leſs axis to the greater.

Farther, if about the two axes of an ellipſe be generated

nerated two ſpheres and two ſpheroids, the four ſolids will be continued proportionals, and the common ratio will be that of the two axes of the ellipſe; that is, as the greater ſphere, or the ſphere upon the greater axe, is to the oblate Spheroid, ſo is the oblate Spheroid to the oblong Spheroid, and ſo is the oblong Spheroid to the leſs ſphere, and ſo is the tranſverſe axis to the conjugate. See my Menſuration, pa. 327 &c, 2d ed. where may be ſeen many other rules for the ſolid contents of Spheroids, and their various parts. See alſo Archimedes on Spheroids and Conoids.

Dr. Halley has demonſtrated, that in a ſphere, Mercator's nautical meridian line is a ſcale of logarithmic tangents of the half complements of the latitudes. But as it has been found that the ſhape of the earth is ſpheroidal, this figure will make ſome alteration in the numbers reſulting from Dr. Halley's theorem. Maclaurin has therefore given a rule, by which the meridional parts to any Spheroid may be found with the ſame exactneſs as in a ſphere. There is alſo an ingenious tract by Mr. Murdoch on the ſame ſubject. See Philoſ. Tranſ. No. 219. Mr. Cotes has alſo demonſtrated the ſame propoſition, Harm. Menſ. pa. 20, 21. See MERIDIONAL *Parts*.

Univerſal SPHEROID, a name given to the ſolid generated by the rotation of an ellipſe about ſome other diameter, which is neither the tranſverſe nor conjugate axis. This produces a figure reſembling a heart. See my Menſuration, pa. 352, 2d ed.

SPINDLE, in Geometry, a ſolid body generated by the revolution of ſome curve line about its baſe or double ordinate AB; in oppoſition to a conoid, which is generated by the rotation of the curve about its axis or abſciſs, perpendicular to its ordinate.

The Spindle is denominated circular, elliptic, hyperbolic, or parabolic, &c, according to the figure of its generating curve. See my Menſur. in ſeveral places.

SPINDLE, in Mechanics, ſometimes denotes the axis of a wheel, or roller, &c; and its ends are the pivots.

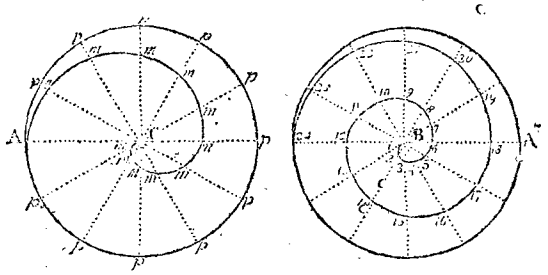
See alſo *Double* CONE.

SPIRAL, in Geometry, a curve line of the circular kind, which, in its progreſs, recedes always more and more from a point within, called its centre; as in winding from the vertex of a cone down to its baſe.

The firſt treatiſe on a Spiral is by Archimedes, who thus deſcribes it: Divide the circumference of a circle A*pp* &c into any number of equal parts, by a continual biſection at the points *pp* &c. Divide alſo the radius AC into the ſame number of equal parts, and make C*m*, C*m*, C*m*, &c, equal to 1, 2, 3, &c of theſe equal parts; then a line drawn, with a ſteady hand, drawn through all the points *m*, *m*, *m*, &c, will trace out the Spiral.

This is more particularly called the *firſt* Spiral, when it has made one complete revolution to the point A; and the ſpace included between the Spiral and the radius CA, is the *Spiral ſpace*.

The firſt Spiral may be continued to a *ſecond*, by deſcribing another circle with double the radius of the firſt; and the ſecond may be continued to a *third*, by a third circle; and ſo on.



Hence it follows, that the parts of the circumference A*p* are as the parts of the radii C*m*; or A*p* is to the whole circumference, as C*m* is to the whole radius. Conſequently, if *c* denote the circumference, *r* the radius, $x = Cm$, and $y = Ap$; then there ariſes this proportion $r : c :: x : y$, which gives $ry = cx$ for the equation of this Spiral; and which therefore it has in common with the quadratrix of Dinoſtrates, and that of Tſchirnhauſen: ſo that $r^n y^m = c^n x^m$ will ſerve for infinite Spirals and quadratrices. See QUADRATRIX.

The Spiral may alſo be conceived to be thus generated, by a continued uniform motion. If a right line, as AB (*laſt fig. above*) having one end moveable about a fixed point at B, be uniformly turned round, ſo as the other end A may deſcribe the circumference of a circle; and at the ſame time a point be conceived to move uniformly forward from B towards A, in the right line or radius AB, ſo that the point may deſcribe that line, while the line generates the circle; then will the point, with its two motions, deſcribe the curve B, 1, 2, 3, 4, 5, &c, of the ſame Spiral as before.

Again, if the point B be conceived to move twice as ſlow as the line AB, ſo that it ſhall get but half way along BA, when that line ſhall have formed the circle; and if then you imagine a new revolution to be made of the line carrying the point, ſo that they ſhall end their motion at laſt together, there will be formed a *double* Spiral line, as in the laſt figure. From the manner of this deſcription may eaſily be drawn theſe corollaries:

1. That the lines B12, B11, B10, &c, making equal angles with the firſt and ſecond Spiral (as alſo B12, B10, B8), &c, are in arithmetical progreſſion.

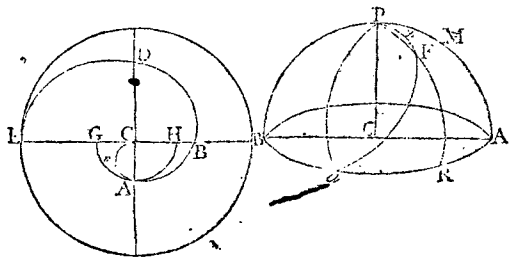
2. The lines B7, B10, &c, drawn any how to the firſt Spiral, are to one another as the arcs of the circle intercepted between BA and thoſe lines; becauſe whatever parts of the circumference the point A deſcribes, as ſuppoſe 7, the point B will alſo have run over 7 parts of the line AB.

3. Any lines drawn from B to the ſecond Spiral, as B18, B22, &c, are to each other as the aforeſaid arcs, together with the whole circumference added on both ſides: for at the ſame time that the point A runs over 12, or the whole circumference, or perhaps 7 parts more, ſhall the point B have run over 12, and 7 parts of the line AB, which is now ſuppoſed to be divided into 24 equal parts.

4. The

4. The firſt Spiral line is equal to half the circumference of the firſt circle; for the radii of the ſectors, and conſequently of the arcs, are in a ſimple arithmetic progreſſion, while the circumference of the circle contains as many arcs equal to the greateſt; therefore the circumference is in proportion to all thoſe Spiral arcs, as 2 to 1.

5. The firſt Spiral ſpace is equal to $\frac{1}{3}$ of the firſt or circumſcribing circle. That is, the area CABDE of the Spiral, is equal to $\frac{1}{3}$ part of the circle deſcribed with the radius CE. In like manner, the whole Spiral area, generated by the ray drawn from the point C to the curve, when it makes two revolutions, is $\frac{2}{3}$ of the circle deſcribed with the radius 2CE.



And, generally, the whole area generated by the ray from the beginning of the motion, till after any number n of revolutions, is equal to $\frac{n}{3}$ of the circle whoſe radius is $n \times$ CE, that is equal to the 3d part of the ſpace which is the ſame multiple of the circle deſcribed with the greateſt ray, as the number of revolutions is of unity.

In like manner alſo, any ſector or portion of the area of the Spiral, terminated by the curve C*m*A and the right line CA, is equal to $\frac{1}{3}$ of the circular ſector CAG terminated by the right lines CA and CG, this latter being the ſituation of the revolving ray when the point that deſcribes the curve ſets out from C. See Maclaurin's Flux. Introd. pa. 30, 31. Se alſo QUADRATURE of the Spiral of Archimedes.

SPIRAL, *Logiſtic*, or *Logarithmic*. See LOGISTIC and QUADRATURE.

SPIRAL *of Pappus*, a Spiral formed on the ſurface of a ſphere, by a motion ſimilar to that by which the Spiral of Archimedes is deſcribed on a plane. This Spiral is ſo called from its inventor Pappus. Collect. Mathem. lib. 4 prop. 30. Thus, if C be the centre of the ſphere, ARBA a great circle, P its pole; and while the quadrant PMA revolves about the pole P with an uniform motion, if a point proceeding from P move with a given velocity along the quadrant, it will trace upon the ſpherical ſurface the Spiral PZF*a*.

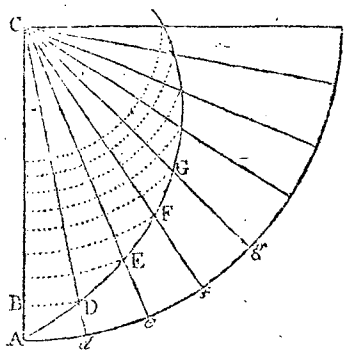
Now if we ſuppoſe the quadrant PMA to make a complete revolution in the ſame time that the point, which traces the Spiral on the ſurface of the ſphere, deſcribes the quadrant, which is the caſe conſidered by Pappus; then the portion of the ſpherical ſurface terminated by the whole Spiral, and the circle ARBA, and the quadrant PMA, will be equal to the ſquare of the diameter AB. In any other caſe, the area PMA*a* FZP is to the ſquare of that diameter AB, as the arc A*a* is to the whole circumference ARBA. And this area is always to the ſpherical triangle PA*a*, as a ſquare is to its circumſcribing circle, or as the diameter of a circle is to half its circumference, or as 2 is to 3·14159 &c. See Maclaurin's Fluxions, Introd. pa. 31—33.

The portion of the ſpherical ſurface, terminated by the quadrant PMA, with the arches AR, FR, and the ſpiral PZF, admits of a perfect quadrature, when the ratio of the arch A*a* to the whole circumference can be aſſigned. See Maclaurin, ibid. pa. 33.

Parabolic SPIRAL. See HELICOID.

Proportional SPIRAL, is generated by ſuppoſing the radius to revolve uniformly, and a point from the circumference to move towards the centre with a motion decreaſing in geometrical progreſſion. See LOGISTIC.

From the nature of a decreaſing geometrical progreſſion, it is eaſy to conceive that the radius CA may be continually divided; and although each ſucceſſive diviſion becomes ſhorter than the next preceding one, yet there muſt be an infinite number of diviſions or terms before the laſt of them become of no finite magnitude. Whence it follows, that this Spiral winds continually round the centre, without ever falling into it in any finite number of revolutions.



It is alſo evident that any Proportional Spiral cuts the intercepted radii at equal angles: for if the diviſions A*d*, *de*, *ef*, *fg*, &c, of the circumference be very ſmall, the ſeveral radii will be ſo cloſe to one another, that the intercepted parts AD, DE, EF, FG, &c, of the Spiral may be taken as right lines; and the triangles CAD, CDE, CEF, &c, will be ſimilar, having equal angles at the point C, and the ſides about thoſe angles proportional; therefore the angles at A, D, E, F, &c, are equal, that is, the ſpiral cuts the radii at equal angles. Robertſon's Elem. of Navig. book 2, pa. 87.

Proportional Spirals are ſuch Spiral lines as the rhumb lines on the terraqueous globe; which, becauſe they make equal angles with every meridian, muſt alſo make equal angles with the meridians in the ſtereographic projection on the plane of the equator, and therefore will be, as Dr. Halley obſerves, Proportional Spirals about the polar point. From whence he demonſtrates, that the meridian line is a ſcale of log. tangents

of the half complements of the latitudes. See RHUMB, LOXODROMY, and MERIDIONAL *Parts*.

SPIRAL *Pump*. See *Archimedes*'s SCREW.

SPIRAL, in Architecture and Sculpture, denotes a curve that aſcends, winding about a cone, or ſpire, ſo that all the points of it continually approach the axis.

By this it is diſtinguiſhed from the Helix, which winds in the ſame manner about a cylinder.

SPORADES, in Aſtronomy, a name by which the ancients diſtinguiſhed ſuch ſtars as were not included in any conſtellation. Theſe the moderns more uſually call *unformed*, or *extraconſtellary* ſtars.

Many of the Sporades of the ancients have been ſince formed into new conſtellations: thus, of thoſe between Urſa Major and Leo, Hevelius has formed a conſtellation named Leo Minor; and of thoſe between Urſa Minor and Auriga, he alſo formed the Lynx; and of thoſe under the tail of Urſa Minor, another called Canis Venaticus; &c.

SPOTS, in Aſtronomy, are dark places obſerved on the diſks or faces of the ſun, moon, and planets.

The Spots on the ſun are ſeldom if ever viſible, except through a teleſcope. I have indeed met with perſons whoſe eyes were ſo good that they have declared they could diſtinguiſh the ſolar Spots; and it is mentioned in Joſephus à Coſta's Natural and Moral Hiſtory of the Weſt Indies, book 1, ch. 2, before the uſe of teleſcopes, that in Peru there are Spots to be ſeen in the ſun, which are not to be ſeen in Europe. See a memoir by Dr. Zach, in the Aſtronomical Ephemeris of the Acad. of Berlin for 1788, relating to the diſcoveries and unpubliſhed papers of Thomas Harriot the celebrated algebraiſt. In that memoir it is ſhewn, for the firſt time, that Harriot was alſo an excellent aſtronomer, both theoretical and practical; that he made innumerable obſervations with teleſcopes from the year 1610, and, amongſt them, 199 obſervations of the ſolar Spots, with their drawings, calculations, and the determinations of the ſun's revolution round his axis. Theſe Spots were alſo diſcovered near about the ſame time by Galileo and Scheiner. See Joh. Fabricius Phryſius De Maculis in Sole obſervatis & apparente eorum cum ſole converſione narratio, 1611; alſo Galileo's Iſtoria e Demonſtrazioni intorne alle Machie Solare e loro accidenti, 1613.

Some diſtinguiſh the Spots into Maculæ, or dark Spots; and Faculæ, or bright Spots; but there ſeems but little foundation for any ſuch diviſion. They are very changeable as to number, form, &c; and are ſometimes in a multitude, and ſometimes none at all. Some imagine they may become ſo numerous, as to hide the whole face of the Sun, or at leaſt the greater part of it; and to this they aſcribe what Plutarch mentions, viz, that in the firſt year of the reign of Auguſtus, the ſun's light was ſo faint and obſcure, that one might look ſteadily at it with the naked eye. To which Kepler adds, that in 1547, the Sun appeared reddiſh, as when viewed through a thick miſt; and hence he conjectures that the Spots in the ſun are a kind of dark ſmoke, or clouds, floating on his ſurface.

Some again will have them ſtars, or planets, paſſing over the body of the ſun: but others, with more probability, think they are opake bodies, in manner of cruſts, formed like the ſcums on the ſurface of liquors.

Dr. Derham, from a variety of particulars, which he has recited, concerning the ſolar Spots, and their congruity to what we obſerve in our own globe, infers, that they are cauſed by the eruption of ſome new volcano in the ſun, which pouring out at firſt a prodigious quantity of ſmoke and other opake matter, cauſeth the Spots: and as that fuliginous matter decays and ſpends itſelf, and the volcano at laſt becomes more torrid and flaming, ſo the Spots decay and become umbræ, and at laſt faculæ: which faculæ he ſuppoſes to be no other than more flaming lighter parts than any other parts of the ſun. Philoſ. Tranſ. vol. 23, p. 1504, or Abr. vol. 4, p. 235.

Dr. Franklin (in his Exper. and Obſerv. p. 266.) ſuggeſts a conjecture, that the parts of the Sun's ſulphur ſeparated by fire, riſe into the atmoſphere, and there being freed from the immediate action of the fire, they collect into cloudy maſſes, and gradually becoming too heavy to be longer ſupported, they deſcend to the ſun, and are burnt over again. Hence, he ſays, the Spots appearing on his face, which are obſerved to diminiſh daily in ſize, then conſuming edges being of particular brightneſs.

For another ſolution of theſe phenomena, ſee MACULÆ. Various other accounts and hypotheſes of theſe Spots may be ſeen in many of the other volumes of the Philoſ. Tranſ. In one of theſe, viz, vol. 57, pa. 398, Dr. Horſley attempts to determine the height of the ſun's atmoſphere from the height of the ſolar Spots above his ſurface.

By means of the obſervations of theſe Spots, has been determined the period of the ſun's rotation about his axis, viz, by obſerving their periodical return.

The lunar Spots are fixed: and aſtronomers reckon about 48 of them on the moon's face; to each of which they have given names. The 21ſt, called *Tycho*, is one of the moſt conſiderable.

Circular SPOTS, in Electricity. See CIRCULAR Spots and COLOURS.

Lucid SPOTS, *in the heavens*, are ſeveral little whitiſh Spots, that appear magnified, and more luminous when ſeen through teleſcopes; and yet without any ſtars in them. One of theſe is in Andromeda's girdle, and was firſt obſerved in 1612, by Simon Marius: it has ſome whitiſh rays near its middle, is liable to ſeveral changes, and is ſometimes inviſible. Another is near the ecliptic, between the head and bow of Sagittarius; it is ſmall, but very luminous. A third is in the back of the Centaur, which is too far ſouth to be ſeen in Britain. A fourth, of a ſmaller ſize, is before Antinous's right foot, having a ſtar in it, which makes it appear more bright. A fifth is in the conſtellation Hercules, between the ſtars ζ and η, which is viſible to the naked eye, though it is but ſmall, when the ſky is clear and the moon abſent. It is probable that with more powerful teleſcopes theſe lucid Spots will be found to be congeries of very minute fixed ſtars.

Planetary SPOTS, are thoſe of the planets. Aſtronomers find that the planets are not without their ſpots. Jupiter, Mars, and Venus, when viewed through a teleſcope, ſhew ſeveral very remarkable ones: and it is

by

by the motion of theſe Spots, that the rotation of the planets about their axes is concluded, in the ſame manner as that of the ſun is deduced from the apparent motion of his maculæ.

SPOUT, or *Water* SPOUT, an extraordinary meteor, or appearance, conſiſting of a moving column or pillar of water; called by the Latins *typho*, and *Ambo*; and by the French *trompe*, from its ſhape, which reſembles a ſpeaking trumpet, the wideſt end uppermoſt.

Its firſt appearance is in form of a deep cloud, the upper part of which is white, and the lower black. From the lower part of this cloud there hangs, or rather falls down, what is properly called the Spout, in manner of a conical tube, largeſt at top. Under this tube is always a great boiling and flying up of the water of the ſea, as in a jet d'eau. For ſome yards above the ſurface of the ſea, the water ſtands as a column, or pillar; from the extremity of which it ſpreads, and goes off, as in a kind of ſmoke. Frequently the cone deſcends ſo low as to the middle of this column, and continues for ſome time contiguous to it; though ſometimes it only points to it at ſome diſtance, either in a perpendicular, or in an oblique line.

Frequently it can ſcarce be diſtinguiſhed, whether the cone or the column appear the firſt, both appearing all of a ſudden againſt each other. But ſometimes the water boils up from the ſea to a great height, without any appearance of a Spout pointing to it, either perpendicularly or obliquely. Indeed, generally, the boiling or flying up of the water has the priority, this always preceding its being formed into a column. For the moſt part the cone does not appear hollow till towards the end, when the ſea water is violently thrown up along its middle, as ſmoke up a chimney: ſoon after this, the Spout or canal breaks and diſappears; the boiling up of the water, and even the pillar, continuing to the laſt, and for ſome time afterwards; ſometimes till the Spout form itſelf again, and appear anew, which it will do ſeveral times in a quarter of an hour. See a deſcription of ſeveral Water-Spouts by Mr. Gordon, and by Dr. Stuart, in Phil. Tranſ. Abr. vol. iv, pa. 103 &c.

M. de la Pryme, from a near obſervation of two or three Spouts in Yorkſhire, deſcribed in the Philoſophical Tranſactions, num. 281, or Abr. vol. iv, pa. 106, concludes, that the Water Spout is nothing but a gyration of clouds by contrary winds meeting in a point, or centre; and there, where the greateſt condenſation and gravitation is, falling down into a pipe, or great tube, ſomewhat like Archimedes's ſpiral ſcrew; and, in its working and whirling motion, abſorbing and raiſing the water, in the ſame manner as the ſpiral ſcrew does; and thus deſtroying ſhips &c.

Thus, June the 21ſt, he obſerved the clouds mightily agitated above, and driven together; upon which they became very black, and were hurried round; whence proceeded a moſt audible whirling noiſe like that uſually heard in a mill. Soon after there iſſued a long tube, or Spout, from the centre of the congregated clouds, in which he obſerved a ſpiral motion, like that of a ſcrew, by which the water was raiſed up.

Again, Auguſt 15, 1687, the wind blowing at the ſame time out of the ſeveral quarters, created a great vortex and whirling among the clouds, the centre of which every now and then dropt down, in ſhape of a long thin black pipe, in which he could diſtinctly behold a motion like that of a ſcrew, continually drawing upwards, and ſcrewing up, as it were, wherever it touched.

In its progreſs it moved ſlowly over a grove of trees, which bent under it like wands, in a circular motion. Proceeding, it tore off the thatch from a barn, bent a huge oak tree, broke one of its greateſt limbs, and threw it to a great diſtance. He adds, that whereas it is commonly ſaid, the water works and riſes in a column, before the tube comes to touch it, this is doubtleſs a miſtake, owing to the fineneſs and tranſparency of the tubes, which do moſt certainly touch the ſurface of the ſea, before any conſiderable motion can be raiſed in it; but which do not become opake and viſible, till after they have imbibed a conſiderable quantity of water.

The diſſolution of Water-Spouts he aſcribes to the great quantity of water they have glutted: which, by its weight, impeding their motion, upon which their force, and even exiſtence depends, they break, and let go their contents; which ule to prove fatal to whatever is found underneath.

A notable inſtance of this may be ſeen in the Philoſophical Tranſactions (num. 363, or Abr. vol. iv. pa 108) related by Dr. Richardſon. A Spout, in 1718, breaking on Emmotmoor, nigh Coln, in Lancaſhire, the country was immediately overflowed; a brook, in a few minutes, roſe ſix feet perpendicularly high; and the ground upon which the Spout fell, which was 66 feet over, was torn up to the very rock, which was no leſs than 7 feet deep; and a deep gulf was made for above half a mile, the earth being raiſed in vaſt heaps on each ſide. See a deſcription and figure of a Water-Spout, with an attempt to account for it in Franklin's Exp. and Obſ. pa. 226, &c.

Signor Beccaria has taken pains to ſhow that Water-Spouts have an electrical origin. To make this more evident, he firſt deſcribes the circumſtances attending their appearance, which are the following.

They generally appear in calm weather. The ſea ſeems to boil, and to ſend up a ſmoke under them, riſing in a hill towards the Spout. At the ſame time, perſons who have been near them have heard a rumbling noiſe. The form of a Water-Spout is that of a ſpeaking trumpet, the wider end being in the clouds, and the narrower end towards the ſea.

The ſize is various, even in the ſame Spout. The colour is ſometimes inclining to white, and ſometimes to black. Their poſition is ſometimes perpendicular to the ſea, ſometimes oblique; and ſometimes the Spout itſelf is in the form of a curve. Their continuance is very various, ſome diſappearing as ſoon as formed, and ſome continuing a conſiderable time. One that he had heard of continued a whole hour. But they often vaniſh, and preſently appear again in the ſame place. The very ſame things that Water-Spouts are at ſea, are ſome kinds of whirlwinds and hurricanes by land. They have been known to tear up trees, to throw down buildings, and make caverns in the earth; and in all theſe caſes, to ſcatter earth, bricks, ſtones, timber, &c.

to

to a great diſtance in every direction. Great quantities of water have been left, or raiſed by them, ſo as to make a kind of deluge; and they have always been attended by a prodigious rumbling noiſe.

That theſe phenomena depend upon electricity cannot but appear very probable from the nature of ſeveral of them; but the conjecture is made more probable from the following additional circumſtances. They generally appear in months peculiarly ſubject to thunder-ſtorms, and are commonly preceded, accompanied, or followed by lightning, rain, or hail, the previous ſtate of the air being ſimilar. Whitiſh or yellowiſh flaſhes of light have ſometimes been ſeen moving with prodigious ſwiftneſs about them. And laſtly, the manner in which they terminate exactly reſembles what might be expected from the prolongation of one of the uniform protuberances of electrified clouds, mentioned before, towards the ſea; the water and the cloud mutually attracting one another: for they ſuddenly contract themſelves, and diſperſe almoſt at once; the cloud riſing, and the water of the ſea under it falling to its level. But the moſt remarkable circumſtance, and the moſt favourable to the ſuppoſition of their depending on electricity, is, that they have been diſperſed by preſenting to them ſharp pointed knives or ſwords. This, at leaſt, is the conſtant practice of mariners, in many parts of the world, where theſe Water-Spouts abound, and he was aſſured by ſeveral of them, that the method has often been undoubtedly effectual.

The analogy between the phenomena of Water Spouts and electricity, he ſays, may be made viſible, by hanging a drop of water to a wire communicating with the prime conductor, and placing a veſſel of water under it. In theſe circumſtances, the drop aſſumes all the various appearances of a Water Spout, both in its riſe, form, and manner of diſappearing. Nothing is wanting but the ſmoke, which may require a great force of electricity to become viſible.

Mr. Wilcke alſo conſiders the Water-Spout as a kind of great electrical cone, raiſed between the cloud ſtrongly electrified, and the ſea or the earth, and he relates a very remarkable appearance which occurred to himſelf, and which ſtrongly confirms his ſuppoſition. On the 20th of July 1758, at three o'clock in the afternoon, he obſerved a great quantity of duſt riſing from the ground, and covering a field, and part of the town in which he then was. There was no wind, and the duſt moved gently towards the eaſt, where appeared a great black cloud, which, when it was near its zenith, electrified his apparatus poſitively, and to as great a degree as ever he had obſerved it to be done by natural electricity. This cloud paſſed his zenith, and went gradually towards the weſt, the duſt then following it, and continuing to riſe higher and higher till it compoſed a thick pillar, in the form of a ſugar-loaf, and at length ſeemed to be in contact with the cloud. At ſome diſtance from this, there came, in the ſame path, another great cloud, together with a long ſtream of ſmaller clouds, moving faſter than the preceding. Theſe clouds electrified his apparatus negatively, and when they came near the poſitive cloud, a flaſh of lightning was ſeen to dart through the cloud of duſt, the poſitive cloud, the large negative cloud, and, as far as the eye could diſtinguiſh, the whole train of ſmaller negative clouds which followed it. Upon this, the negative clouds ſpread very much, and diſſolved in rain, and the air was preſently clear of all the duſt. The whole appearance laſted not above half an hour. See Prieſtley's Electr. vol. 1, pa. 438, &c.

This theory of Water-Spouts has been ſa[illegible] confirmed by the account which Mr. Forſter gives of one of them, in his Voyage Round the World, vol. [illegible] pa. 191, &c. On the coaſt of New Zealand he had an opportunity of ſeeing ſeveral, one of which he has particularly deſcribed. The water, he ſays, in a ſpace of fifty or ſixty fathoms, moved towards the centre, and there riſing into vapour, by the force of the whirling motion, aſcended in a ſpiral form towards the clouds. Directly over the whirlpool, or agitated ſpot in the ſea, a cloud gradually tapered into a long ſlender tube, which ſeemed to deſcend to meet the riſing ſpiral, and ſoon united with it into a ſtraight column of a cylindrical form. The water was whirled upwards with the greateſt violence in a ſpiral, and appeared to leave a hollow ſpace in the centre; ſo that the water ſeemed to form a hollow tube, inſtead of a ſolid column; and that this was the caſe, was rendered ſtill more probable by the colour, which was exactly like that of a hollow glaſs tube. After ſome time, this laſt column was incurvated, and broke like the others; and the appearance of a flaſh of lightning which attended its diſjunction, as well as the hail ſtones which fell at the time, ſeemed plainly to indicate, that Water-Spouts either owe their formation to the electric matter, or, at leaſt, that they have ſome connection with it.

In Pliny's time, the ſeamen uſed to pour vinegar into the ſea, to aſſuage and lay the Spout when it approached them: our modern ſeamen think to keep it off, by making a noiſe with filing and ſcratching violently on the deck; or by diſcharging great guns to diſperſe it.

See the figure of a Water-Spout, fig. 1, plate 27.

SPRING, in Natural Hiſtory, a fountain or ſource of water, riſing out of the ground.

The moſt general and probable opinion among philoſophers, on the formation of Springs, is, that they are owing to rain. The rain-water penetrates the earth till ſuch time as it meets a clayey ſoil, or ſtratum; which proving a bottom ſufficiently ſolid to ſuſtain and ſtop its deſcent, it glides along it that way to which the earth declines, till, meeting with a place or aperture on the ſurface, through which it may eſcape, it forms a Spring, and perhaps the head of a ſtream or brook.

Now, that the rain is ſufficient for this effect, appears from hence, that upon calculating the quantity of rain and ſnow which falls yearly on the tract of ground that is to furniſh, for inſtance, the water of the Seine, it is found that this river does not take up above one-ſixth part of it.

Springs commonly riſe at the bottom of mountains; the reaſon is, that mountains collect the moſt waters, and give them the greateſt deſcent the ſame way. And if we ſometimes ſee Springs on high grounds, and even on the tops of mountains, they muſt come from other remoter places, conſiderably higher, along beds of clay, or clayey ground, as in their natural channels. So that if there happen to be a valley between a mountain on whoſe top is a Spring, and the mountain which is to

furniſh it with water, the Spring muſt be conſidered as water conducted from a reſervoir of a certain height, through a ſubterraneous channel, to make a jet of an almoſt equal height.

As to the manner in which this water is collected, ſo as to form reſervoirs for the different kinds of Springs, it ſeems to be this: the tops of mountains uſually abound with cavities and ſubterraneous caverns, formed by nature to ſerve as reſervoirs; and their pointed ſummits, which ſeem to pierce the clouds, ſtop thoſe vapours which float in the atmoſphere; which being thus condenſed, they precipitate in water, and by their gravity and fluidity eaſily penetrate through beds of ſand and the lighter earth, till they become ſtopped in their deſcent by the denſer ſtrata, ſuch as beds of clay, ſtone, &c, where they form a baſon or cavern, and working a paſſage horizontally, or a little declining, they iſſue out at the ſides of the mountains. Many of theſe Springs diſcharge water, which running down between the ridges of hills, unite their ſtreams, and form rivulets or brooks, and many of theſe uniting again on the plain, become a river.

The perpetuity of divers Springs, always yielding the ſame quantity of water, equally when the leaſt rain or vapour is afforded as when they are the greateſt, furniſh, in the opinion of ſome, conſiderable objections to the univerſality or ſufficiency of the theory above. Dr. Derham mentions a Spring in his own pariſh of Upminſter, which he could never perceive by his eye was diminiſhed in the greateſt droughts, even when all the ponds in the country, as well as an adjoining brook, had been dry for ſeveral months together; nor ever to be increaſed in the moſt rainy ſeaſons, excepting perhaps for a few hours, or at moſt for a day, from ſudden and violent rains. Had this Spring, he thought, derived its origin from rain or vapours, there would be found an increaſe and decreaſe of its water correſponding to thoſe of its cauſes; as we actually find in ſuch temporary Springs, as have undoubtedly their riſe from rain and vapour.

Some naturaliſts therefore have recourſe to the ſea, and derive the origin of Springs immediately from thence. But how the ſea-water ſhould be raiſed up to the ſurface of the earth, and even to the tops of the mountains, is a difficulty, in the ſolution of which they cannot agree. Some fancy a kind of hollow ſubterranean rocks to receive the watery vapours raiſed from channels communicating with the ſea, by means of an internal fire, and to act the part of alembics, in freeing them from their ſaline particles, as well as condenſing and converting them into water. This kind of ſubterranean laboratory, ſerving for the diſtillation of ſea-water, was the invention of Des Cartes: ſee his Princip. part 4, § 64. Others, as De la Hire &c (Mem. de l'Acad. 1703) ſet aſide the alembics, and think it enough that there be large ſubterranean reſervoirs of water at the height of the ſea, from whence the warmth of the bottom of the earth, &c, may raiſe vapours; which pervade not only the intervals and fiſſures of the ſtrata, but the bodies of the ſtrata themſelves, and at length arrive near the ſurface; where, being condenſed by the cold, they glide along on the firſt bed of clay they meet with, till they iſſue forth by ſome aperture in the ground. De la Hire adds, that the ſalts of ſtones and minerals may contribute to the detaining and fixing the vapours, and converting them into water. Farther, it is urged by ſome, that there is a ſtill more natural and eaſy way of exhibiting the riſe of the ſea-water up into mountains &c, viz, by putting a little heap of ſand, or aſhes, or the like, into a baſon of water; in which caſe the ſand &c will repreſent the dry land, or an iſland; and the baſon of water, the ſea about it. Here, ſay they, the water in the baſon will riſe to the top of the heap, or nearly ſo, in the ſame manner, and from the ſame principle, as the waters of the ſea, lakes, &c, riſe in the hills. The principle of aſcent in both is accordingly ſuppoſed to be the ſame with that of the aſcent of liquids in capillary tubes, or between contiguous planes, or in a tube filled with aſhes; all which are now generally accounted for by the doctrine of attraction.

Againſt this laſt theory, Perrault and others have urged ſeveral unanſwerable objections. It ſuppoſes a variety of ſubterranean paſſages and caverns, communicating with the ſea, and a complicated apparatus of alembics, with heat and cold, &c, of the exiſtence of all which we have no ſort of proof. Beſides, the water that is ſuppoſed to aſcend from the depths of the ſea, or from ſubterranean canals proceeding from it, through the porous parts of the earth, as it riſes in capillary tubes, aſcends to no great height, and in much too ſmall a quantity to furniſh ſprings with water, as Perrault has ſufficiently ſhewn. And though the ſand and earth through which the water aſcends may acquire ſome ſaline particles from it, they are nevertheleſs incapable of rendering it ſo freſh as the water of our fountains is generally found to be. Not to add, that in proceſs of time the ſaline particles of which the water is deprived, either by ſubterranean diſtillation or filtration, muſt clog and obſtruct thoſe canals and alembics, by which it is ſuppoſed to be conveyed to our Springs, and the ſea muſt likewiſe gradually loſe a conſiderable quantity of its ſalt.

Different ſorts of SPRINGS. Springs are either ſuch as run continually, called perennial; or ſuch as run only for a time, and at certain ſeaſons of the year, and therefore called *temporary* Springs. Others again are called *intermitting* Springs, becauſe they flow and then ſtop, and flow and ſtop again; and *reciprocating* Springs, whoſe waters riſe and fall, or flow and ebb, by regular intervals.

In order to account for theſe differences in Springs, let ABCDE (fig. 2, pl. 27) repreſent the declivity of a hill, along which the rain deſcends; paſſing through the fiſſures or channels BF, CG, DH, and LK, into the cavity or reſervoir FGHKMI; from this cavity let there be a narrow drain or duct KE, which diſcharges the water at E. As the capacity of the reſervoir is ſuppoſed to be large in proportion to that of the drain, it will furniſh a conſtant ſupply of water to the ſpring at E. But if the reſervoir FGHKMI be ſmall, and the drain large, the water contained in the former, unleſs it is ſupplied by rain, will be wholly diſcharged by the latter, and the Spring will become dry: and ſo it will continue, even though it rains, till the water has had time to penetrate through the earth, or to paſs through the channels into the reſervoir; and the time neceſſary for furniſhing a new ſupply to the drain KE will depend on the ſize of the fiſſures, the nature

ture of the ſoil, and the depth of the cavity with which it communicates. Hence it may happen, that the Spring at E may remain dry for a conſiderable time, and even while it rains; but when the water has found its way into the cavity of the hill, the Spring will begin to run. Springs, of this kind, it is evident, may be dry in wet weather, eſpecially if the duct KE be not exactly level with the bottom of the cavity in the hill, and diſcharge water in dry weather; and the intermiſſions of the Spring may continue ſeveral days. But if we ſuppoſe XOP to repreſent another cavity, ſupplied with water by the channel NO, as well as by fiſſures and clefts in the rock, and by the draining of the adjacent earth; and another channel STV, communicating with the bottom of it at S, aſcending to T, and terminating on the ſurface at V, in the form of a ſiphon; this diſpoſition of the internal cavities of the earth, which we may reaſonably ſuppoſe that nature has formed in a variety of places, will ſerve to explain the principle of reciprocating Springs; for it is plain, that the cavity XOP muſt be ſupplied with water to the height QPT, before it can paſs over the bend of the channel at T, and then it will flow through the longer leg of the ſiphon TV, and be diſcharged at the end V, which is lower than S. Now if the channel STV be conſiderably larger than NO, by which the water is principally conveyed into the reſervoir XOP, the reſervoir will be emptied of its water by the ſiphon; and when the water deſcends below its orifice S, the air will drive the remaining water out of the channel STV, and the Spring will ceaſe to flow. But in time the water in the reſervoir will again riſe to the height QPT, and be diſcharged at V as before. It is eaſy to conceive, that the diameters of the channels NO and STV may be ſo proportioned to one another, as to afford an intermiſſion and renewal of the Spring V at regular intervals. Thus, if NO communicates with a well ſupplied by the tide, during the time of flow, the quantity of water conveyed by it into the cavity XOP may be ſufficient to fill it up to QPT; and STV may be of ſuch a ſize as to empty it, during the time of ebb. It is eaſy to apply this reaſoning to more complicated caſes, where ſeveral reſervoirs and ſiphons communicating with each other, may ſupply Springs with circumſtances of greater variety. See Muſſchenbroek's Introd. ad Phil. Nat. tom. ii. pa. 1010. Deſagu. Exp. Phil. vol. ii, pa. 173, &c.

We ſhall here obſerve, that Deſaguliers calls thoſe *reciprocating* Springs which flow conſtantly, but with a ſtream ſubject to increaſe and decreaſe; and thus he diſtinguiſhes them from *intermitting* Springs, which flow or ſtop alternately.

It is ſaid that in the dioceſe of Paderborn, in Weſtphalia, there is a Spring which diſappears after twenty-four hours, and always returns at the end of ſix hours with a great noiſe, and with ſo much force, as to turn three mills, not far from its ſource. It is called the Bolderborn, or boiſterous Spring. Phil. Tranſ. num. 7, pa. 127.

There are many Springs of an extraordinary nature in our own country, which it is needleſs to recite, as they are explicable by the general principles already illuſtrated.

SPRING, *Ver*, in Aſtronomy and Coſmography, denotes one of the ſeaſons of the year; commencing, in the northern parts of the earth, on the day the ſun enters the firſt degree of Aries, which is about the 21ſt day of March, and ending when the ſun enters Cancer, at the ſummer ſolſtice, about the 21ſt of June: Spring ending when the ſummer begins.

Or, more ſtrictly and generally, for any part of the earth, or on either ſide of the equator, the Spring ſeaſon begins when the meridian altitude of the ſun, being on the increaſe, is at a medium between the greateſt and leaſt; and ends when the meridian altitude is at the greateſt. Or the Spring is the ſeaſon, or time, from the moment of the ſun's croſſing the equator till he riſe to the greateſt height above it.

Elater SPRING, in Phyſics, denotes a natural faculty, or endeavour, of certain bodies, to return to their firſt ſtate, after having been violently put out of the ſame by compreſſing, or bending them, or the like.

This faculty is uſually called by phyſicians, the *force*, or *elaſticity*.

SPRING, in Mechanics, is uſed to ſignify a body of any ſhape, perfectly elaſtic.

Elaſticity of a SPRING. See ELASTICITY.

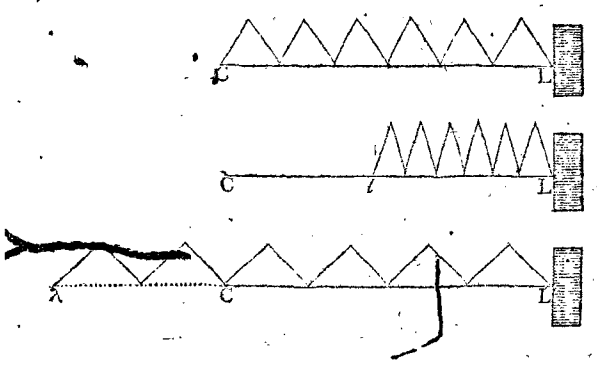
Length of a SPRING, ſignify from its etymology, ſignify the length of any elaſtic body; but it is particularly uſed by Dr. Jurin for the greateſt length to which a Spring can be forced inwards, or drawn outwards, without prejudice to its elaſticity. He obſerves, this would be the whole length, were the Spring conſidered as a mathematical line; but in a material Spring, it is the difference between the whole length, when the Spring is in its natural ſituation, or the ſituation it will reſt in when not diſturbed by any external force, and the length or ſpace it takes up when wholly compreſſed and cloſed, or when drawn out.

Strength or Force of a SPRING, is uſed for the force or weight which, when the Spring is wholly compreſſed or cloſed, will juſt prevent it from unbending itſelf. Alſo the Force of a Spring partly bent or cloſed, is the force or weight which is juſt ſufficient to keep the Spring in that ſtate, by preventing it from unbending itſelf any farther.

The theory of Springs is founded on this principle, *ut intenſio, ſic vis*; that is, the intenſity is as the compreſſing force; or if a Spring be any way forced or put out of its natural ſituation, its reſiſtance is proportional to the ſpace by which it is removed from that ſituation. This principle has been verified by the experiments of Dr. Hook, and ſince him by thoſe of others, particularly by the accurate hand of Mr. George Graham. Lectures De Potentia Reſtitutiva, 1678.

For elucidating this principle, on which the whole theory of Springs depends, ſuppoſe a Spring CL, reſting at L againſt any immoveable ſupport, but otherwiſe lying in its natural ſituation, and at full liberty. Then if this Spring be preſſed inwards by any force p, or from C towards L, through the ſpace of one inch, and can be there detained by that force p, the reſiſtance of the Spring, and the force p, exactly counterbalancing each other; then will the double force $2p$ bend the Spring through the ſpace of 2 inches, and the triple force $3p$ through 3 inches, and the quadruple force $4p$ through 4 inches, and ſo on. The ſpace CL through which the Spring is bent, or by which its end C is removed from its natural ſituation, being always

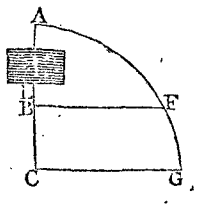
ways proportional to the force which will bend it ſo far, and will juſt detain it when ſo bent. On the other hand, if the end C be drawn outwards to any place λ, and be there detained from returning back by any force p, the ſpace Cλ, through which it is ſo drawn outwards, will be alſo proportional to the force p, which is juſt able to retain it in that ſituation.



It may here be obſerved, that the Spring of the air, or its elaſtic force, is a power of a different nature, and governed by different laws, from that of a palpable rigid Spring. For ſuppoſing the line LC to repreſent a cylindrical volume of air, which by compreſſion is reduced to Ll, or by dilatation is extended to Lλ, its elaſtic force will be reciprocally as Ll or Lλ; whereas the force or reſiſtance of a Spring is directly as Cl or Cλ.

This principle being premiſed, Dr. Jurin lays down a general theorem concerning the action of a body ſtriking on one end of a Spring, while the other end is ſuppoſed to reſt againſt an immoveable ſupport.

Thus, if a Spring of the ſtrength P, and the length CL, lying at full liberty upon an horizontal plane, reſt with one end L againſt an immoveable ſupport; and a body of the weight M, moving with the velocity V, in the direction of the axis of the Spring, ſtrike directly on the other end C, and ſo force the Spring inwards, or bend it through any ſpace CB; and if a mean proportional CG be taken between $\frac{M}{P} \times CL$ and $2a$, where a denotes the height to which a body would aſcend in vacuo with the velocity V; and farther, if upon the radius $R = CG$ be deſcribed the quadrant of a circle GFA:



then,

1. When the Spring is bent through the right ſine CB of any arc GF, the velocity v of the body M is to the original velocity V, as the coſine BF is to the radius CG; that is $v : V :: BF : CG$, or $v = \frac{BF}{R} \times V$.

2. The time t of bending the Spring through the ſame ſine CB, is to T, the time of a heavy body's aſcending in vacuo with the velocity V, as the correſponding arc is to $2a$; that is $t : T :: GF : 2a$, or $t = \frac{GF}{2a} \times T$.

The doctor gives a demonſtration of this theorem, and deduces a great many curious corollaries from it. Theſe he divides into three claſſes. The firſt contains ſuch corollaries as are of more particular uſe when the Spring is wholly cloſed before the motion of the body ceaſes: the ſecond comprehends thoſe relating to the caſe, when the motion of the body ceaſes before the Spring is wholly cloſed: and the third when the motion of the body ceaſes at the inſtant that the Spring is wholly cloſed.

We ſhall here mention ſome of the laſt claſs, as being the moſt ſimple; having firſt premiſed, that P = the ſtrength of the Spring, L = its length, V = the initial velocity of the body cloſing the Spring, M = its maſs, t = time ſpent by the body in cloſing the Spring, A = height from which a heavy body will fall in vacuo in a ſecond of time, a = the height to which a body would aſcend in vacuo with the velocity V, C = the velocity gained by the fall, m = the circumference of a circle, whoſe diameter is 1. Then, the motion of the ſtriking body ceaſing when the Spring is wholly cloſed, it will be,

1. $V = C\sqrt{\frac{PL}{2MA}}$.

2. $Vt = \frac{mCL}{4A} \times 1''$.

3. $MV = C\sqrt{\frac{PLM}{2A}}$ the firſt momentum.

4. If a quantity of motion MV bend a Spring through its whole length, and be deſtroyed by it; no other quantity of motion equal to the former, as $nM \times \frac{V}{n}$, will cloſe the ſame Spring, and be wholly deſtroyed by it.

5. But a quantity of motion, greater or leſs than MV, in any given ratio, may cloſe the ſame Spring, and be wholly deſtroyed in cloſing it; and the time ſpent in cloſing the Spring will be reſpectively greater or leſs, in the ſame given ratio.

6. The initial vis viva, or MV^2 is $= \frac{C^2PL}{2A}$; and $2aM = PL$; alſo the initial vis viva is as the rectangle under the length and ſtrength of the Spring, that is, MV^2 is as PL.

7. If the vis viva MV^2 bend a Spring through its whole length, and be deſtroyed in cloſing it; any other vis viva, equal to the former, as $n^2M \times \frac{V^2}{n^2}$, will cloſe the ſame Spring, and be deſtroyed by it.

8. But the time of cloſing the Spring by the vis viva $n^2M \times \frac{V^2}{n^2}$, will be to the time of cloſing it by the vis viva MV^2, as n to 1.

9. If the vis viva MV^2 be wholly conſumed in cloſing a Spring, of the length L, and ſtrength P; then the

vis viva n^2MV^2 will be ſufficient to cloſe, 1ſt, Either a Spring of the length L and ſtrength n^2P. 2d, Or a Spring of the length nL and ſtrength nP. 3d, Or of the length n^2L and ſtrength P. 4th, Or, if n be a whole number, the number n^2 of Springs, each of the length L and ſtrength P.—It may be added, that it appears from hence, that the number of ſimilar and equal Springs a given body in motion can wholly cloſe, is always proportional to the ſquares of the velocity of that body. And it is from this principle that the chief argument, to prove that the force of a body in motion is as the ſquare of its velocity, is deduced. See FORCE.

The theorem given above, and its corollaries, will equally hold good, if the Spring be ſuppoſed to have been at firſt bent through a certain ſpace, and by unbending itſelf to preſs upon a body at reſt, and thus to drive that body before it, during the time of its expanſion: only V, inſtead of being the initial velocity with which the body ſtruck the Spring, will now be the final velocity with which the body parts from the Spring when totally expanded.

It may alſo be obſerved, that the theorem, &c, will equally hold good, if the Spring, inſtead of being preſſed inward, be drawn outward by the action of the body. The like may be ſaid, if the Spring be ſuppoſed to have been already drawn outward to a certain length, and in reſtoring itſelf draw the body after it. And laſtly, the theorem extends to a Spring of any form whatever, provided L be the greateſt length it can be extended to from its natural ſituation, and P the force which will confine it to that length. See Philoſ. Tranſ. num. 472, ſect. 10, or vol. 43, art. 10.

SPRING is more particularly uſed, in the Mechanic Arts, for a piece of tempered ſteel, put into various machines to give them motion, by the endeavour it makes to unbend itſelf.

In watches, it is a fine piece of well-beaten ſteel, coiled up in a cylindrical caſe, or frame; which by ſtretching itſelf forth, gives motion to the wheels, &c.

SPRING *Arbor*, in a Watch, is that part in the middle of the Spring-box, about which the Spring is wound or turned, and to which it is hooked at one end.

SPRING *Box*, in a Watch, is the cylindrical caſe, or frame, containing within it the Spring of the watch.

SPRING-*Compaſſes*. See COMPASSES.

SPRING *of the Air*, or its elaſtic force. See AIR, and ELASTICITY.

SPRING-*Tides*, are the higher tides, about the times of the new and full moon. See TIDE.

SPRINGY, or *Elaſtic Body*. See ELASTIC *Body*.

SQUARE, in Geometry, a quadrilateral figure, whoſe angles are right, and ſides equal. Or it is an equilateral rectangle. Or an equilateral rectangular parallelogram.

A Square, and indeed any other parallelogram, is biſected by its diagonal. And the ſide of a Square is incommenſurable to its diagonal, being in the ratio of 1 to $\sqrt{2}$.

To find the Area of a SQUARE. Multiply the ſide by itſelf, and the product is the area. So, if the ſide be 10, the area is 100; and if the ſide be 12, the area is 144.

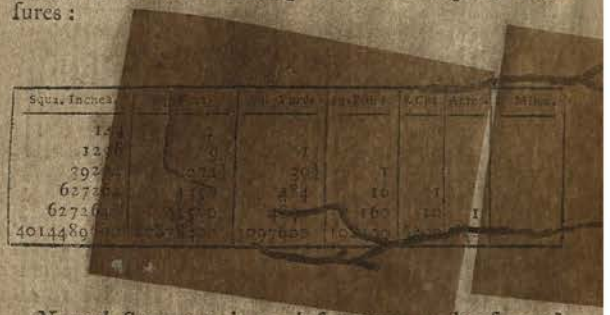
SQUARE *Foot*, is a Square each ſide of which is equal to a foot, or 12 inches; and the area, or Square foot is equal to 144 ſquare inches.

Geometrical SQUARE, a compartment often added on the face of a quadrant, called alſo *Line of Shadows*, and QUADRANT.

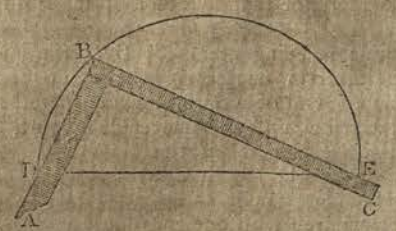
Gunner's SQUARE. See QUADRANT.

Magic SQUARE. See MAGIC *Square*.

SQUARE *Meaſures*, the Squares of the lineal meaſures; as in the following Table of Square Meaſures:



Normal SQUARE, is an inſtrument, made of wood or metal, ſerving to deſcribe and meaſure right angles;



ſuch is ABC. It conſiſts of two rulers or branches faſtened together perpendicularly. When the two legs are moveable on a joint, it is called a bevel.

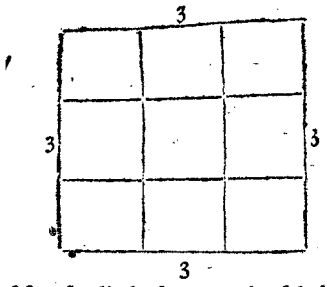
To examine whether the Square is exact or not. Deſcribe a ſemicircle DBE, with any radius at pleaſure; in the circumference of which apply the angle of the Square to any point as B, and the edge of one leg to one end of the diameter as D, then if the other leg paſs juſt by the other extremity at E, the Square is true; otherwiſe not.

SQUARE *Number*, is the product ariſing from a number multiplied by itſelf. Thus, 4 is the Square of 2, and 16 the Square of 4.

The ſeries of Square integers, is 1, 4, 9, 16, 25, 36, &c; which are the Squares of - - 1, 2, 3, 4, 5, 6, &c.

Or the Square fractions - - $\frac{1}{4}, \frac{4}{9}, \frac{9}{16}, \frac{16}{25}, \frac{25}{36}, \frac{36}{49}$, &c, which are the Squares of - - $\frac{1}{2}, \frac{2}{3}, \frac{3}{4}, \frac{4}{5}, \frac{5}{6}, \frac{6}{7}$, &c.

A Square number is ſo called, either becauſe it denotes the area of a Square, whoſe ſide is expreſſed by the root of the Square number; as in the annexed Square, which



which consists of 9 little squares, the side being equal to 3; or else, which is much the same thing, because the points in the number may be ranged in the form of a Square, by making the root, or factor, the side of the

. . .
. . .
. . .

Some properties of Squares are as follow: 1. Of the

Natural series of Squares, $1^2, 2^2, 3^2, 4^2$, &c,
which are equal to 1, 4, 9, 16, &c;

The mean proportional mn between any two of these Squares m^2 and n^2, is equal to the less square *plus* its root multiplied by the difference of the roots; or also equal to the greater square *minus* its root multiplied by the said difference of the roots. That is,

$$mn = m^2 + dm = n^2 - dn;$$

where $d = n - m$ is the difference of their roots.

2. An arithmetical mean between any two Squares m^2 and n^2, exceeds their geometrical mean, by half the Square of the difference of their roots.

That is $\frac{1}{2}m^2 + \frac{1}{2}n^2 = mn + \frac{1}{2}d^2$.

3. Of three equidistant Squares in the Series, the geometrical mean between the extremes, is less than the middle Square by the Square of their common distance in the Series, or of the common difference of their roots.

That is, $mp = n^2 - d^2$;

where m, n, p, are in arithmetical progression, the common difference being d.

4. The difference between the two adjacent Squares m^2, and n^2, is $n^2 - m^2 = 2m + 1$;

in like manner, $p^2 - n^2 = 2n + 1$, the difference between the next two adjacent Squares n^2 and p^2; and so on, for the next following Squares. Hence the difference of these differences, or the second difference of the Squares, is $2n - 2m = 2 \times \overline{n - m} = 2$ only, because $n - m = 1$; that is, the second differences of the Squares are each the same constant number 2: therefore the first differences will be found by the continual addition of the number 2; and then the Squares themselves will be found by the continual addition of the first differences; and thus the whole series of Squares is constructed by addition only, as here below:

2d Diff.		2	2	2	2	2	2	&c.
1st Diff.	1	3	5	7	9	11	13	&c.
Squares.	1	4	9	16	25	36	49	&c.

And this method of constructing the table of Square numbers I find first noticed by Peletarius, in his Algebra.

5. Another curious property, also noted by the same author, is, that the sum of any number of the cubes of the natural series 1, 2, 3, 4, &c, taken from the beginning, always makes a Square number; and that the series of Squares, so formed, have for their roots the numbers 1, 3, 6, 10, 15, 21, &c, the diffs. of which are 1, 2, 3, 4, 5, 6, &c, viz, $1^3 = 1^2$,

$1^3 + 2^3 = 3^2$,

$1^3 + 2^3 + 3^3 = 6^2$,

$1^3 + 2^3 + 3^3 + 4^3 = 10^2$; and in general

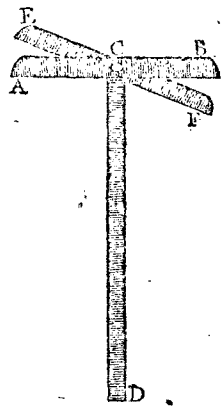
$1^3 + 2^3 + 3^3 + n^3 = (1+2+3+n)^2 = \frac{1}{2}n.\overline{n+1}$;

where n is the number of the terms or cubes.

SQUARE *Root*, a number considered as the root of a second power or Square number: or a number which multiplied by itself, produces the given number. See EXTRACTION *of Roots*, and also the article ROOT, where tables of Squares and roots are inserted.

T. SQUARE, or *Tee* SQUARE, an instrument used in drawing, so called from its resemblance to the capital letter T.

This instrument consists of two straight rulers AB and CD, fixed at right angles to each other. To which is sometimes added a third EF, moveable about the pin C, to set it to make any angle with CD.—It is very useful for drawing parallel and perpendicular lines, on the face of a smooth drawing-board.



SQUARED-*square*, SQUARED-*cube*, &c. See POWER.

SQUARING. See QUADRATURE.

SQUARING *the Circle*, is the making or finding a Square whose area shall be equal to the area of a given circle.

The best mathematicians have not yet been able to resolve this problem accurately, and perhaps never will. But they can easily come to any proposed degree of approximation whatever; for instance, so near as not to err so much in the area, as a grain of sand would cover, in a circle whose diameter is equal to that of the orbit of Saturn. The following proportion is near enough the truth for any real use, viz, as 1 is to ·88622692, so is the diameter of any circle, to the side of the square of an equal area. Therefore, if the diameter of the circle be called d, and the side of the equal square s;

then is $s = \cdot 88622692d = \frac{7}{8}\frac{9}{0}d$ nearly,

and $d = \frac{s}{\cdot 88622692} = \frac{4}{3}\frac{4}{5}s$ nearly.

See CIRCLE, DIAMETER, and QUADRATURE.

STADIUM, an ancient Greek long meaſure, containing 125 geometrical paces, or 625 Roman feet; correſponding to our furlong.

Eight Stadia make a geometrical or Roman mile; and 20, according to Dacier, a French league: but according to others, 800 Stadia make 41⅔ leagues.

Guilletiere obſerves, that the Stadium was only 600 Athenian feet, which amount to 625 Roman, or 566 French, or 604 Engliſh feet: ſo that the Stadium ſhould have been only 113 geometrical paces. It muſt be obſerved however, that the Stadium was different at different times and places.

STAFF, *Almucantar's*, *Augural*, *Back*, *Croſs*, *Fore*, *Offset*, *&c.* See theſe ſeveral articles.

STAR, STELLA, in Aſtronomy, a general name for all the heavenly bodies.

The Stars are diſtinguiſhed, from the phenomena, &c, into *fixed* and *erratic* or *wandering*.

Erratic or *Wandering* STARS, are thoſe which are continually changing their places and diſtances, with regard to each other. Theſe are what are properly called *planets*. Though to the ſame claſs may likewiſe be referred comets or blazing Stars.

Fixed STARS, called alſo barely *Stars*, by way of eminence, are thoſe which have uſually been obſerved to keep the ſame diſtance, with regard to each other.

The chief circumſtances obſervable in the fixed Stars, are their *diſtance*, *magnitude*, *number*, *nature*, and *motion*. Of each of which in their order.

Diſtance of the Fixed STARS. The fixed Stars are ſo extremely remote from us, that we have no diſtances in the planetary ſyſtem to compare to them. Their immenſe diſtance appears from hence, that they have no ſenſible parallax; that is, that the diameter of the earth's annual orbit, which is nearly 190 millions of miles, bears no ſenſible proportion to their diſtance.

Mr. Huygens (Coſmotheor. lib. 4) attempts to determine the diſtance of the Stars, by making the aperture of a teleſcope ſo ſmall, as that the ſun through it appears no larger than Sirius; which he found to be only as 1 to 27664 of his diameter, when ſeen with the naked eye. So that, were the ſun's diſtance 27664 times as much as it is, it would then be ſeen of the ſame diameter with Sirius. And hence, ſuppoſing Sirius to be a ſun of the ſame magnitude with our ſun, the diſtance of Sirius will be found to be 27664 times the diſtance of the ſun, or 345 million times the earth's diameter.

Dr. David Gregory inveſtigated the diſtance of Sirius, by ſuppoſing it of the ſame magnitude with the ſun, and of the ſame apparent diameter with Jupiter in oppoſition: as may be ſeen at large in his Aſtronomy, lib. 3, prop. 47.

Caſſini (Mem. Acad. 1717), by comparing Jupiter and Sirius, when viewed through the ſame teleſcope, inferred, that the diameter of that planet was 10 times as great as that of the Star; and the diameter of Jupiter being 50″, he concluded that the diameter of Sirius was about 5″; ſuppoſing then that the real magnitude of Sirius is equal to that of the ſun, and the diſtance of the ſun from us 12000 diameters of the earth, and the apparent diameter of Sirius being to that of the ſun as 1 to 384, the diſtance of Sirius becomes equal to 4608000 diameters of the earth.

Theſe methods of Huygens, Gregory, and Caſſini, are conjectural and precarious; both becauſe the ſun and Sirius are ſuppoſed of equal magnitude, and alſo becauſe it is ſuppoſed the diameter of Sirius is determined with ſufficient exactneſs.

Mr. Michell has propoſed an enquiry into the probable parallax and magnitude of the fixed Stars, from the quantity of light which they afford us, and the peculiar circumſtances of their ſituation. With this view he ſuppoſes, that they are on a medium, equal in magnitude and natural brightneſs to the ſun: and then proceeds to inquire, What would be the parallax of the ſun, if he were to be removed ſo far from us, as to make the quantity of the light which we ſhould then receive from him no more than equal to that of the fixed Stars. Accordingly, he eſtimates Saturn in oppoſition, as equal or nearly equal in light to the brighteſt fixed Star. As the mean diſtance of Saturn from the ſun is equal to about 2082 of the ſun's ſemidiameters, the denſity of the ſun's light at Saturn will conſequently be leſs than at his own ſurface, in the ratio of the ſquare of 2082 or 4334724 to 1. If Saturn therefore reflected all the light that falls upon him, he would be leſs luminous in that ſame proportion. And beſides, his apparent diameter, in the meridian, being but about the 105th part of that of the ſun, the quantity of light which we receive from him muſt be again diminiſhed in the ratio of the ſquare of 105 or 11025 to 1. Conſequently, by multiplying theſe two numbers together, we ſhall have the whole of the light of the ſun to that of Saturn, as the ſquare nearly of 220,000 or 48,400,000,000 to 1. Hence, removing the ſun to 220,000 times his preſent diſtance, he would ſtill appear at leaſt as bright as Saturn, and his whole parallax upon the diameter of the earth's orbit would be leſs than 2 ſeconds: and this muſt be aſſumed for the parallax of the brighteſt of the fixed Stars, upon the ſuppoſition that their light does not exceed that of Saturn.

By a like computation it may be found, that the diſtance, at which the ſun would afford us as much light as we receive from Jupiter, is not leſs than 46,000 times his preſent diſtance, and his whole parallax in that caſe, upon the diameter of the earth's orbit, would not be more than 9 ſeconds; the light of Jupiter and Saturn, as ſeen from the earth, being in the ratio of about 22 to 1, when they are both in oppoſition, and ſuppoſing them to reflect equally in proportion to the whole of the light that falls upon them. But if Jupiter and Saturn, inſtead of reflecting the whole of the light that falls upon them, ſhould really reflect only a part of it, as a 4th, or a 6th, which may be the caſe, the above diſtances muſt be increaſed in the ratio of 2 or 2½ to 1, to make the ſun's light no more than equal to theirs; and his parallax would be leſs in the ſame proportion. Suppoſing then that the fixed Stars are of the ſame magnitude and brightneſs with the ſun, it is no wonder that their parallax ſhould hitherto have eſcaped obſervation; ſince in this caſe it could hardly amount to 2 ſeconds, and probably not more than one in Sirius himſelf, though he had been placed in the pole of the ecliptic; and in thoſe that appear much leſs luminous, as γ Draconis, which is only of the 3d magnitude, it could hardly be expected to be ſenſible with ſuch inſtruments as have hitherto been uſed. However, Mr. Michell

chell ſuggeſts, that it is not impracticable to conſtruct inſtruments capable of diſtinguiſhing even to the 20th part of a ſecond, provided the air will admit of that degree of exactneſs. This ingenious writer apprehends that the quantity of light which we receive from Sirius does not exceed the light we receive from the leaſt fixed Star of the 6th magnitude, in a greater ratio than that of 1000 to 1, nor leſs than that of 400 to 1; and the ſmaller Stars of the 2d magnitude ſeem to be about a mean proportional between the other two. Hence the whole parallax of the leaſt fixed Stars of the 6th magnitude, ſuppoſing them of the ſame ſize and native brightneſs with the ſun, ſhould be from about 2‴ to 3‴, and their diſtance from about 8 to 12 million times that of the ſun: and the parallax of the ſmaller Stars of the 2d magnitude, upon the ſame ſuppoſition, ſhould be about 12‴, and their diſtance about 2 million times [illegible] the ſun.

This author farther ſuggeſts, that, from the apparent ſituation of the Stars in the heavens, there is the greateſt probability that the Stars are collected together in cluſters in ſome places, where they form a kind of ſyſtems, whilſt in others there are either few or none of them; whether this diſpoſition be owing to their mutual gravitation, or to ſome other law or appointment of the Creator. Hence it may be inferred, that ſuch double Stars, &c. as appear to conſiſt of two or more Stars placed very near together, do really conſiſt of Stars placed near together, and under the influence of ſome general law: and he proceeds to inquire whether, if the Stars be collected into ſyſtems, the ſun does not likewiſe make one of ſome ſyſtem, and which fixed Stars thoſe are that belong to the ſame ſyſtem with him.

Thoſe Stars, he apprehends, which are found in cluſters, and ſurrounded by many others at a ſmall diſtance from them, belong probably to other ſyſtems, and not to ours. And thoſe Stars, which are ſurrounded with nebulæ, are probably only very large Stars which, on account of their ſuperior magnitude, are ſingly viſible, while the others, which compoſe the remaining parts of the ſame ſyſtem, are ſo ſmall as to eſcape our ſight. And thoſe nebulæ in which we can diſcover either none or only a few Stars, even with the aſſiſtance of the beſt teleſcopes, are probably ſyſtems that are ſtill more diſtant than the reſt. For other particulars of this inquiry, ſee Philoſ. Tranſ. vol. 57, pa. 234 &c.

As the diſtance of the fixed Stars is beſt determined by their parallax, various methods have been purſued, though hitherto without ſucceſs, for inveſtigating it; the reſult of the moſt accurate obſervations having given us little more than a diſtant approximation; from which however we may conclude, that the neareſt of the fixed Stars cannot be leſs than 40 thouſand diameters of the whole annual orbit of the earth diſtant from us.

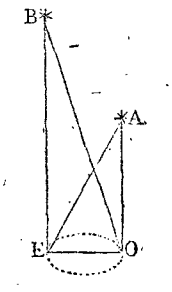
The method pointed out by Galileo, and attempted by Hook, Flamſteed, Molyneux, and Bradley, of taking the diſtances of ſuch Stars from the zenith as paſs very near it, has given us a much juſter idea of the immenſe diſtance of the Stars, and furniſhed an approximation to their parallax, much nearer the truth, than any we had before.

Dr. Bradley aſſures us (Philoſ. Tranſ. num. 406, or Abr. vol. 6, pa. 162), that had the parallax amounted to a ſingle ſecond, or two at moſt, he ſhould have perceived it in the great number of obſervations which he made, eſpecially upon γ Draconis; and that it ſeemed to him very probable, that the annual parallax of this Star does not amount to a ſingle ſecond, and conſequently that it is above 400 thouſand times farther from us than the ſun.

But Dr. Herſchel, to whoſe induſtry and ingenuity, in exploring the heavens, aſtronomy is already much indebted, remarks, that the inſtrument uſed on this occaſion, being the ſame with the preſent zenith ſectors, can hardly be allowed capable of ſhewing an angle of one or even two ſeconds, with accuracy: and beſides, the Star on which the obſervations were made, is only a bright Star of the 3d magnitude, or a ſmall Star of the 2d; and that therefore its parallax is probably much leſs than that of a Star of the firſt magnitude. So that we are not warranted in inferring, that the parallax of the Stars in general does not exceed 1″, whereas thoſe of the firſt magnitude may have, notwithſtanding the reſult of Dr. Bradley's obſervations, a parallax of ſeveral ſeconds.

As to the method of zenith diſtances, it is liable to conſiderable errors, on account of refraction, the change of poſition of the earth's axis, ariſing from nutation, preceſſion of the equinoxes, or other cauſes, and the aberration of light.

Dr. Herſchel has propoſed another method, by means of double Stars, which is free from theſe errors, and of ſuch a nature, that the annual parallax, even if it ſhould not exceed the 10th part of a ſecond, may ſtill become viſible, and be aſcertained at leaſt much nearer than heretofore. This method, which was firſt propoſed in an imperfect manner by Galileo, and has been alſo mentioned by other authors, is capable of every improvement which the teleſcope and mechaniſm of micrometers can furniſh. To give a general idea of it, let O and E be two oppoſite points of the annual orbit, taken in the ſame plane with two ſtars A, B, of unequal magnitudes. Let the angle AOB be obſerved when the earth is at O, and AEB be obſerved when the earth is at E. From the difference of theſe angles, when there is any, the parallax of the Stars may be computed, according to the theory ſubjoined. Theſe two Stars ought to be as near as poſſible to each other, and alſo to differ as much in magnitude as we can find them.



This theory of the annual parallax of double Stars, with the method of computing from thence what is uſually called the parallax of the fixed Stars, or of ſingle Stars of the firſt magnitude, ſuch as are neareſt to us, ſuppoſes 1ſt, that the Stars are all about the ſize of the ſun; and 2dly, that the difference in their apparent magnitudes, is owing to their different diſtances, ſo as that a Star of the 2d, 3d, or 4th magnitude, is 2, 3, or 4 times as far off as one of the firſt. Theſe principles, which Dr. Herſchel premiſes as poſtulata, have ſo great a probability in their favour, that they will ſcarcely

ſcarcely be objected to by thoſe who are in the leaſt acquainted with the doctrine of chances. See Mr. Michell's Inquiry, &c. already cited. And Philoſ. Tranſ. vol. 57, pa. 234 - - - - 240. Alſo Dr. Halley, on the Number, Order, and Light of the fixed Stars, in the Philoſ. Tranſ. vol. 31, or Abr. vol. 6, pa. 148.

Therefore, let EO be the whole diameter of the earth's annual orbit; and let A, B, C be three Stars ſituated in the ecliptic, in ſuch a manner, that they may appear all in one line OABC when the earth is at O. Now if OA, AB, BC be equal to each other, A will be a Star of the firſt magnitude, B of the ſecond, and C of the third. Let us next ſuppoſe the angle OAE, or parallax of the whole orbit of the earth, to be $1''$ of a degree; then, becauſe very ſmall angles, having the ſame ſubtenſe EO, may be taken to be in the inverſe ratio of the lines OA, OB, OC, &c, we ſhall have EBO $= \frac{1}{2}''$, and ECO $= \frac{1}{3}''$, &c, alſo becauſe EA $=$ AB nearly, the angle AEB $=$ ABE $= \frac{1}{1}''$; and becauſe BC $= \frac{1}{2}$ BO $= \frac{1}{2}$ BE nearly, the angle BEC $= \frac{1}{2}$ BCE $= \frac{1}{6}''$, and hence AEC $= \frac{1}{2} + \frac{1}{6} = \frac{2}{3}''$; from all which it follows that, when the earth is at E,

the Stars A and B appear at $\frac{1}{2}''$ diſtant from one another,
the Stars A and C at $\frac{2}{3}''$ diſtant, and
the Stars B and C only $\frac{1}{6}''$ diſtant. In like manner may be deduced a general expreſſion for the parallax that will become viſible in the change of diſtance between the two Stars, by the removal of the earth from one extreme of her orbit to the other. Let P denote the total parallax of a fixed Star of the magnitude of the M order, and m the number of the order of a ſmaller Star, p denoting the partial parallax to be obſerved by the change in the diſtance of a double Star;

then is $p = \frac{m-M}{mM}P$, or $P = \frac{mMp}{m-M}$, which gives P, when p is found by obſervation.

For Ex. Suppoſe a Star of the 1ſt magnitude ſhould have a ſmall Star of the 12th magnitude near it; then will the partial parallax we are to expect to ſee be $\frac{12-1}{12\times 1}P = \frac{11}{12}P$, or $\frac{11}{12}$ of the total parallax of the larger Star; and if we ſhould, by obſervation, find the partial parallax between two ſuch Stars to amount to $1''$, then will the total parallax $P = \frac{12}{11}p = 1''\frac{1}{11}$. Again, if the Stars be of the 3d and 24th magnitude, the total parallax will be $P = \frac{24\times 3}{24-3}p = \frac{72}{21}p = \frac{24}{7}p$; ſo that if by obſervation p be found to be $\frac{1}{10}$ of a ſecond, the whole parallax P will come out $\frac{24}{70}'' = 0''.3428$.

Farther, the Stars being ſtill in the ecliptic, ſuppoſe they ſhould appear in one line, when the earth is in ſome other part of her orbit between E and O; then will the parallax be ſtill expreſſed by the ſame algebraic formula, and one of the maxima will ſtill be at E, the other at O; but the whole effect will be divided into two parts, which will be in proportion to each other, as radius $-$ ſine to radius $+$ ſine of the Star's diſtance from the neareſt conjunction or oppoſition.

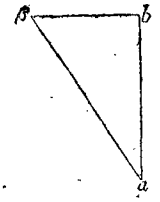
When the Stars are any where out of the ecliptic, ſituated ſo as to appear in one line OABC perpendicular to EO, the maximum of parallax will ſtill be expreſſed by $\frac{m-M}{mM}P$; but there will ariſe another additional parallax in the conjunction and oppoſition, which will be to that which is found 90° before or after the ſun, as the ſine (λ) of the latitude of the Stars is to radius (1); and the effect of this parallax will be divided into two parts; half of it lying on one ſide of the large Star, the other half on the other ſide of it. This latter parallax will alſo be compounded with the former, ſo that the diſtances of the Stars in the conjunction and oppoſition will then be extended to the diagonal of a parallelogram whoſe ſides are the two ſemiparallaxes, a general expreſſion for which will be $\frac{m-M}{2mM}P\sqrt{1+\lambda^2}$, or $\frac{1}{2}p\sqrt{1+\lambda^2}$.

When the Stars are in the pole of the ecliptic, λ will be $= 1$, and the laſt formula becomes $\frac{1}{2}p\sqrt{2} = \cdot 7071p$.

Again, let the Stars be at ſome diſtance, as $5''$, from each other, and let them be both in the ecliptic. This caſe is reſolvable into the firſt; for imagine the Star A to ſtand at I; then the angle AEI may be accounted equal to AOI; and as the foregoing formula, $p = \frac{m-M}{mM}P$, gives us the angles AEB, AEC, we are to add AEI or $5''$ to AEB, which will give IEB. In general, let the diſtance of the Stars be d, and let the obſerved diſtance at E be D; then will $D = d + p$, and therefore the whole parallax of the annual orbit will be expreſſed by $\frac{D-d}{m-M}Dd = P$.

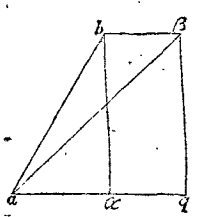
Suppoſe now the Stars to differ only in latitude, one being in the ecliptic, the other at ſome diſtance as $5''$ north, when ſeen at O. This caſe may alſo be reſolved by the former; for imagine the Stars B and C to be elevated at right angles above the plane of the figure, ſo that AOB, or AOC, may make an angle of $5''$ at O; then inſtead of the lines OABC, EA, EB, EC, imagine them all to be planes at right angles to the figure; and it will appear that the parallax of the Stars in longitude, muſt be the ſame as if the ſmall Star had been without latitude. And ſince the Stars B, C, by the motion of the earth from O to E, will not change their latitude, we ſhall have the following conſtruction for finding the diſtance of the Stars AB and AC at E, and from thence the parallax P.

Let



Let the triangle $ab\beta$ represent the situation of the Stars; ab is the subtenſe of $5''$, the angle under which they are ſuppoſed to be ſeen at O. The quantity $b\beta$ by the former theorem is found $= \frac{m-M}{mM}P$, which is the partial parallax, that would have been ſeen by the earth's moving from O to E, if both Stars had been in the ecliptic; but, on account of the difference in latitude, it will now be repreſented by $a\beta$, the hypotenuſe of the triangle $ab\beta$: therefore in general, putting $ab = d$, $a\beta = D$, we have $\frac{mM}{m-M}\sqrt{D^2-d^2} = P$. Hence, D being found by obſervation, and the three d, m, M given, the total parallax is obtained.

When the Stars differ in longitude as well as latitude, this caſe may be reſolved in the following manner. Let the triangle $ab\beta$ repreſent the ſituation of the Stars, $ab = d$ being their diſtance ſeen at O, $a\beta = D$, their diſtance ſeen at E. That the change $b\beta$, which is produced by the earth's motion, will be truly expreſſed by $\frac{m-M}{mM}P$, may be proved as before, by ſuppoſing the Star a to have been placed at α.



Now let the angle of poſition $ba\alpha$ be taken by a micrometer, or by any other method ſufficiently exact; then, by reſolving the triangle $ab\alpha$, we obtain the longitudinal and latitudinal differences $a\alpha$ and $b\alpha$ of the two ſtars. Put $a\alpha = x$, $b\alpha = y$, and it will be $x + b\beta = aq$, whence

$$D = \sqrt{(x + \frac{m-M}{mM}P)^2 + y^2}; \text{ and } P = \frac{\sqrt{D^2-y^2}-x}{m-M}mM.$$

If neither of the Stars ſhould be in the ecliptic, nor have the ſame longitude or latitude, the laſt theorem will ſtill ſerve to calculate the total parallax, whoſe maximum will lie in E. There will alſo ariſe another parallax, whoſe maximum will be in the conjunction and oppoſition, which will be divided, and lie on different ſides of the large Star; but as the whole parallax is extremely ſmall, it is not neceſſary to inveſtigate every particular caſe of this kind; for by reaſon of the diviſion of the parallax, which renders obſervations taken at any other time, except where it is greateſt, very unfavourable, the formulæ would be of little uſe.

Dr. Herſchel cloſes his account of this theory, with a general obſervation on the time and place where the maxima of parallax will happen. Thus, when two unequal Stars are both in the ecliptic, or, not being in the ecliptic, have equal latitudes, north or ſouth, and the larger Star has moſt longitude, the maximum of the apparent diſtance will be when the ſun's longitude is 90° more than the Star's, or when obſerved in the morning: and the minimum, when the longitude of the ſun is 90° leſs than that of the Star, or when obſerved in the evening. But when the ſmall Star has moſt longitude, the maximum and minimum, as well as the time of obſervation, will be the reverſe of the former. And when the Stars differ in latitude, this makes no alteration in the place of the maximum or minimum, nor in the time of obſervation; that is, it is immaterial which of the two Stars has the greater latitude. Philoſ. Tranſ. vol. 72, art. 11.

The diſtance of the Star γ Draconis appears, by Bradley's obſervations, already recited, to be at leaſt 400,000 times that of the ſun, and the diſtance of the neareſt fixed Star, not leſs than 40,000 diameters of the earth's annual orbit: that is, the diſtance from the earth, of the former at leaſt 38,000,000,000,000 miles, and the latter not leſs than 7,600,000,000,000 miles.

As theſe diſtances are immenſely great, it may both be amuſing, and help to a clearer and more familiar idea, to compare them with the velocity of ſome moving body, by which they may be meaſured.

The ſwifteſt motion we know of, is that of light, which paſſes from the ſun to the earth in about 8 minutes; and yet this would be above 6 years traverſing the firſt ſpace, and near a year and a quarter in paſſing from the neareſt fixed Star to the earth. But a cannon ball, moving on a medium at the rate of about 20 miles in a minute, would be 3 million 8 hundred thouſand years in paſſing from γ Draconis to the earth, and 760 thouſand years paſſing from the neareſt fixed Star. Sound, which moves at the rate of about 13 miles in a minute, would be 5 million 600 thouſand years traverſing the former diſtance, and 1 million 128 thouſand, in paſſing through the latter.

The celebrated Huygens purſued ſpeculations of this kind ſo far, as to believe it not impoſſible, that there may be Stars at ſuch inconceivable diſtances, that their light has not yet reached the earth ſince its creation.

Dr. Halley has alſo advanced, what he ſays ſeems to be a metaphyſical paradox (Philoſ. Tranſ. number 361, or Abr. vol. 6, pa. 148), viz, that the number of fixed Stars muſt be more than finite, and ſome of them more than at a finite diſtance from others: and Addiſon has juſtly obſerved, that this thought is far from being extravagant, when we conſider that the univerſe is the work of infinite power, prompted by infinite goodneſs, and having an infinite ſpace to exert itſelf in; ſo that our imagination can ſet no bounds to it.

Magnitude of the fixed STARS. The magnitudes of the Stars appear to be very different from one another; which difference may probably ariſe, partly from a diverſity in their real magnitude, but principally from their diſtances, which are different.

To the bare eye, the Stars appear of ſome ſenſible magnitude, owing to the glare of light ariſing from the numberleſs reflections from the aërial particles &c about the eye: this makes us imagine the Stars to be much larger than they would appear, if we ſaw them only by the few rays which come directly from them, ſo as to enter our eyes without being intermixed with others.

Any perſon may be ſenſible of this, by looking at a Star of the firſt magnitude through a long narrow tube; which, though it takes in as much of the ſky as would hold a thouſand ſuch ſtars, ſcarce renders that one viſible.

The

The Stars, on account of their apparently various ſizes, have been diſtributed into ſeveral claſſes, called *magnitudes*. The 1ſt claſs, or Stars of the firſt magnitude, are thoſe that appear largeſt, and may probably be neareſt to us. Next to theſe, are thoſe of the 2d magnitude; and ſo on to the 6th, which comprehends the ſmalleſt Stars viſible to the naked eye. All beyond theſe, that can be perceived by the help of teleſcopes, are called *teleſcopic* ſtars. Not that all the Stars of each claſs appear juſtly of the ſame magnitude; there being great latitude in this reſpect; and thoſe of the firſt magnitude appearing almoſt all different in luſtre and ſize. There are alſo other Stars, of intermediate magnitudes, which aſtronomers cannot refer to one claſs rather than another, and therefore they place them between the two. Procyon, for inſtance, which Ptolomy makes of the firſt magnitude, and Tycho of the 2d, Flamſteed lays down as between the 1ſt and 2d. So that, inſtead of 6 magnitudes, we may ſay there are almoſt as many orders of Stars, as there are Stars; ſo great variations being obſervable in the magnitude, colour, and brightneſs of them.

There ſeems to be little chance of diſcovering with certainty the real ſize of any of the fixed Stars; we muſt therefore be content with an approximation, deduced from their parallax, if this ſhould ever be found; and the quantity of light they afford us, compared with that of the ſun. And to this purpoſe, Dr. Herſchel informs us, that with a magnifying power of 6450, and by means of his new micrometer, he found the apparent diameter of α Lyræ to be $0''{\cdot}355$.

The Stars are alſo diſtinguiſhed, with regard to their ſituation, into *aſteriſms*, or *conſtellations*; which are nothing but aſſemblages of ſeveral neighbouring Stars, conſidered as conſtituting ſome determinate figure, as of an animal, &c, from which it is therefore denominated: a diviſion as ancient as the book of Job, in which mention is made of Orion, the Pleiades, &c.

Beſides the Stars thus diſtinguiſhed into magnitudes and conſtellations, there are others not reduced to either. Thoſe not reduced into conſtellations, are called *informes*, or *unformed* Stars; of which kind ſeveral, ſo left at large by the ancients, have ſince been formed into new conſtellations by the modern aſtronomers, and eſpecially by Hevelius.

Thoſe not reduced to claſſes or magnitudes, are called nebulous Stars; but ſuch as only appear faintly in cluſters, in form of little lucid ſpots, nebulæ, or clouds.

Ptolomy ſets down five of ſuch nebulæ, viz, one at the extremity of the right hand of Perſeus, which appears through the teleſcope, thick ſet with Stars; one in the middle of the crab, called *Præſepe*, or the Manger, in which Galileo counted above 40 Stars; one unformed near the ſting of the Scorpion; another in the eye of Sagittarius, in which two Stars may be ſeen in a clear ſky with the naked eye, and ſeveral more with the teleſcope; and the fifth in the head of Orion, in which Galileo counted 21 Stars.

Flamſteed obſerved a cloudy Star before the bow of Sagittarius, which conſiſts of a great number of ſmall Stars; and the Star *d* above the right ſhoulder of this conſtellation is encompaſſed with ſeveral more. Flamſteed and Caſſini alſo diſcovered one between the great and little dog, which is very full of Stars, that are viſible only by the teleſcope.

But the moſt remarkable of all the cloudy ſtars, is that in the middle of Orion's ſword, in which Huygens and Dr. Long obſerved 12 Stars, 7 of which (3 of them, now known to be 4, being very cloſe together) ſeem to ſhine through a cloud, very bright near the middle, but faint and ill defined about the edges. But the greateſt diſcoveries of nebulæ and cluſters of Stars, we owe to the powerful teleſcopes of Dr. Herſchel, who has given accounts of ſome thouſands of ſuch nebulæ, in many of which the Stars ſeem to be innumerable, like grains of ſand. See Philoſ. Tranſ. 1784, 1785, 1786, 1789. See GALAXY, and MAGELLANIC *clouds*, and *luci* SPOTS.

Caſſini is of opinion, that the brightneſs of the Milky Way proceeds from Stars ſo minute, as not to be diſtinguiſhed by the beſt glaſſes: and this opinion is fully confirmed by the obſervations of Dr. Herſchel, whoſe powerful teleſcopes ſhew thoſe lucid ſpecks to be compoſed entirely of maſſes of ſmall Stars, like heaps of ſand.

There are alſo many Stars which, though they appear ſingle to the naked eye, are yet diſcovered by the teleſcope to be double, triple, &c. Of theſe, ſeveral have been obſerved by Caſſini, Hooke, Long, Maskelyne, Hornſby, Pigott, Mayer, &c; but Dr. Herſchel has been much the moſt ſucceſsful in obſervations of this kind; and his ſucceſs has been chiefly owing to the very extraordinary magnifying powers of the Newtonian 7 feet reflector which he has uſed, and the advantage of an excellent micrometer of his own conſtruction. The powers which he has uſed, have been 146, 227, 278, 460, 754, 932, 1159, 1536, 2010, 3168, and even 6450. He has already formed a catalogue, containing 269 double Stars, 227 of which, as far as he knows, have not been noticed by any other perſon. Among theſe there are alſo ſome Stars that are treble, double-double, quadruple, double-treble, and multiple. His catalogue comprehends the names of the Stars, and the number in Flamſteed's catalogue, or ſuch a deſcription of thoſe that are not contained in it, as will be found ſufficient to diſtinguiſh them; alſo the comparative ſize of the Stars; their colours as they appeared to his view; their diſtances determined in ſeveral different ways; their angle of poſition with regard to the parallel of declination; and the dates when he firſt perceived the Stars to be double, treble, &c. His obſervations appear to commence with the year 1776, but almoſt all of them were made in the years 1779, 1780, 1781.

Dr. Herſchel has diſtributed the double Stars contained in his catalogue, into 6 different claſſes. In the firſt he has placed all thoſe which require a very ſuperior teleſcope, with the utmoſt clearneſs of air, and every other favourable circumſtance, to be ſeen at all, or well enough to judge of them; and there are 24 of theſe. To the 2d claſs belong all thoſe double Stars that are proper for eſtimations by the eye, and very delicate meaſures by the micrometer; the number being 38. The 3d claſs comprehends all thoſe double Stars, that are between $5''$ and $15''$ aſunder; the number of them being 46. The 4th, 5th, and 6th claſſes contain double

ſurveying.—In levelling, the inſtrument is rectified, or placed level at each Station, and obſervations made forwards and backwards.

There is a method of meaſuring diſtances at one Station, in the Philoſ. Tranſ. numb. 7, by means of a teleſcope. I have heard of another, by Mr. Ramſden, and have ſeen a third ingenious way by Mr. Green of Deptford, not yet publiſhed; this conſiſts of a permanent ſcale of diviſions, placed at any point whoſe diſtance is required; then the number of diviſions ſeen through the teleſcope, gives the diſtance ſought.

STATION-*Line*, in Surveying, and *Line of Station*, in Perſpective. See LINE.

STATIONARY, in Aſtronomy, the ſtate of a planet when, to an obſerver on the earth, it appears for ſome time to ſtand ſtill, or remain immoveable in the ſame place in the heavens. For as the planets, to ſuch an obſerver, have ſometimes a progreſſive motion, and ſometimes a retrograde one, there muſt be ſome point between the two where they muſt appear Stationary. Now a planet will be ſeen Stationary, when the line that joins the centres of the earth and planet is conſtantly directed to the ſame point in the heavens, which is, when it keeps parallel to itſelf. For all right lines drawn from any point of the earth's orbit, parallel to one another, do all point to the ſame ſtar; the diſtance of theſe lines being inſenſible, in compariſon of that of the fixed ſtars.

The planet Herſchel is ſeen Stationary at the diſtance of from the ſun; Saturn at ſomewhat more than 90°; Jupiter at the diſtance of 52°; and Mars at a much greater diſtance; Venus at 47°, and Mercury at 28°.

Herſchel is Stationary days, Saturn 8, Jupiter 4, Mars 2, Venus $1\frac{1}{2}$, and Mercury $\frac{1}{2}$ a day: though the ſeveral ſtations are not always equal; becauſe the orbits of the planets are not circles which have the ſun in their centre.

STEAM, the ſmoke or vapour ariſing from water, or any other liquid or moiſt body, when conſiderably heated. Subterranean Steams often affect the ſurface of the earth in a remarkable manner, and promote or prevent vegetation more than any thing elſe. It has been imagined that Steams may be the generative cauſe of both minerals and metals, and of all the peculiarities of ſprings. See Philoſ. Tranſ. vol. 5, pa. 1154, or Abr. vol. 2, pa. 833.—Of the uſe of the air to elevate the Steams of bodies, ſee pa. 2048 and 297 ib.—Concerning the warm and fertilizing temperature and Steams of the earth, ſee Phil. Tranſ. vol. 10, pa. 307 and 357. See alſo Dr. Hamilton "On the Aſcent of Vapours."

The Steam raiſed from hot water is an elaſtic fluid, which, like elaſtic air, has its elaſticity proportional to its denſity when the heat is the ſame, or proportional to the heat when the denſity is the ſame. The Steam raiſed with the ordinary heat of boiling water, is almoſt 3000 times rarer than water, or about $3\frac{1}{2}$ times rarer than air, and has its elaſticity about equal to that of the common air of the atmoſphere. And by great heat it has been found that the Steam may be expanded into 14000 times the ſpace of water, or may be made about 5 times ſtronger than the atmoſphere. But from ſome accidents that have happened, it appears that Steam, ſuddenly raiſed from water, or moiſt ſubſtances, by the immediate application of ſtrong heat, is vaſtly ſtronger than the atmoſphere, or even than gunpowder itſelf. Witneſs the accident that happened to a foundery of cannon at Moorfields, when upon the hot metal firſt running into the mould in the earth, ſome ſmall quantity of water in the bottom of it was ſuddenly changed into Steam, which by its exploſion, blew the foundery all to pieces. I remember another ſuch accident at a foundery at Newcaſtle; the founder having purchaſed, among ſome old braſs, a hollow braſs ball that had been uſed for many years as a valve in a pump, withinſide of which it would ſeem ſome water had got inſinuated; and having put it into his fire to melt, when it had become very hot, it ſuddenly burſt with a prodigious noiſe, and blew the adjacent parts of the furnace in pieces.

Steam may be applied to many purpoſes uſeful in life, but one of its chief uſes is in the Steam-engine deſcribed in the following article.

STEAM *Engine*, an engine for raiſing water by the force of Steam produced from boiling water; and often called the *Fire-engine*, on account of the fire employed in boiling the water to produce the Steam. This is one of the moſt curious and uſeful machines, which modern art can boaſt, for raiſing water from ponds, wells, or pits, for draining mines, &c. Were it not for the uſe of this moſt important invention, it is probable we ſhould not now have the benefit of coal fires in England; as our forefathers had, before the preſent century, excavated all the mines of coal as deep as it could be worked, without the benefit of this engine to draw the water from greater depths.

This engine is commonly a forcing pump, having its rod fixed to one end of a lever, which is worked by the weight or preſſure of the atmoſphere upon a piſton, at the other end, a temporary vacuum being made below it, by ſuddenly condenſing the Steam, that had been let into the cylinder in which this piſton works, by a jet of cold water thrown into it. A partial vacuum being thus made, the weight of the atmoſphere preſſes down the piſton, and raiſes the other end of the ſtraight lever with the water from the well &c. Then immediately a hole is uncovered in the bottom of the cylinder, by which a freſh fill of hot Steam ruſhes in from a boiler of water below it, which proves a counterbalance for the atmoſphere above the piſton, upon which the weight of the pump rods at the other end of the lever carries that end down, and raiſes the piſton of the Steam cylinder. Immediately the Steam hole is ſhut, and the cock opened for injecting the cold water into the cylinder of Steam, which condenſes it to water again, and thus making another vacuum below the piſton, the atmoſphere above it preſſes it down, and raiſes the pump rods with another lift of water; and ſo on continually. This is the common principle: but there are alſo other modes of applying the force of the Steam, as we ſhall ſee in the following ſhort hiſtory of this invention and its various improvements.

The earlieſt account to be met with of the invention of this engine, is in the marquis of Worceſter's ſmall book intitled a Century of Inventions (being a deſcription of 100 notable diſcoveries), publiſhed in the year 1663, where he propoſed the raiſing of great quantities

of water by the force of Steam, raiſed from water by means of fire; and he mentions an engine of that kind, of his own contrivance, which could raiſe a continual ſtream like a fountain 40 feet high, by means of two cocks which were alternately and ſucceſſively turned by a man to admit the Steam, and to re-fill the veſſel with cold water, the fire being continually kept up.

However, this invention not meeting with encouragement, probably owing to the confuſed ſtate of public affairs at that time, it was neglected, and lay dormant ſeveral years, until one Captain Thomas Savery, having read the marquis of Worceſter's books, ſeveral years afterwards, tried many experiments upon the force and power of Steam; and at laſt hit upon a method of applying it to raiſe water. He then bought up and deſtroyed all the marquis's books that could be got, and claimed the honour of the invention to himſelf, and obtained a patent for it, pretending that he had diſcovered this ſecret of nature by accident. He contrived an engine which, after many experiments, he brought to ſome degree of perfection, ſo as to raiſe water in ſmall quantities: but he could not ſucceed in raiſing it to any great height, or in large quantities, for the draining of mines; to effect which by his method, the Steam was required to be ſo ſtrong as would have burſt all his veſſels; ſo that he was obliged to limit himſelf to raiſing the water only to a ſmall height, or in ſmall quantities. The largeſt engine he erected, was for the York-buildings Company in London, for ſupplying the inhabitants in the Strand and that neighbourhood with water.

The principle of this machine was as follows: H (fig. 3, pl. 27) repreſents a copper boiler placed on a furnace. E is a ſtrong iron veſſel, communicating with the boiler by means of a pipe at top, and with the main pipe AB by means of a pipe I at bottom; AB is the main pipe immerſed in the water at B; D and C are two fixed valves, both opening upwards, one being placed above, and the other below the pipe of communication I. Laſtly, at G is a cock that ſerves occaſionally to wet and cool the veſſel E, by water from the main pipe, and F is a cock in the pipe of communication between the veſſel E and the boiler.

The engine is ſet to work, by filling the copper in part with water, and alſo the upper part of the main pipe above the valve C, the fire in the furnace being lighted at the ſame time. When the water boils ſtrongly, the cock F is opened, the Steam ruſhes into the veſſel E, and expels the air from thence through the valve C. The veſſel E thus filled, and violently heated by the Steam, is ſuddenly cooled by the water which falls upon it by turning the cock C; the cock F being at the ſame time ſhut, to prevent any freſh acceſſion of Steam from the boiler. Hence, the Steam in E becoming condenſed, it leaves the cavity within almoſt intirely a vacuum; and therefore the preſſure of the atmoſphere at B forces the water through the valve D till the veſſel E is nearly filled. The condenſing cock G is then ſhut, and the Steam cock F again opened; hence the Steam, ruſhing into E, expels the water through the valve C, as it before did the air. Thus E becomes again filled with hot Steam, which is again cooled and condenſed by the water from G, the ſupply of Steam being cut off by ſhutting F, as in the former operation: the water conſequently ruſhes through D, by the preſſure of the atmoſphere at B, and E is again filled. This water is forced up the main pipe through C, by opening F and ſhutting G, as before. And thus it is eaſy to conceive, that by this alternate opening and ſhutting the cocks, water will be continually raiſed, as long as the boiler continues to ſupply the Steam.

For the ſake of perſpicuity, the drawing is diveſted of the apparatus that ſerves to turn the two cocks at once, and of the contrivances for filling the copper to the proper quantity. But it may be found complete, with a full account of its uſes and application, in Mr. Savery's book intituled the *Miner's Friend*. The engines of this conſtruction were uſually made to work with two receivers or Steam veſſels, one to receive the Steam, while the other was raiſing water by the condenſation. This engine has been ſince improved, by adapting the end of the condenſing pipe G into the veſſel E, by which means the Steam is more ſuddenly and effectually condenſed than by water on the outſide of the veſſel.

The advantages of this engine are, that it may be erected in almoſt any ſituation, that it requires but little room, and is ſubject to very little friction in its parts.—Its diſadvantages are, that great part of the Steam is condenſed and loſes its force upon coming into contact with the water in the veſſel E, and that the heat and elaſticity of the Steam muſt be increaſed in proportion to the height that the water is required to be raiſed to. On both theſe accounts a large fire is required, and the copper muſt be very ſtrong, when the height is conſiderable, otherwiſe there is danger of its burſting.

While captain Savery was employed in perfecting his engine, Dr. Papin of Marburg was contriving one on the ſame principles, which he deſcribes in a ſmall book publiſhed in 1707, intitled *Ars Nova ad Aquam Ignis adminiculo efficaciſſimè elevandam*. Capt. Savery's engine however was much completer than that propoſed by Dr. Papin.

About the ſame time alſo one Monſ. Amontons of Paris was engaged in the ſame purſuit: but his method of applying the force of Steam was different from thoſe before-mentioned; for he intended it to drive or turn a wheel, which he called a *fire-mill*, which was to work pumps for raiſing water; but he never brought it to perfection. Each of theſe three gentlemen claimed the originality of the invention; but it is moſt probable they all took the hint from the book publiſhed by the marquis of Worceſter, as before-mentioned.

In this imperfect ſtate it continued, without farther improvements, till the year 1705, when Mr. Newcomen, an iron-monger, and Mr. John Cowley, a glazier, both of Dartmouth, contrived another way to raiſe water by Steam, bringing the engine to work with a beam and piſton, and where the Steam, even at the greateſt depths of mines, is not required to be greater than the preſſure of the atmoſphere: and this is the ſtructure of the engine as it has ſince been chiefly uſed. Theſe gentlemen obtained a patent for the ſole uſe of this invention, for 14 years. The firſt propoſal they made for draining of mines by this engine, was in the year 1711; but they were very coldly received by many

many perſons in the ſouth of England, who did not underſtand the nature of it. In 1712 they came to an agreement with the owners of a colliery at Griff in Warwickſhire, where they erected an engine with a cylinder of 22 inches diameter. At firſt they were under great difficulties in many things; but by the aſſiſtance of ſome good workmen they got all the parts put together in ſuch a manner, as to anſwer their intention tolerably well: and this was the firſt engine of the kind erected in England. There was at firſt one man to attend the Steam-cock, and another to attend the injection cock; but they afterwards contrived a method of opening and ſhutting them by ſome ſmall machinery connected with the working beam. The next engine erected by theſe patentees, was at a colliery in the county of Durham, about the year 1718, where was concerned, as an agent, Mr. Henry Beighton, F. R. S. and conductor of the Ladies' Diary from the year 1714 to the year 1744: this gentleman, not approving of the intricate manner of opening and ſhutting the cocks by ſtrings and catches, as in the former engine, ſubſtituted the hanging beam for that purpoſe as at preſent uſed, and likewiſe made improvements in the pipes, valves, and ſome other parts of the engine.

In a few years afterwards, theſe engines came to be better underſtood than they had been, and their advantages, eſpecially in draining of mines, became more apparent: and from the great number of them erected, they received additional improvements from different perſons, till they arrived at their preſent degree of perfection: as will appear in the ſequel, after we have a little conſidered the general principles of this engine, which are as follow.

Principles of the Steam Engine.

The principles on which this engine acts, are truly philoſophical; and when all the parts of the machine are proportioned to each other according to theſe principles, it never fails to anſwer the intention of the engineer.

1. It has been proved in pneumatics, that the preſſure of the atmoſphere upon a ſquare inch at the earth's ſurface, is about 14¾lb avoirdupois at a medium, or 11½lb on a circular inch, that is on a circle of an inch diameter. And,

2. If a vacuum be made by any means in a cylinder, which has a moveable piſton ſuſpended at one end of a lever equally divided, the air will endeavour to ruſh in, and will preſs down the piſton, with a force proportionable to the area of the ſurface, and will raiſe an equal weight at the other end of the lever.

3. Water may be rarefied near 14000 times by being reduced into Steam, and violently heated: the particles of it are ſo ſtrongly repellent, as to drive away air of the common denſity, only by a heat ſufficient to keep the water in a boiling ſtate, when the Steam is almoſt 3000 times rarer than water, or 3½ times rarer than air, as appears by an experiment of Mr. Beighton's: by increaſing the heat, the Steam may be rendered much ſtronger; but this requires great ſtrength in the veſſels. This Steam may be again condenſed into its former ſtate by a jet of cold water diſperſed through it; ſo that 14000 cubic inches of Steam admitted into a cylinder, may be reduced into the ſpace of one cubic inch of water only, by which means a partial vacuum is obtained.

4. Though the preſſure of the atmoſphere be about 14¾ pounds upon every ſquare inch, or 11½ pounds upon a circular inch; yet, on account of the friction of the ſeveral parts, the reſiſtance from ſome air which is unavoidably admitted with the jet of cold water, and from ſome remainder of Steam in the cylinder, the vacuum is very imperfect, and the piſton does not deſcend with a force exceeding 8 or 9 pounds upon every ſquare inch of its ſurface.

5. The gallon of water of 282 cubic inches weighs 10⅕ pounds avoirdupois, or a cubic foot 62½ pounds, or 1000 ounces. The piſton being preſſed by the atmoſphere with a force proportional to its area in inches, multiplied by about 8 or 9 pounds, depreſſes that end of the lever, and raiſes a column of water in the pumps of equal weight at the other end, by means of the pump-rods ſuſpended to it. When the Steam is again admitted, the pump-rods ſink by their ſuperior weight, and the piſton riſes; and when that Steam is condenſed, the piſton deſcends, and the pump-rods lift; and ſo on alternately as long as the piſton works.

It has been obſerved above, that the piſton does not deſcend with a force exceeding 8 or 9 pounds upon every ſquare inch of its ſurface; but by reaſon of accidental frictions, and alterations in the denſity of the air, it will be ſafeſt, in calculating the power of the cylinder, to allow ſomething leſs than 8 pounds for the preſſure of the atmoſphere, upon every ſquare inch, viz 7lb. 10 oz. = 7·64lb. or juſt 6lb. upon every circular inch; and it being allowed that the gallon of water, of 282 cubic inches, weighs 10⅕lb, from theſe premiſes the dimenſions of the cylinder, pumps, &c, for any Steam-engine, may be deduced as follows:—

Suppoſe

c = the cylinder's diameter in inches,
p = the pump's ditto,
f = the depth of the pit in fathoms,
g = gallons drawn by a ſtroke of 6 feet or a fathom,
h = the hogſheads drawn per hour,
s = the number of ſtrokes per minute.

Then c^2 is the area of the cylinder in circular inches, therefore $6c^2$ is the power of the cylinder in pounds.

And $\frac{p^2 \times \cdot 7854 \times 72}{282}$ or $\frac{1}{5}p^2$ is $= g$ the gallons contained in one fathom or 72 inches of any pump; which multiplied by f fathoms, gives $\frac{1}{5}p^2f$ for the gallons contained in f fathoms of any pump whoſe diameter is p.

Hence $\frac{1}{5}p^2f \times 10\frac{1}{5}$lb. gives $2p^2f$ nearly, for the weight in pounds of the column of water which is to be equal to the power of the cylinder, which was before found equal to $6c^2$. Hence then we have the 2d equation,

viz, $6c^2 = 2p^2f$, or $3c^2 = p^2f$;

the firſt equation being $\frac{1}{5}p^2 = g$, or $p^2 = 5g$.

From which two equations, any particular circumſtance may be determined.

Or if, inſtead of 6lb, for the preſſure of the air on each circular inch of the cylinder, that force be ſuppoſed

poſed any number as a pounds; then will the power of the cyclinder be ac^2, and the 2d equation becomes $ai^2 = 2p^2f = 10fg$, by ſubſtituting $5g$ inſtead of p^2.

And farther, $63h = 60gs$, or $21h = 20gs$.

From a compariſon of theſe equations, the following theorems are derived, which will determine the ſize of the cylinder and pumps of any Steam-engine capable of drawing a certain quantity of water from any aſſigned depth, with the preſſure of the atmoſphere on each circular inch of the cylinder's area.

Theſe theorems are more particularly adapted to one pump in a pit. But it often happens in practice, that an engine has to draw ſeveral pumps of different diameters from different depths; and in this caſe, the ſquare of the diameter of each pump muſt be multiplied by its depth, and double the ſum of all the products will be the weight of water drawn at each ſtroke, which is to be uſed inſtead of $2p^2f$ for the power of the cylinder.

The following is a Table, calculated from the foregoing theorems, of the powers of cylinders from 30 to 70 inches diameter; and the diameter and lengths of pumps which thoſe cylinders are capable of working, from a 6 inch bore to that of 20 inches, together with the quantity of water drawn per ſtroke and per hour, allowing the engine to make 12 ſtrokes of 6 feet per minute, and the preſſure of the atmoſphere at the rate of 7 lb 10 oz per ſquare inch, or 6 lb per circular inch.

A TABLE *of* THEOREMS *for the readier computing the Powers of a* STEAM-ENGINE.

1	$a = \frac{2fp^2}{c^2} = \frac{10fg}{c^2} = \frac{21fh}{2c^2s}$
2	$c = \sqrt{\frac{2fp^2}{a}} = \sqrt{\frac{10fg}{a}} = \sqrt{\frac{21fh}{2as}}$
3	$f = \frac{ac^2}{2p^2} = \frac{ac^2}{10g} = \frac{2ac^2s}{21h}$
4	$g = \frac{p^2}{5} = \frac{ac^2}{10f} = \frac{21h}{20s}$
5	$h = \frac{4p^2s}{21} = \frac{20gs}{21} = \frac{2ac^2s}{21f}$
6	$p = \sqrt{5g} = \sqrt{\frac{ac^2}{2g}} = \sqrt{\frac{21h}{4s}}$
7	$s = \frac{21h}{4p^2} = \frac{21h}{20g} = \frac{21fh}{2ac^2}$

Let us now deſcribe the ſeveral parts of an engine, and exemplify the application of the foregoing principles, in the conſtruction of one of the completeſt of the modern engines. See fig. 4. pl. 27.

A repreſents the fire-place under the boiler, for the boiling of the water, and the aſh-hole below it.

B, the boiler, filled with water about three feet above the bottom, made of iron plates.

C, the Steam pipe, through which the Steam paſſes from the boiler into the receiver.

D, the receiver, a cloſe iron veſſel, in which is the regulator or Steam-cock, which opens and ſhuts the hole of communication at each ſtroke.

E, the communication pipe between the receiver and the cylinder; it riſes 5 or 6 inches up, in the inſide of the cylinder bottom, to prevent the injected water from deſcending into the receiver.

F, the cylinder, of caſt iron, about 10 feet long, bored ſmooth in the inſide; it has a broad flanch in the middle on the outſide, by which it is ſupported when hung in the cylinder-beams.

G, the piſton, made to fit the cylinder exactly: it has a flanch riſing 4 or 5 inches upon its upper ſurface, between which and the ſide of the cylinder a quantity of junk or oakum is ſtuffed, and kept down by weights, to prevent the entrance of air or water and the eſcaping of Steam.

H, the chain and piſton-ſhank, by which it is connected to the working beam.

I I, the working-beam or lever: it is made of two or more large logs of timber, bent together at each end, and kept at the diſtance of 8 or 9 inches from each other in the middle by the gudgeon, as repreſented in the Plate. The arch-heads, II, at the ends, are for giving a perpendicular direction to the chains of the piſton and pump-rods.

K, the pump-rod which works in the ſucking pump.

L, and draws the water from the bottom of the pit to the ſurface.

M, a ciſtern, into which the water drawn out of the pit is conducted by a trough, ſo as to keep it always full: and the ſuperfluous water is carried off by another trough.

N, the jack-head pump, which is a ſucking-pump wrought by a ſmall lever or working-beam, by means of a chain connected to the great beam or lever near the arch *g* at the inner end, and the pump-rod at the outer end. This pump commonly ſtands near the corner of the front of the houſe, and raiſes the column of water up to the ciſtern O, into which it is conducted by a trough.

O, the jack-head ciſtern for ſupplying the injection, which is always kept full by the pump N: it is fixed ſo high as to give the jet a ſufficient velocity into the cylinder when the cock is opened. This ciſtern has a pipe on the oppoſite ſide for conveying away the ſuperfluous water.

P P, the injection-pipe, of 3 or 4 inches diameter, which turns up in a curve at the lower end, and enters the cylinder bottom: it has a thin plate of iron upon the end *a*, with 3 or 4 adjutage holes in it, to prevent the jet of cold water of the jack-head ciſtern from flying up againſt the piſton, and yet to condenſe the Steam each ſtroke, when the injection-cock is open.

e, a valve upon the upper end of the injection pipe within the ciſtern, which is ſhut when the engine is not working, to prevent any waſte of the water.

f, a ſmall pipe which branches off from the injection-pipe, and has a ſmall cock to ſupply the piſton with a little water to keep it air-tight.

Q, the working plug, ſuſpended by a chain to the arch *g* of the working beam. It is uſually a heavy piece of timber, with a ſlit vertically down its middle, and holes bored horizontally through it, to receive pins for the purpoſe of opening and ſhutting the injection and Steam cocks, as it aſcends and deſcends by the motion of the working beam.

h, the handle of the ſteam-cock or regulator. It is fixed to the regulator by a ſpindle which comes up through the top of the receiver. The regulator is a circular plate of braſs or caſt iron, which is moved horizontally by the handle *h*, and opens or ſhuts the communication at the lower end of the pipe E within the receiver. It is repreſented in the plate by a circular dotted line.

i i, the ſpanner, which is a long rod or plate of iron for communicating motion to the handle of the regulator: to which it is fixed by means of a ſlit in the latter, and ſome pins put through to faſten it.

k l, the vibrating lever, called the Y, having the weight *k* at one end and two legs at the other end. It is fixed to an horizontal axis, moveable about its centre-pins or pivots *mn*, by means of the two ſhanks *op* fixed to the ſame axis, which are alternately thrown backwards and forwards by means of two pins in the working plug; one pin on the outſide depreſſing the ſhank *o*, throws the loaded end *k* of the Y from the cylinder into the poſition repreſented in the plate, and cauſes the leg *l* to ſtrike againſt the end of the ſpanner; which forcing back the handle of the regulator or ſteam cock, opens the communication, and permits the ſteam to fly into the cylinder. The piſton immediately riſing by the admiſſion of the Steam, the working beam II riſes; which alſo raiſes the working-plug, and another pin which goes through the ſlit raiſes the ſhank *p*, which throws the end *k* of the Z towards the cylinder, and, ſtriking the end of the ſpanner, forces it forward, and ſhuts the regulator Steam-cock.

qr, the lever for opening and ſhutting the injection cock, called the F. It has two toes from its centre, which take between them the key of the injection cock. When the working plug has aſcended nearly to its greateſt height, and ſhut the regulator, a pin catches the end *q* of the F and raiſes it up, which opens the injection-cock, admits a jet of cold water to fly into the cylinder, and, condenſing the Steam, makes a vacuum; then the preſſure of the atmoſphere bringing down the piſton in the cylinder, and alſo the plug-frame, another pin fixed in it catches the end of the lever in its deſcent, and, by preſſing it down, ſhuts the injection-cock, at the ſame time the regulator is opened to admit Steam, and ſo on alternately; when the regulator is ſhut the injection is open, and when the former is open the latter is ſhut.

R, the

R, the hot-well, a ſmall ciſtern made of planks, which receives all the waſte water from the cylinder.

S, the ſink-pit to convey away the water which is injected into the cylinder at each ſtroke. Its upper end is even with the inſide of the cylinder bottom, its lower end has a lid or cover moveable on a hinge which ſerves as a valve to let out the injected water, and ſhuts cloſe each ſtroke of the engine, to prevent the water being forced up again when the vacuum is made.

T, the feeding pipe, to ſupply the boiler with water from the hot-well. It has a cock to let in a large or ſmall quantity of water as occaſion requires, to make up for what is evaporated; it goes nearly down to the boiler bottom.

U, two gage cocks, the one larger than the other, to try when a proper quantity of water is in the boiler: upon opening the cocks, if one give Steam and the other water, it is right; if they both give Steam, there is too little water in the boiler; and if they both give water, there is too much.

W, a plate which is ſcrewed on to a hole on the ſide of the boiler, to allow a paſſage into the boiler for the convenience of cleaning or repairing it.

X, the Steam-clack or puppet valve, which is a braſs valve on the top of a pipe opening into the boiler, to let off the Steam when it is too ſtrong. It is loaded with lead, at the rate of one pound to an inch ſquare; and when the Steam is nearly ſtrong enough to keep it open, it will do for the working of the engine.

f, the ſniſting valve, by which the air is diſcharged from the cylinder each ſtroke, which was admitted with the injection, and would otherwiſe obſtruct the due operation of the engine.

tt, the cylinder-beams; which are ſtrong joiſts going through the houſe for ſupporting the cylinder.

v, the cylinder cap of lead, ſoldered on the top of the cylinder, to prevent the water upon the piſton from flaſhing over when it riſes too high.

w, the waſte-pipe, which conducts the ſuperfluous water from the top of the cylinder to the hot-well.

xx, iron bars, called the catch-pins, fixed horizontally through each arch-head, to prevent the beam deſcending too low in caſe the chain ſhould break.

yy, two ſtrong wooden ſprings, to weaken the blow given by the catch pins when the ſtroke is too long.

zz, two friction-wheels, on which the gudgeon or centre of the great beam is hung; they are the third or fourth part of a circle, and move a little each way as the beam vibrates. Their uſe is to diminiſh the friction of the axis, which, in ſo heavy a lever, would otherwiſe be very great.

When this engine is to be ſet to work, the boiler muſt be filled about three or four feet deep with water, and a large fire made under it; and when the Steam is found to be of a ſufficient ſtrength by the puppet-clack, then by thruſting back the ſpanner, which opens the regulator or Steam-cock, the Steam is admitted into the cylinder, which raiſes the piſton to the top of the cylinder, and forces out all the air at the ſniſting valve; then by turning the key of the injection-cock, a jet of cold water is admitted into the cylinder, which condenſes the Steam and makes a vacuum; and the atmoſphere then preſſing upon the piſton, forces it down to the lower part of the cylinder, and makes a ſtroke by raiſing the column of water at the other end of the beam. After two or three ſtrokes are made in this manner, by a man opening and ſhutting the cocks to try if they be right, then the pins may be put into the pin-holes in the working plug, and the engine left to turn the cocks of itſelf; which it will do with greater exactneſs than any man can do.

There are in ſome engines, methods of ſhutting and opening the cocks different from the one above deſcribed, but perhaps none better adapted to the purpoſe; and as the principles on which they all act are originally the ſame, any difference in the mechanical conſtruction of the ſmall machinery will have no influence of conſequence upon the total effect of the grand machine.

The furnace or fire-place ſhould not have the bars ſo cloſe as to prevent the free admiſſion of freſh air to the fire, nor ſo open as to permit the coals to fall through them; for which purpoſe two inches or thereabouts is ſufficient for the diſtance betwixt the bars. The ſize of the furnace depends upon the ſize of the boiler; but in every caſe the aſh-hole ought to be capacious to admit the air, and the greater its height the better. If the flame is conducted in a flue or chimney round the outſide of the boiler, or in a pipe round the inſide of it, it ought to be gradually diminiſhed from the entrance at the furnace to its egreſs at the chimney; and the ſection of the chimney at that place ſhould not exceed the ſection of the flue or pipe, and ſhould alſo be ſomewhat leſs at the chimney-top.

The boiler or veſſel in which the water is rarefied by the force of fire, may be made of iron plates, or caſt iron, or ſuch other materials as can withſtand the effects of the fire, and the elaſtic force of the Steam. It may be conſidered as conſiſting of two parts; the upper part which is expoſed to the Steam, and the under part which is expoſed to the fire. The form of the latter ſhould be ſuch as to receive the full force of the fire in the moſt advantageous manner, ſo that a certain quantity of fuel may have the greateſt poſſible effect in heating and evaporating the water; which is beſt done by making the ſides cylindrical, and the bottom a little concave, and then conducting the flame by an iron flue or pipe round the inſide of the boiler beneath the ſurface of the water, before it reach the chimney. For, by this means, after the fire in the furnace has heated the water by its effect on the bottom, the flame heats it again by the pipe being wholly included in the water, and having every part of its ſurface in contact with it; which is preferable to carrying it in a flue or chimney round the outſide of the boiler, as a third or a half of the ſurface of the flame only could be in contact with the boiler, the other being ſpent upon the brick-work. This cylindric lower part may be leſs in its diameter than the upper part, and may contain from four to ſix feet perpendicular height of water in it.

The upper part of the boiler is beſt made hemiſpherical, for reſiſting the elaſticity of the Steam; yet any other form may do, provided it be of ſufficient ſtrength for the purpoſe. The quick going of the engine depends much on the capaciouſneſs of the boiler-top; for if it be too ſmall, it requires the Steam to be heated to a great degree, to increaſe its elaſtic force ſo much as to work the engine. If the top is ſo capacious as to contain eight or ten times the quantity of Steam uſed each ſtroke, it will require no more fire to preſerve its elaſticity than is ſufficient to keep the water in a proper ſtate of boiling; this, therefore, is the beſt ſize for a boiler top. If the diameter of the cylinder be c, and works a ſix-foot ſtroke, and the diameter of the boiler be ſuppoſed b, then

$$200c^2 = b^3, \text{ or } b = \sqrt[3]{200c^2}.$$

The effect of the injection in condenſing the Steam in the cylinder, depends upon the height of the reſervoir and the diameter of the adjutage. If the engine makes a 6 feet ſtroke, then the jackhead ciſtern ſhould be 12 feet perpendicular above the bottom of the cylinder or the adjutage. The ſize of the adjutage may be from 1 to 2 inches in diameter; or if the cylinder be very large, it is proper to have three or four holes rather than one large one, in order that the jet may be diſperſed the more effectually over the whole area of the cylinder. The injection pipe, or pipe of conduct, ſhould be ſo large as to ſupply the injection freely with water; if the diameter of the injection pipe be called p, and the diameter of the adjutage, a, then $4a^2 = p^2$, and $a^2 = \frac{1}{4}p^2$, or $a = \frac{1}{2}p$.

For a further account of theſe engines, ſee Deſaguliers's Exp. Philoſ. vol. 2, ſect. 14, pa. 465, &c.; or for an abſtract, Martin's Phil. Brit. number 461, or Nicholſon's Nat. Philoſ. p. 83 &c. And for an account of the improvement made in the fire-engine by Mr. Payne, ſee Philoſ. Tranſ. number 461, or Martin's Philoſ. Brit. p. 87 &c.

Mr. Blakey communicated to the Royal Society, in 1752, remarks on the beſt proportions for Steam-engine cylinders of a given content: and Mr. Smeaton deſcribes an engine of this kind, invented by Mr. De Moura of Portugal, being an improvement of Savery's conſtruction, to render it capable of working itſelf: for both which accounts, ſee Philoſ. Tranſ. vol. 47 art. 29 and 72.

We are informed in the new edit. of the Biograph. Brit. in the article Brindley, that in 1756 this gentleman, ſo well known for his concern in our inland navigations, undertook to erect a Steam-engine near Newcaſtle-under-Line, upon a new plan. The boiler of it was made with brick and ſtone, inſtead of iron plates, and the water was heated by iron flues of a peculiar conſtruction; by which contrivances the conſumption of fuel, neceſſary for working a Steam engine, was reduced one half. He introduced alſo in his engine, wooden cylinders, made in the manner of cooper's ware, inſtead of iron ones; the former being both cheaper and more eaſily managed in the ſhafts: and he likewiſe ſubſtituted wood for iron in the chains which worked at the end of the beam. He had formed deſigns of introducing other improvements into the conſtruction of this uſeful engine; but was diſcouraged by obſtacles that were thrown in his way.

Mr. Blakey, ſome years ago, obtained a patent for his improvement of Savery's Steam-engine, by which it is excellently adapted for raiſing water out of ponds, rivers, wells, &c, and for forcing it up to any height wanted for ſupplying houſes, gardens, and other places; though it has not power ſufficient to drain off the water from a deep mine. The principles of his conſtruction are explained by Mr. Ferguſon, in the Supplement to his Lectures, pa. 105; and a more particular deſcription of it, accompanied with a drawing, is given by the patentee himſelf in the Gentleman's Magazine for 1769, p. 392.

Mr. Blakey, it is ſaid, is the firſt perſon who ever thought of making uſe of air as an intermediate body between Steam and water; by which means the Steam is always kept from touching the water, and conſequently from being condenſed by it: and on this new principle he has obtained a patent. The engine may be built at a trifling expence, in compariſon of the common fire-engine now in uſe; it will ſeldom need repairs, and will not conſume half ſo much fuel. And as it has no pumps with piſtons, it is clear of all their friction; and the effect is equal to the whole ſtrength or compreſſive force of the Steam; which the effect of the common fire-engine never is, on account of the great friction of the piſtons in their pumps.

Ever ſince Mr. Newcomen's invention of the Steam fire engine, the great conſumption of fuel with which it is attended, has been complained of as an immenſe drawback upon the profits of our mines. It is a known fact, that every fire-engine of conſiderable ſize conſumes to the amount of three thouſand pounds worth of coals in every year. Hence many of our engineers have endeavoured, in the conſtruction of theſe engines, to ſave fuel. For this purpoſe, the fire-place has been diminiſhed, the flame has been carried round from the bottom of the boiler in a ſpiral direction, and conveyed through the body of the water in a tube before its arrival at the chimney; ſome have uſed a double boiler, ſo that fire might act in every poſſible point of contact; and ſome have built a moor-ſtone boiler, heated by three tubes of flame paſſing through it. But the moſt important improvements which have been made in the Steam-engine for more than thirty years paſt, we owe to the ſkill of Mr. James Watt; of which we ſhall give ſome account: premiſing, that the internal ſtructure of his new engines ſo much reſembles that of the common ones, that thoſe who are acquainted with them will not fail to underſtand the mechaniſm of his from the following deſcription: he has contrived to obſerve an uniform heat in the cylinder of his engines, by ſuffering no cold water to touch it, and by protecting it from the air, or other cold bodies, by a ſurrounding caſe filled with Steam, or with hot air or water, and by coating it over with ſubſtances that tranſmit heat ſlowly. He makes his vacuum to approach nearly to that of the barometer, by condenſing the Steam in a ſeparate veſſel, called the condenſer, which may be cooled at pleaſure without cooling the cylinder, either by an injection of cold water, or by ſurrounding

the condenſer with it, and generally by both. He extracts the injection water, and detached air, from the cylinder or condenſer by pumps, which are wrought by the engine itſelf, or blows them out by the Steam. As the entrance of air into the cylinder would ſtop the operation of the engines, and as it is hardly to be expected that ſuch enormous piſtons as thoſe of Steam-engines can move up and down, and yet be abſolutely tight in the common engines; a ſtream of water is kept always running upon the piſton, which prevents the entry of the air: but this mode of ſecuring the piſton, though not hurtful in the common ones, would be highly prejudicial to the new engines. Their piſton is therefore made more accurately; and the outer cylinder, having a lid, covers it, the Steam is introduced above the piſton; and when a vacuum is produced under it, acts upon it by its elaſticity, as the atmoſphere does upon common engines by its gravity. This way of working effectually excludes the air from the inner cylinder, and gives the advantage of adding to the power, by increaſing the elaſticity of the Steam.

In Mr. Watt's engines, the cylinder, the great beams, the pumps, &c, ſtand in their uſual poſitions. The cylinder is ſmaller than uſual, in proportion to the load, and is very accurately bored.

In the moſt complete engines, it is ſurrounded at a ſmall diſtance, with another cylinder, furniſhed with a bottom and a lid. The interſtice between the cylinders communicates with the boilers by a large pipe, open at both ends: ſo that it is always filled with Steam, and thereby maintains the inner cylinder always of the ſame heat with the Steam, and prevents any condenſation within it, which would be more detrimental than an equal condenſation in the outer one. The inner cylinder has a bottom and piſton as uſual: and as it does not reach up quite to the lid of the outer cylinder, the Steam in the interſtice has always free acceſs to the upper ſide of the piſton. The lid of the outer cylinder has a hole in its middle; and the piſton rod, which is truly cylindrical, moves up and down through that hole, which is kept Steam-tight by a collar of oakum ſcrewed down upon it. At the bottom of the inner cylinder, there are two regulating valves, one of which admits the Steam to paſs from the interſtice into the inner cylinder below the piſton, or ſhuts it out at pleaſure: the other opens or ſhuts the end of a pipe, which leads to the condenſer. The condenſer conſiſts of one or more pumps furniſhed with clacks and buckets (nearly the ſame as in common pumps) which are wrought by chains faſtened to the great working beam of the engine. The pipe, which comes from the cylinder, is joined to the bottom of theſe pumps, and the whole condenſer ſtands immerſed in a ciſtern of cold water ſupplied by the engine. The place of this ciſtern is either within the houſe or under the floor, between the cylinder and the lever wall; or without the houſe between that wall and the engine ſhaft, as conveniency may require. The condenſer being exhauſted of air by blowing, and both the cylinders being filled with Steam, the regulating valve which admits the Steam into the inner cylinder is ſhut, and the other regulator which communicates with the condenſer is opened, and the Steam ruſhes into the vacuum of the condenſer with violence: but there it comes into contact with the cold ſides of the pumps and pipes, and meets a jet of cold water, which was opened at the ſame time with the exhauſtion regulator; theſe inſtantly deprive it of its heat, and reduce it to water; and the vacuum remaining perfect, more Steam continues to ruſh in, and be condenſed until the inner cylinder be exhauſted. Then the Steam which is above the piſton, ceaſing to be counteracted by that which was below it, acts upon the piſton with its whole elaſticity, and forces it to deſcend to the bottom of the cylinder, and ſo raiſes the buckets of the pumps which are hung to the other end of the beam. The exhauſtion regulator is now ſhut, and the Steam one opened again, which, by letting in the Steam, allows the piſton to be pulled up by the ſuperior weight of the pump rods; and ſo the engine is ready for another ſtroke.

But the nature of Mr. Watt's improvement will be perhaps better underſtood from the following deſcription of it as referred to a figure.—The cylinder or Steam veſſel A, of this engine (fig. 5, pl. 27), is ſhut at bottom and opened at top as uſual; and is included in an outer cylinder or caſe BB, of wood or metal, covered with materials which tranſmit heat ſlowly. This caſe is at a ſmall diſtance from the cylinder, and cloſe at both ends. The cover C has a hole in it, through which the piſton rod E ſlides; and near the bottom is another hole F, by which the Steam from the boiler has always free entrance into this caſe or outer cylinder, and by the interſtice GG between the two cylinders has acceſs to the upper ſide of the piſton HH. To the bottom of the inner cylinder A is joined a pipe I, with a cock or valve K, which is opened and ſhut when neceſſary, and forms a paſſage to another veſſel L called a *Condenſer*, made of thin metal. This veſſel is immerſed in a ciſtern M full of cold water, and it is contrived ſo as to expoſe a very great ſurface externally to the water, and internally to the Steam. It is alſo made air-tight, and has pumps N wrought by the engine, which keep it always exhauſted of air and water.

Both the cylinders A and BB being filled with Steam, the paſſage K is opened from the inner one to the condenſer L, into which the Steam violently ruſhes by its elaſticity, becauſe that veſſel is exhauſted; but as ſoon as it enters it, coming into contact with the cold matter of the condenſer, it is reduced to water, and, the vacuum ſtill remaining, the Steam continues to ruſh in till the inner cylinder A below the piſton is left empty. The Steam which is above the piſton, ceaſing to be counteracted by that which is below it, acts upon the piſton HH, and forces it to deſcend to the bottom of the cylinder, and ſo raiſes the bucket of the pump by means of the lever. The paſſage K between the inner cylinder and the condenſer is then ſhut, and another paſſage O is opened, which permits the Steam to paſs from the outer cylinder, or from the boiler into the inner cylinder under the piſton; and then the ſuperior weight of the bucket and pump rods pulls down the outer end of the lever or great beam, and raiſes the piſton, which is ſuſpended to the inner end of the ſame beam.

The advantages that accrue from this conſtruction are, firſt, that the cylinder being ſurrounded with the Steam from the boiler, it is kept always uniformly as hot as the Steam itſelf, and is therefore incapable of deſtroy-

ing any part of the Steam, which ſhould fill it, as the common engines do. Secondly, the condenſer being kept always as cold as water can be procured, and colder than the point at which it boils in vacuo, the Steam is perfectly condenſed, and does not oppoſe the deſcent of the piſton; which is therefore forced down by the full power of the Steam from the boiler, which is ſomewhat greater than that of the atmoſphere.

In the common fire-engines, when they are loaded to 7 pounds upon the inch, and are of a middle ſize, the quantity of Steam which is condenſed in reſtoring to the cylinder the heat which it had been deprived of by the former injection of cold water, is about one full of the cylinder, beſides what it really required to fill that veſſel; ſo that twice the full of the cylinder is employed to make it raiſe a column of water equal to about 7 pounds for each ſquare inch of the piſton: or, to take it more ſimply, a cubic foot of Steam raiſes a cubic foot of water about 8 feet high, beſides overcoming the friction of the engine, and the reſiſtance of the water to motion.

In the improved engine, about one full and a fourth of the cylinder is required to fill it, becauſe the Steam is one-fourth more denſe than in the common engine. This engine raiſes a load equal to 12 pounds and a half upon the ſquare inch of the piſton; and each cubic foot of Steam of the denſity of the atmoſphere, raiſes one cubic foot of water 22 feet high.

The working of theſe engines is more regular and ſteady than the common ones, and from what has been ſaid, their other advantages ſeem to be very conſiderable.

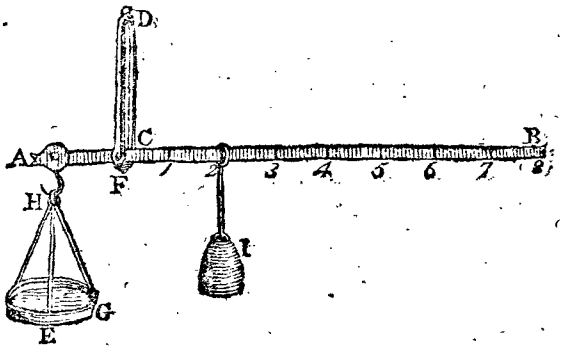
It is ſaid, that the ſavings amount at leaſt to two thirds of the fuel, which is an important object, eſpecially where coals are dear. The new engines will raiſe from twenty thouſand to twenty-four thouſand cubic feet of water, to the height of twenty-four feet by one hundred weight of good pit coal: and Mr. Watt has propoſed to produce engines upon the ſame principles, though ſomewhat differing in conſtruction, which will require ſtill much leſs fuel, and be more convenient for the purpoſes of mining, than any kind of engine yet uſed. Mr. Watt has alſo contrived a kind of mill wheel, which turns round by the power of Steam exerted within it.

The improvements above recited were invented by Mr. James Watt, at Glaſgow, in Scotland, in 1764: he obtained the king's letters patent for the ſole uſe of his invention in 1768; but meeting with difficulties in the execution of a large machine, and being otherwiſe employed, he laid aſide the undertaking till the year 1774, when, in conjunction with Mr. Boulton near Birmingham, he completed both a reciprocating and rotative or wheel engine. He then applied to parliament for a prolongation of the term of his patent, which was granted by an act paſſed in 1775. Since that time, Mr. Watt and Mr. Boulton have erected ſeveral engines in Staffordſhire, Shropſhire, and Warwickſhire, and a ſmall one at Stratford near London. They have alſo lately finiſhed another at Hawkeſbury colliery near Coventry, which is juſtly ſuppoſed to be the moſt powerful engine in England. It has a cylinder 58 inches in diameter, which works a pump 14 inches in diameter, 65 fathoms high, and makes regularly twelve ſtrokes, each 8 feet long, in a minute. They have alſo erected ſeveral engines in Cornwall; one of which has a cylinder 30 inches in diameter, that works a pump 6½ inches in diameter in two ſhafts, by ſtat rods with great friction, 300 feet diſtant from each other, 45 fathoms high in each ſhaft, equal in all to 90 fathoms, and can make 14 ſtrokes, 8 feet long, in a minute, with a conſumption of coals leſs than 20 buſhels in 24 hours. The terms they offer to the public are, to take in lieu of all profits, one third part of the annual ſavings in fuel, which their engine makes when compared with a common engine of the ſame dimenſions in the neighbourhood. The engines are built at the expence of thoſe who uſe them, and Meſſrs. Boulton and Watt furniſh ſuch drawings, directions, and attendance, as may be neceſſary to enable a reſident engineer to complete the machine. See the appendix to Pryce's Mineralogia, &c, 1778.

It has been ſaid that ſome uſeful improvements have been made in the Steam engine by Mr. William Powel, who had lately the direction and care of an engine of this kind at a colliery near Swanſea, in Glamorganſhire.

It is hardly neceſſary to add, that Dr. Falck, in 1776, publiſhed an account and deſcription of an improved Steam-engine, which, as he ſays, will, with the ſame quantity of fuel, and in an equal ſpace of time, raiſe above double the quantity of water raiſed by any lever engine of the ſame dimenſions; as he does not ſeem to have conſtructed even a working model of his propoſed engine. The principal improvement, however, which he ſuggeſts, is to uſe two cylinders; into which the Steam is let alternately to aſcend, by a common regulator, which always opens the communication of the Steam to one, whilſt it ſhuts up the opening of the other: the piſton rods are kept (by means of a wheel fixed to an arbour) in a continual aſcending and deſcending motion, by which they move the common arbour, to which is affixed another wheel, moving the pump rods, in the ſame alternate direction as the piſton rods, by which continual motion the pumps are kept in conſtant action.

STEELYARD, or STILYARD, in Mechanics, a kind of balance, called alſo, *Statera Romana*, or the *Roman Balance*, by means of which the weights of different bodies are diſcovered by uſing one ſingle weight only.



The common Steelyard conſiſts of an iron beam AB, in

in which is assumed a point at pleasure, as C, on which is raised a perpendicular CD. On the shorter arm AC is hung a scale or bason to receive the bodies weighed: the moveable weight I is shifted backward and forward on the beam, till it be a counterbalance to 1, 2, 3, 4, &c pounds placed in the scale; and the points are noted where the constant weight I weighs, as 1, 2, 3, 4, &c pounds. From this construction of the Steelyard, the manner of using it is evident. But the instrument is very liable to deceit, and therefore is not much used in ordinary commerce.

Chinese STEELYARD. The Chinese carry this Statera about them to weigh their gems, and other things of value. The beam or yard is a small rod of wood or ivory, about a foot in length: upon this are three rules of measure, made of a fine silver-studded work; they all begin from the end of the beam, whence the first is extended 8 inches, the second $6\frac{1}{2}$, the third $8\frac{1}{2}$. The first is the European measure, the other two seem to be Chinese measures. At the other end of the yard hangs a round scale, and at three several distances from this end are fastened so many slender strings, as different points of suspension. The first distance makes $1\frac{3}{5}$ or $\frac{8}{5}$ of an inch, the second $3\frac{1}{5}$ or double the first, and the third $4\frac{4}{5}$ or triple of the first. When they weigh any thing, they hold up the yard by some one of these strings, and hang a sealed weight, of about $1\frac{1}{4}$oz troy weight, upon the respective divisions of the rule, as the thing requires. Grew's Museum, pa. 369.

Spring STEELYARD, is a kind of portable balance, serving to weigh any matter, from 1 to about 40 pounds

It is composed of a brass or iron tube, into which goes a rod, and about that is wound a spring of tempered steel in a spiral form. On this rod are the divisions of pounds and parts of pounds, which are made by successively hanging on, to a hook fastened to the other end, 1, 2, 3, 4, &c, pounds.

Now the spring being fastened by a screw to the bottom of the rod; the greater the weight is that is hung upon the hook, the more will the spring be contracted, and consequently a greater part of the rod will come out of the tube; the proportions or quantities of which greater weights are indicated by the figures appearing against the extremity of the tube.

STEELYARD *Swing*. In the Philos. Trans. (no. 462, sect. 5) is given an account of a Steelyard swing, proposed as a mechanical method for assisting children labouring under deformities, owing to the contraction of the muscles on one side of the body. The crooked person is suspended with cords under his arm, and these are placed at equal distances from the centre of the beam. It is supposed that the gravity of the body will affect the contracted side, so as to put the muscles upon the stretch; and hence by degrees the defect may be remedied.

STEEPLE, an appendage usually raised on the western end of a church to contain the bells.—Steeples are denominated from their form, either *spires*, or *towers*. The first are such as rise continually diminishing like a cone or other pyramid. The latter are mere parallelopipedons, or some other prism, and are covered at top platform-like.—In each kind there is usually a sort of windows, or loop-holes, to let out the sound, and so contrived as to throw it downward.

Masius, in his treatise on bells, treats likewise of Steeples. The most remarkable in the world, it is said, is that at Pisa, which leans so much to one side, that you fear every moment it will fall; yet is in no danger. This odd disposition, he observes, is not owing to a shock of an earthquake, as is generally imagined; but was contrived so at first by the architect; as is evident from the cielings, windows, doors, &c, which are all in the bevel.

STEERAGE, in a ship, that part next below the quarter-deck, before the bulk-head of the great cabin, where the steersman stands in most ships of war. In large ships of war it is used as a hall, through which it is necessary to pass to or from the great cabin. In merchant ships it is mostly the habitation of the lower officers and ship's crew.

STEERAGE, in Sea-language, is also used to express the effort of the helm: and hence

STEERAGE-*way* is that degree of progressive motion communicated to a ship, by which she becomes susceptible of the effect of the helm to govern her course.

STEERING, in Navigation, the art of directing the ship's way by the movements of the helm; or of applying its efforts to regulate her course when she advances.

The perfection of Steering consists in a vigilant attention to the motion of the ship's head, so as to check every deviation from the line of her course in the first instant of its motion; and in applying as little of the power of the helm as possible. By this means she will run more uniformly in a straight path, as declining less to the right and left; whereas, if a greater effort of the helm be employed, it will produce a greater declination from the course, and not only increase the difficulty of Steering, but also make a crooked and irregular path through the water.

The helmsman, or steersman, should diligently watch the movements of the head by the land, clouds, moon, or stars; because, although the course is in general regulated by the compass, yet the vibrations of the needle are not so quickly perceived, as the sallies of the ship's head to the right or left, which, if not immediately restrained, will acquire additional velocity in every instant of their motion, and require a more powerful impulse of the helm to reduce them; the application of which, will operate to turn her head as far on the contrary side of her course.

The phrases used in Steering a ship, vary according to the relation of the wind to her course. Thus, when the wind is large or fair, the phrases used by the pilot or officer who superintends the Steerage, are *port*, *starboard*, and *steady*: the first of which is intended to direct the ship's course farther to the right; the second to the left; and the last is designed to keep her exactly in the line on which she advances, according to the intended course. The excess of the first and second movement is called *hard-a-port*, and *hard-a-starboard*; the former of which gives her the greatest possible inclination to the right, and the latter an equal tendency to the left.—If, on the contrary, the wind be scant or foul, the phrases are *luff*, *thus*, and *no nearer*: the first of which is the order to keep her close to the wind; the second, to retain her

her in her preſent ſituation; and the third, to keep her ſails full.

STELLA. See STAR.

STENTOROPHONIC *Tube*, a *Speaking Trumpet*, or tube employed to ſpeak to a perſon at a great diſtance. It has been ſo called from Stentor, a perſon mentioned in the 5th book of the Iliad, who, as Homer tells us, could call out louder than 50 men. The Stentorophonic horn of Alexander the Great is famous; with this it is ſaid he could give orders to his army at the diſtance of 100 ſtadia, which is about 12 Engliſh miles.

The preſent ſpeaking trumpet it is ſaid was invented by Sir Samuel Moreland. But Derham, in his Phyſico-Theology, lib. 4, ch. 3, ſays, that Kircher found out this inſtrument 20 years before Moreland, and publiſhed it in his Meſurgia; and it is farther ſaid that Gaſpar Schottus had ſeen one at the Jeſuits' College at Rome. Alſo one Conyers, in the Philoſ. Tranſ. number 141, gives a deſcription of an inſtrument of this kind, different from thoſe commonly made. Graveſande, in his Philoſophy, diſapproves of the uſual figures of theſe inſtruments; he would have them to be parabolic conoids, with the focus of one of its parabolic ſections at the mouth.—Concerning this inſtrument, ſee Sturmy's Collegium Curioſum, Pt. 2, Tentam. 8; alſo Philoſ. Tranſ. vol. 6, pa. 3056, vol. 12, pa. 1027, or Abridg. vol. 1, pa. 505.

STEREOGRAPHIC *Projection of the Sphere*, is that in which the eye is ſuppoſed to be placed in the ſurface of the ſphere. Or it is the projection of the circles of the ſphere on the plane of ſome one great circle, when the eye, or a luminous point, is placed in the pole of that circle.—For the fundamental principles and chief properties of this kind of projection, ſee PROJECTION.

STEREOGRAPHY, is the art of drawing the forms of ſolids upon a plane.

STEVIN, STEVINUS (SIMON), a Flemiſh mathematician of Bruges, who died in 1633. He was maſter of mathematics to prince Maurice of Naſſau, and inſpector of the dykes in Holland. It is ſaid he was the inventor of the ſailing chariots, ſometimes made uſe of in Holland. He was a good practical mathematician and mechaniſt, and was author of ſeveral uſeful works: as, treatiſes on Arithmetic, Algebra, Geometry, Statics, Optics, Trigonometry, Geography, Aſtronomy, Fortification, and many others, in the Dutch language, which were tranſlated into Latin, by Snellius, and printed in 2 volumes folio. There are alſo two editions in the French language, in folio, both printed at Leyden, the one in 1608, and the other in 1634, with curious notes and additions, by Albert Girard.—For a particular account of Stevin's inventions and improvements in Algebra, which were many and ingenious, ſee our article Algebra, vol. 1, pa. 82 and 83.

STEWART (the Rev. Dr. MATTHEW), late profeſſor of mathematics in the univerſity of Edinburgh, was the ſon of the reverend Mr. Dugald Stewart, miniſter of Rothſay in the Iſle of Bute, and was born at that place in the year 1717. After having finiſhed his courſe at the grammar ſchool, being intended by his father for the church, he was ſent to the univerſity of Glaſgow, and was entered there as a ſtudent in 1734. His academical ſtudies were proſecuted with diligence and ſucceſs; and he was ſo happy as to be particularly diſtinguiſhed by the friendſhip of Dr. Hutcheſon, and Dr. Simſon the celebrated geometrician, under whom he made great progreſs in that ſcience.

Mr. Stewart's views made it neceſſary for him to attend the lectures in the univerſity of Edinburgh in 1741; and that his mathematical ſtudies might ſuffer no interruption, he was introduced by Dr. Simſon to Mr. Maclaurin, who was then teaching with ſo much ſucceſs, both the geometry and the philoſophy of Newton, and under whom Mr. Stewart made that proficiency which was to be expected from the abilities of ſuch a pupil, directed by thoſe of ſo great a maſter. But the modern analyſis, even when thus powerfully recommended, was not able to withdraw his attention from the reliſh of the ancient geometry, which he had imbibed under Dr. Simſon. He ſtill kept up a regular correſpondence with this gentleman, giving him an account of his progreſs, and of his diſcoveries in geometry, which were now both numerous and important, and receiving in return many curious communications with reſpect to the *Loci Plani*, and the Poriſms of Euclid. Mr. Stewart purſued this latter ſubject in a different, and new direction. In doing ſo, he was led to the diſcovery of thoſe curious and intereſting propoſitions, which were publiſhed, under the title of *General Theorems*, in 1746. They were given without the demonſtrations; but they did not fail to place their diſcoverer at once among the geometricians of the firſt rank. They are, for the moſt part, Poriſms, though Mr. Stewart, careful not to anticipate the diſcoveries of his friend, gave them only the name of Theorems. They are among the moſt beautiful, as well as moſt general propoſitions, known in the whole compaſs of geometry, and are perhaps only equalled by the remarkable locus to the circle in the ſecond book of Apollonius, or by the celebrated theorem of Mr. Cotes.

Such is the hiſtory of the invention of theſe propoſitions; and the occaſion of the publication of them was as follows. Mr. Stewart, while engaged in them, had entered into the church, and become miniſter of Roſeneath. It was in that retired and romantic ſituation, that he diſcovered the greater part of thoſe theorems. In the ſummer of 1746, the mathematical chair in the univerſity of Edinburgh became vacant, by the death of Mr. Maclaurin. The General Theorems had not yet appeared; Mr. Stewart was known only to his friends; and the eyes of the public were naturally turned on Mr. Stirling, who then reſided at Leadhills, and who was well known in the mathematical world. He however declined appearing as a candidate for the vacant chair; and ſeveral others were named, among whom was Mr. Stewart. Upon this occaſion he printed the *General Theorems*, which gave their author a decided ſuperiority above all the other candidates. He was accordingly elected profeſſor of mathematics in the univerſity of Edinburgh, in September 1747.

The duties of this office gave a turn ſomewhat different to his mathematical purſuits, and led him to think of the moſt ſimple and elegant means of explaining thoſe difficult propoſitions, which were hitherto only acceſſible to men deeply verſed in the modern analyſis. In doing this, he was purſuing the object which,

of

of all others, he moſt ardently wiſhed to attain, viz, the application of geometry to ſuch problems as the algebraic calculus alone had been thought able to reſolve. His ſolution of Kepler's problem was the firſt ſpecimen of this kind which he gave to the world; and it was perhaps impoſſible to have produced one more to the credit of the method he followed, or of the abilities with which he applied it. Among the excellent ſolutions hitherto given of this famous problem, there were none of them at once direct in its method, and ſimple in its principles. Mr. Stewart was ſo happy as to attain both theſe objects. He founds his ſolution on a general property of curves, which, though very ſimple, had perhaps never been obſerved; and by a moſt ingenious application of that property, he ſhows how the approximation may be continued to any degree of accuracy, in a ſeries of reſults which converge with great rapidity.

This ſolution appeared in the ſecond volume of the Eſſays of the Philoſophical Society of Edinburgh, for the year 1756. In the firſt volume of the ſame collection, there are ſome other propoſitions of Mr. Stewart's, which are an extenſion of a curious theorem in the 4th book of Pappus. They have a relation to the ſubject of Poriſms, and one of them forms the 91ſt of Dr. Simſon's Reſtoration.

It has been already mentioned, that Mr. Stewart had formed the plan of introducing into the higher parts of mixed mathematics, the ſtrict and ſimple form of ancient demonſtration. The proſecution of this plan produced the *Tracts Phyſical and Mathematical*, which were publiſhed in 1761. In the firſt of theſe, Mr. Stewart lays down the doctrine of centripetal forces, in a ſeries of propoſitions, demonſtrated (if we admit the quadrature of curves) with the utmoſt rigour, and requiring no previous knowledge of the mathematics, except the elements of plane Geometry, and of Conic Sections. The good order of theſe propoſitions, added to the clearneſs and ſimplicity of the demonſtrations, renders this Tract perhaps the beſt elementary treatiſe of Phyſical Aſtronomy that is any where to be found.

In the three remaining Tracts, our author had it in view to determine, by the ſame rigorous method, the effect of thoſe forces which diſturb the motions of a ſecondary planet. From this he propoſed to deduce, not only a theory of the moon, but a determination of the ſun's diſtance from the earth. The former, it is well known, is the moſt difficult ſubject to which mathematics have been applied, and the reſolution required and merited all the clearneſs and ſimplicity which our author poſſeſſed in ſo eminent a degree. It muſt be regretted therefore, that the decline of Dr. Stewart's health, which began ſoon after the publication of the Tracts, did not permit him to purſue this inveſtigation.

The other object of the Tracts was, to determine the diſtance of the ſun, from his effect in diſturbing the motions of the moon; and his enquiries into the lunar irregularities had furniſhed him with the means of accompliſhing it.

The theory of the compoſition and reſolution of forces enables us to determine what part of the ſolar force is employed in diſturbing the motions of the moon; and therefore, could we meaſure the inſtantaneous effect of that force, or the number of feet by which it accelerates or retards the moon's motion in a ſecond, we ſhould be able to determine how many feet the whole force of the ſun would make a body, at the diſtance of the moon, or of the earth, deſcend in a ſecond of time, and conſequently how much the earth is, in every inſtant, turned out of its rectilineal courſe. Thus the curvature of the earth's orbit, or, which is the ſame thing, the radius of that orbit, that is, the diſtance of the ſun from the earth, would be determined. But the fact is, that the inſtantaneous effects of the ſun's diſturbing force are too minute to be meaſured; and that it is only the effect of that force, continued for an entire revolution, or ſome conſiderable portion of a revolution, which aſtronomers are able to obſerve.

There is yet a greater difficulty which embarraſſes the ſolution of this problem. For as it is only by the difference of the forces exerted by the ſun on the earth and on the moon, that the motions of the latter are diſturbed, the farther off the ſun is ſuppoſed, the leſs will be the force by which he diſturbs the moon's motions; yet that force will not diminiſh beyond a fixed limit, and a certain diſturbance would obtain, even if the diſtance of the ſun were infinite. Now the ſun is actually placed at ſo great a diſtance, that all the diſturbances, which he produces on the lunar motions, are very near to this limit, and therefore a ſmall miſtake in eſtimating their quantity, or in reaſoning about them, may give the diſtance of the ſun infinite, or even impoſſible. But all this did not deter Dr. Stewart from undertaking the ſolution of the problem, with no other aſſiſtance than that which geometry could afford. Indeed the idea of ſuch a problem had firſt occurred to Mr. Machin, who, in his book on the laws of the moon's motion, has juſt mentioned it, and given the reſult of a rude calculation (the method of which he does not explain), which aſſigns 8″ for the parallax of the ſun. He made uſe of the motion of the nodes; but Dr. Stewart conſidered the motion of the apogee, or of the longer axis of the moon's orbit, as the irregularity beſt adapted to his purpoſe. It is well known that the orbit of the moon is not immoveable; but that, in conſequence of the diſturbing force of the ſun, the longer axis of that orbit has an angular motion, by which it goes back about 3 degrees in every lunation, and completes an entire revolution in 9 years nearly. This motion, though very remarkable and eaſily determined, has the ſame fault, in reſpect of the preſent problem, that was aſcribed to the other irregularities of the moon: for a very ſmall part of it only depends on the parallax of the ſun; and of this Dr. Stewart ſeems not to have been perfectly aware.

The propoſitions however which defined the relation between the ſun's diſtance and the mean motion of the apogee, were publiſhed among the Tracts, in 1761. The tranſit of Venus happened in that ſame year: the aſtronomers returned, who had viewed that curious phenomenon, from the moſt diſtant ſtations; and no very ſatisfactory reſult was obtained from a compariſon of their obſervations. Dr. Stewart then reſolved to apply the principles he had already laid down; and, in 1763, he publiſhed his eſſay on the Sun's Diſtance, where the computation being actually made, the parallax of the ſun was found to be no more than 6″·9,

and consequently his distance almost 29875 semidiameters of the earth, or nearly 119 millions of miles.

A determination of the sun's distance, that so far exceeded all former estimations of it, was received with surprise, and the reasoning on which it was founded was likely to undergo a severe examination. But, even among astronomers, it was not every one who could judge in a matter of such difficult discussion. Accordingly, it was not till about 5 years after the publication of the sun's distance, that there appeared a pamphlet, under the title of *Four Propositions*, intended to point out certain errors in Dr. Stewart's investigation, which had given a result much greater than the truth. From his desire of simplifying, and of employing only the geometrical method of reasoning, he was reduced to the necessity of rejecting quantities, which were considerable enough to have a great effect on the last result. An error was thus introduced, which, had it not been for certain compensations, would have become immediately obvious, by giving the sun's distance near three times as great as that which has been mentioned.

The author of the pamphlet, referred to above, was the first who remarked the dangerous nature of these simplifications, and who attempted to estimate the error to which they had given rise. This author remarked what produced the compensation above mentioned, viz, the immense variation of the sun's distance, which corresponds to a very small variation of the motion of the moon's apogee. And it is but justice to acknowledge that, besides being just in the points already mentioned, they are very ingenious, and written with much modesty and good temper. The author, who at first concealed his name, but has now consented to its being made public, was Mr. Dawson, a surgeon at Sudbury in Yorkshire, and one of the most ingenious mathematicians and philosophers this country now possesses.

A second attack was soon after this made on the Sun's Distance, by Mr. Landen; but by no means with the same good temper which has been remarked in the former. He fancied to himself errors in Dr. Stewart's investigation, which have no existence; he exaggerated those that were real, and seemed to triumph in the discovery of them with unbecoming exultation. If there are any subjects on which men may be expected to reason dispassionately, they are certainly the properties of number and extension; and whatever pretexts moralists or divines may have for abusing one another, mathematicians can lay claim to no such indulgence. The asperity of Mr. Landen's animadversions ought not therefore to pass uncensured, though it be united with sound reasoning and accurate discussion. The error into which Dr. Stewart had fallen, though first taken notice of by Mr. Dawson, whose pamphlet was sent by me to Mr. Landen as soon as it was printed (for I had the care of the edition of it) yet this gentleman extended his remarks upon it to greater exactness. But Mr. Landen, in the zeal of correction, brings many other charges against Dr. Stewart, the greater part of which seem to have no good foundation. Such are his objections to the second part of the investigation, where Dr. Stewart finds the relation between the disturbing force of the sun, and the motion of the apses of the lunar orbit. For this part, instead of being liable to objection, is deserving of the greatest praise, since it resolves, by geometry alone, a problem which had eluded the efforts of some of the ablest mathematicians, even when they availed themselves of the utmost resources of the integral calculus. Sir Isaac Newton, though he assumed the disturbing force very near the truth, computed the motion of the apses from thence only at one half of what it really amounts to; so that, had he been required, like Dr. Stewart, to invert the problem, he would have committed an error, not merely of a few thousandth parts, as the latter is alleged to have done, but would have brought out a result double of the truth. (*Princip. Math. lib.* 3, *prop.* 3.) Machin and Callendrini, when commenting on this part of the Principia, found a like inconsistency between their theory and observation. Three other celebrated mathematicians, Clairaut, D'Alembert, and Euler, severally experienced the same difficulties, and were led into an error of the same magnitude. It is true, that, on resuming their computations, they found that they had not carried their approximations to a sufficient length, which when they had at last accomplished, their results agreed exactly with observation. Mr. Walmsley and Dr. Stewart were, I think, the first mathematicians who, employing in the solution of this difficult problem, the one the algebraic calculus, and the other the geometrical method, were led immediately to the truth; a circumstance so much for the honour of both, that it ought not to be forgotten. It was the business of an impartial critic, while he examined our author's reasonings, to have remarked and to have weighed these considerations.

The *Sun's Distance* was the last work which Dr. Stewart published; and though he lived to see the animadversions made on it, that have been taken notice of above, he declined entering into any controversy. His disposition was far from polemical; and he knew the value of that quiet, which a literary man should rarely suffer his antagonists to interrupt. He used to say, that the decision of the point in question was now before the public; that if his investigation was right, it would never be overturned, and that if it was wrong, it ought not to be defended.

A few months before he published the Essay just mentioned, he gave to the world another work, entitled, *Propositiones More Veterum Demonstratæ*. It consists of a series of geometrical theorems, mostly new; investigated, first by an analysis, and afterwards synthetically demonstrated by the inversion of the same analysis. This method made an important part in the analysis of the ancient geometricians; but few examples of it have been preserved in their writings, and those in the *Propositiones Geometricæ* are therefore the more valuable.

Doctor Stewart's constant use of the geometrical analysis had put him in possession of many valuable propositions, which did not enter into the plan of any of the works that have been enumerated. Of these, not a few have found a place in the writings of Dr. Simson, where they will for ever remain, to mark the friendship of these two mathematicians, and to evince the esteem which Dr. Simson entertained for the abilities of his pupil. Many of these are in the work upon the Porisms, and others in the Conic Sections, viz, marked with the letter *x*; also a theorem in the edition of Euclid's Data.

Soon

Soon after the publication of the *Sun's Diſtance*, Dr. Stewart's health began to decline, and the duties of his office became burdenſome to him. In the year 1772, he retired to the country, where he afterwards ſpent the greater part of his life, and never reſumed his labours in the univerſity. He was however ſo fortunate as to have a ſon to whom, though very young, he could commit the care of them with the greateſt confidence. Mr. Dugald Stewart, having begun to give lectures for his father from the period above mentioned, was elected joint profeſſor with him in 1775, and gave an early ſpecimen of thoſe abilities, which have not been confined to a ſingle ſcience.

After mathematical ſtudies (on account of the bad ſtate of health into which Dr. Stewart was falling) had ceaſed to be his buſineſs, they continued to be his amuſement. The analogy between the circle and hyperbola had been an early object of his admiration. The extenſive views which that analogy is continually opening; the alternate appearance and diſappearance of reſemblance in the midſt of ſo much diſſimilitude, make it an object that aſtoniſhes the experienced, as well as the young geometrician. To the conſideration of this analogy therefore the mind of Dr. Stewart very naturally returned, when diſengaged from other ſpeculations. His uſual ſucceſs ſtill attended his inveſtigations; and he has left among his papers ſome curious approximations to the areas, both of the circle and hyperbola. For ſome years toward the end of his life, his health ſcarcely allowed him to proſecute ſtudy even as an amuſement. He died the 23d of January 1785, at 68 years of age.

The habits of ſtudy, in a man of original genius, are objects of curioſity, and deſerve to be remembered. Concerning thoſe of Dr. Stewart, his writings have made it unneceſſary to remark, that from his youth he had been accuſtomed to the moſt intenſe and continued application. In conſequence of this application, added to the natural vigour of his mind, he retained the memory of his diſcoveries in a manner that will hardly be believed. He ſeldom wrote down any of his inveſtigations, till it became neceſſary to do ſo for the purpoſe of publication. When he diſcovered any propoſition, he would ſet down the enunciation with great accuracy, and on the ſame piece of paper would conſtruct very neatly the figure to which it referred. To theſe he truſted for recalling to his mind, at any future period, the demonſtration, or the analyſis, however complicated it might be. Experience had taught him that he might place this confidence in himſelf without any danger of diſappointment; and for this ſingular power, he was probably more indebted to the activity of his invention, than to the mere tenaciouſneſs of his memory.

Though Dr. Stewart was extremely ſtudious, he read but few books, and thus verified the obſervation of D'Alembert, that, of all the men of letters, mathematicians read leaſt of the writings of one another. Our author's own inveſtigations occupied him ſufficiently; and indeed the world would have had reaſon to regret the miſapplication of his talents, had he employed, in the mere acquiſition of knowledge, that time which he could dedicate to works of invention.

It was Dr. Stewart's cuſtom to ſpend the ſummer at a delightful retreat in Ayrſhire, where, after the academical labours of the winter were ended, he found the leiſure neceſſary for the proſecution of his reſearches. In his way thither, he often made a viſit to Dr. Simſon of Glaſgow, with whom he had lived from his youth in the moſt cordial and uninterrupted friendſhip. It was pleaſing to obſerve, in theſe two excellent mathematicians, the moſt perfect eſteem and affection for each other, and the moſt entire abſence of jealouſy, though no two men ever trode more nearly in the ſame path. The ſimilitude of their purſuits ſerved only to endear them to each other, as it will ever do with men ſuperior to envy. Their ſentiments and views of the ſcience they cultivated, were nearly the ſame; they were both profound geometricians; they equally admired the ancient mathematicians, and were equally verſed in their methods of inveſtigation; and they were both apprehenſive that the beauty of their favourite ſcience would be forgotten, for the leſs elegant methods of algebraic computation. This innovation they endeavoured to oppoſe; the one, by reviving thoſe books of the ancient geometry which were loſt; the other, by extending that geometry to the moſt difficult enquiries of the moderns. Dr. Stewart, in particular, had remarked the intricacies, in which many of the greateſt of the modern mathematicians had involved themſelves in the application of the calculus, which a little attention to the ancient geometry would certainly have enabled them to avoid. He had obſerved too the elegant ſynthetical demonſtrations that, on many occaſions, may be given of the moſt difficult propoſitions, inveſtigated by the inverſe method of fluxions. Theſe circumſtances had perhaps made a ſtronger impreſſion than they ought, on a mind already filled with admiration of the ancient geometry, and produced too unfavourable an opinion of the modern analyſis. But if it be confeſſed that Dr. Stewart rated, in any reſpect too high, the merit of the former of theſe ſciences, this may well be excuſed in the man whom it had conducted to the diſcovery of the *General Theorems*, to the *ſolution of Kepler's Problem*, and to an *accurate* determination of the *Sun's diſturbing force*. His great modeſty made him aſcribe to the method he uſed, that ſucceſs which he owed to his own abilities.

The foregoing account of Dr. Stewart and his writings, is chiefly extracted from the learned hiſtory of them, by Mr. Playfair, in the 1ſt volume of the Edinburgh Philoſophical Tranſactions, pa. 57, &c.

STIFELS, STIFELIUS (MICHAEL), a Proteſtant miniſter, and very ſkilful mathematician, was born at Eſlingen a town in Germany; and died at Jena in Thuringia, in the year 1567, at 58 years of age according to Voſſius, but ſome others ſay 80. Stifels was one of the beſt mathematicians of his time. He publiſhed, in the German language, a treatiſe on Algebra, and another on the Calendar or Eccleſiaſtical computation. But his chief work, is the *Arithmetica Integra*, a complete and excellent treatiſe, in Latin, on Arithmetic and Algebra, printed in 4to at Norimberg 1544. In this work there are a number of ingenious inventions, both in common arithmetic and in algebra; of which, thoſe relating to the latter are amply explained under the article *Algebra* in this dictionary, vol. 1, pa. 77 &c; to which may be added ſome par-

ticulars concerning the arithmetic, from my volume of *Tracts* printed in 1786, pa. 68. In this original work are contained many curious things, ſome of which have miſtakenly been aſcribed to a much later date. He here treats pretty fully and ably, of progreſſional and figurate numbers, and in particular of the triangular table, for conſtructing both them and the coefficients of the terms of all powers of a binomial; which has been ſo often uſed ſince his time for theſe and other purpoſes, and which more than a century after was, by Paſcal, otherwiſe called the Arithmetical Triangle, and who only mentioned ſome additional properties of the table. Stifels ſhews, that the horizontal lines of the table furniſh the coefficients of the terms of the correſponding powers of a binomial; and teaches how to make uſe of them in the extraction of roots of all powers whatever. Cardan ſeems to aſcribe the invention of that table to Stifelius; but I apprehend that is only to be underſtood of its application to the extraction of roots.

It is remarkable too, how our author, at p. 35 &c of the ſame book, treats of the nature and uſe of logarithms; not under that name indeed, but under the idea of a ſeries of arithmeticals, adapted to a ſeries of geometricals. He there explains all their uſes; ſuch as, that the addition of them anſwers to the multiplication of their geometricals; ſubtraction to diviſion; multiplication of exponents, to involution; and dividing of exponents to evolution. He alſo exemplifies the uſe of them in caſes of the Rule-of-three, and in finding mean proportionals between given terms, and ſuch like, exactly as is done in logarithms. So that he ſeems to have been in the full poſſeſſion of the idea of logarithms, and wanted only the neceſſity of troubleſome calculations to induce him to make a table of ſuch numbers.

Stifels was a zealous, though weak diſciple of Luther. He took it into his head to become a prophet, and he predicted that the end of the world would happen on a certain day in the year 1553, by which he terrified many people. When the propoſed day arrived, he repaired early, with multitudes of his followers, to a particular place in the open air, ſpending the whole day in the moſt fervent prayers and praiſes, in vain looking for the coming of the Lord, and the univerſal conflagration of the elements, &c.

STILE. See STYLE.

STILYARD. See STEELYARD.

STOFLER (JOHN), a German mathematician, was born at Juſtingen in Suabia, in 1452, and died in 1531, at 79 years of age. He taught mathematics at Tubinga, where he acquired a great reputation, which however he in a great meaſure loſt again, by intermeddling with the prediction of future events. He announced a great deluge, which he ſaid would happen in the year 1524, a prediction with which he terrified all Germany, where many perſons prepared veſſels proper to eſcape with from the floods. But happily the prediction failing, it enraged the aſtrologer, though it ſerved to convince him of the vanity of his prognoſtications.—He was author of ſeveral works in mathematics, and aſtrology, full of fooliſh and chimerical ideas; ſuch as,

1. Elucidatio Fabric. Uſuſque Aſtrolabii; fol. 1513.
2. Procli Sphæram Comment. fol. 154.
3. Coſmographicæ aliquot Deſcriptiones; 4to, 1537.

STONE, (EDMUND), a good Scotch mathematician, who was author of ſeveral ingenious works. I know not the particular place or date of his birth, but it was probably in the ſhire of Argyle, and about the beginning of the preſent century, or concluſion of the laſt. Nor have we any memoirs of his life, except a letter from the Chevalier de Ramſay, author of the Travels of Cyrus, in a letter to father Caſtel, a Jeſuit at Paris, and publiſhed in the Memoires de Trevoux, p. 109; as follows: "True genius overcomes all the diſadvantages of birth, fortune, and education; of which Mr. Stone is a rare example. Born a ſon of a gardener of the duke of Argyle, he arrived at 8 years of age before he learnt to read.—By chance a ſervant having taught young Stone the letters of the alphabet, there needed nothing more to diſcover and expand his genius. He applied himſelf to ſtudy, and he arrived at the knowledge of the moſt ſublime geometry and analyſis, without a maſter, without a conductor, without any other guide but pure genius."

"At 18 years of age he had made theſe conſiderable advances without being known, and without knowing himſelf the prodigies of his acquiſitions. The duke of Argyle, who joined to his military talents, a general knowledge of every ſcience that adorns the mind of a man of his rank, walking one day in his garden, ſaw lying on the graſs a Latin copy of Sir Iſaac Newton's celebrated Principia. He called ſome one to him to take and carry it back to his library. Our young gardener told him that the book belonged to him. *To you?* replied the Duke. *Do you underſtand geometry, Latin, Newton?* I know a little of them, replied the young man with an air of ſimplicity ariſing from a profound ignorance of his own knowledge and talents. The Duke was ſurpriſed; and having a taſte for the ſciences, he entered into converſation with the young mathematician: he aſked him ſeveral queſtions, and was aſtoniſhed at the force, the accuracy, and the candour of his anſwers. *But how*, ſaid the Duke, *came you by the knowledge of all theſe things?* Stone replied, *A ſervant taught me, ten years ſince, to read: does one need to know any thing more than the 24 letters in order to learn every thing elſe that one wiſhes?* The Duke's curioſity redoubled—he ſat down upon a bank, and requeſted a detail of all his proceedings in becoming ſo learned."

"*I firſt learned to read*, ſaid Stone: *the maſons were then at work upon your houſe: I went near them one day, and I ſaw that the architect uſed a rule, compaſſes, and that he made calculations. I enquired what might be the meaning of and uſe of theſe things; and I was informed that there was a ſcience called Arithmetic; I purchaſed a book of arithmetic, and I learned it.—I was told there was another ſcience called Geometry: I bought the books, and I learnt geometry. By reading I found that there were good books in theſe two ſciences in Latin: I bought a dictionary, and I learned Latin. I underſtood alſo that there were good books of the ſame kind in French: I bought a dictionary, and I learned French. And this, my lord, is what I have done: it ſeems to me that we may learn every thing when we know the 24 letters of the alphabet.*

This account charmed the Duke. He drew this wonderful genius out of his obſcurity; and he provided him with an employment which left him plenty of

of time to apply himſelf to the ſciences. He diſcovered in him alſo the ſame genius for muſic, for painting, for architecture, for all the ſciences which depend on calculations and proportions."

"I have ſeen Mr. Stone. He is a man of great ſimplicity. He is at preſent ſenſible of his own knowledge: but he is not puffed up with it. He is poſſeſſed with a pure and diſintereſted love for the mathematics; though he is not ſolicitous to paſs for a mathematician; vanity having no part in the great labour he ſuſtains to excel in that ſcience. He deſpiſes fortune alſo; and he has ſolicited me twenty times to requeſt the duke to give him leſs employment, which may not be worth the half of that he now has, in order to be more retired, and leſs taken off from his favourite ſtudies. He diſcovers ſometimes, by methods of his own, truths which others have diſcovered before him. He is charmed to find on theſe occaſions that he is not a firſt inventor, and that others have made a greater progreſs than he thought. Far from being a plagiary, he attributes ingenious ſolutions, which he gives to certain problems, to the hints he has found in others, although the connection is but very diſtant," &c.

Mr. Stone was author and tranſlator of ſeveral uſeful works; viz.

1. A New Mathematical Dictionary, in 1 vol. 8vo, firſt printed in 1726.

2. Fluxions, in 1 vol. 8vo, 1730. The Direct Method is a tranſlation from the French, of Hoſpital's Analyſe des Infiniments Petits; and the Inverſe Method was ſupplied by Stone himſelf.

3. The Elements of Euclid, in 2 vols. 8vo, 1731. A neat and uſeful edition of thoſe Elements, with an account of the life and writings of Euclid, and a defence of his elements againſt modern objectors.

Beſide other ſmaller works.

Stone was a fellow of the Royal Society, and had inſerted in the Philoſ. Tranſactions (vol. 41, pa. 218) an "Account of two ſpecies of lines of the 3d order, not mentioned by Sir Iſaac Newton, or Mr. Stirling."

STRABO, a celebrated Greek geographer, philoſopher, and hiſtorian, was born at Amaſia, and was deſcended from a family ſettled at Gnoſſus in Crete. He was the diſciple of Xenarchus, a Peripatetic philoſopher, but at length attached himſelf to the Stoics. He contracted a ſtrict friendſhip with Cornelius Gallus, governor of Egypt; and travelled into ſeveral countries, to obſerve the ſituation of places, and the cuſtoms of nations.

Strabo flouriſhed under Auguſtus; and died under Tiberius about the year 25, in a very advanced age.—He compoſed ſeveral works; all of which are loſt, except his *Geography*, in 17 books; which are juſtly eſteemed very precious remains of antiquity. The firſt two books are employed in ſhowing, that the ſtudy of geography is not only worthy of a philoſopher, but even neceſſary to him; the 3d deſcribes Spain; the 4th, Gaul and the Britannic iſles; the 5th and 6th, Italy and the adjacent iſles; the 7th, which is imperfect at the end, Germany, the countries of the Getæ and Illyrii, Taurica, Cherſoneſus, and Epirus; the 8th, 9th, and 10th, Greece with the neighbouring iſles; the four following, Aſia within Mount Taurus; the 15th and 16th, Aſia without Taurus, India, Perſia, Syria, Arabia; and the 17th, Egypt, Ethiopia, Carthage, and other parts of Africa.

Strabo's work was publiſhed with a Latin verſion by Xylander, and notes by Iſaac Caſaubon, at Paris 1620, in folio; but the beſt edition is that of Amſterdam in 1707, in 2 volumes folio, by the learned Theodore Janſon of Almelooveen, with the entire notes of Xylander, Caſaubon, Meurſius, Cluver, Holſten, Salmaſius, Bochart, Ez. Spanheim, Cellar, and others. To this edition is ſubjoined the *Chreſtomathiæ*, or Epitome of Strabo; which, according to Mr. Dodſwell, who has written a very elaborate and learned diſſertation about it, was made by ſome unknown perſon, between the years of Chriſt 676 and 996. It has been found of ſome uſe, not only in helping to correct the original, but in ſupplying in ſome meaſure the defect in the 7th book. Mr. Dodſwell's diſſertation is prefixed to this edition.

STRAIT, or STRAIGHT, or STREIGHT, in Hydrography, is a narrow channel or arm of the ſea, ſhut up between lands on either ſide, and uſually affording a paſſage out of one great ſea into another. As the Straits of Magellan, of Le Maire, of Gibraltar, &c.

STRAIT is alſo ſometimes uſed, in Geography, for an iſthmus, or neck of land between two ſeas, preventing their communication.

STRENGTH, *vis*, force, power.

Some authors make the Strength of animals, of the ſame kind, to depend on the quantity of blood; but moſt on the ſize of the bones, joints, and muſcles; though we find by daily experience, that the animal ſpirits contribute greatly to Strength at different times.

Emerſon has moſt particularly treated of the Strength of bodies depending on their dimenſions and weight. In the General Scholium after his propoſitions on this ſubject, he adds; If a certain beam of timber be able to ſupport a given weight; another beam, of the ſame timber, ſimilar to the former, may be taken ſo great, as to be able but juſt to bear its own weight: while any larger beam cannot ſupport itſelf, but muſt break by its own weight; but any leſs beam will bear ſomething more. For the Strength being as the cube of the depth; and the ſtreſs, being as the length and quantity of matter, is as the 4th power of the depth; it is plain therefore, that the ſtreſs increaſes in a greater ratio than the Strength. Whence it follows, that a beam may be taken ſo large, that the ſtreſs may far exceed the Strength: and that, of all ſimilar beams, there is but one that will juſt ſupport itſelf, and nothing more. And the like holds true in all machines, and in all animal bodies. And hence there is a certain limit, in regard to magnitude, not only in all machines and artificial ſtructures, but alſo in natural ones, which neither art nor nature can go beyond; ſuppoſing them made of the ſame matter, and in the ſame proportion of parts.

Hence it is impoſſible that mechanic engines can be increaſed to any magnitude at pleaſure. For when they arrive at a particular ſize, their ſeveral parts will break and fall aſunder by their weight. Neither can any buildings of vaſt magnitudes be made to ſtand, but muſt fall to pieces by their great weight, and go to ruin.

It is likewiſe impoſſible for nature to produce animals of any vaſt ſize at pleaſure: except ſome ſort of matter can be found, to make the bones of, which may be ſo much harder and ſtronger than any hitherto known: or elſe that the proportion of the parts be ſo much altered, and the bones and muſcles made thicker in proportion; which will make the animal diſtorted, and of a monſtrous figure, and not capable of performing any proper actions. And being made ſimilar and of common matter, they will not be able to ſtand or move; but, being burthened with their own weight, muſt fall down. Thus, it is impoſſible that there can be any animal ſo large as to carry a caſtle upon his back; or any man ſo ſtrong as to remove a mountain, or pull up a large oak by the roots: nature will not admit of theſe things; and it is impoſſible that there can be animals of any ſort beyond a determinate ſize.

Fiſh may indeed be produced to a larger ſize than land animals; becauſe their weight is ſupported by the water. But yet even theſe cannot be increaſed to immenſity, becauſe the internal parts will preſs upon one another by their weight, and deſtroy their fabric.

On the contrary, when the ſize of animals is diminiſhed, their Strength is not diminiſhed in the ſame proportion as the weight. For which reaſon a ſmall animal will carry far more than a weight equal to its own, whilſt a great one cannot carry ſo much as its weight. And hence it is that ſmall animals are more active, will run faſter, jump farther, or perform any motion quicker, for their weight, than large animals: for the leſs the animal, the greater the proportion of the Strength to the ſtreſs. And nature ſeems to know no bounds as to the ſmallneſs of animals, at leaſt in regard to their weight.

Neither can any two unequal and ſimilar machines reſiſt any violence alike, or in the ſame proportion; but the greater will be more hurt than the leſs. And the ſame is true of animals; for large animals by falling break their bones, while leſſer ones, falling higher, receive no damage. Thus a cat may fall two or three yards high, and be no worſe, and an ant from the top of a tower.

It is likewiſe impoſſible in the nature of things, that there can be any trees of immenſe ſize; if there were any ſuch, their limbs, boughs, and branches, muſt break off and fall down by their own weight. Thus it is impoſſible there can be an oak a quarter of a mile high; ſuch a tree cannot grow or ſtand, but its limbs will drop off by their weight. And hence alſo ſmaller plants can better ſuſtain themſelves than large ones.

As to the due proportion of Strength in ſeveral bodies, according to their particular poſitions, and the weights they are to bear; he farther obſerves that, If a piece of timber is to be pierced with a mortiſe-hole, the beam will be ſtronger when it is taken out of the middle, than when taken out of either ſide. And in a beam ſupported at both ends, it is ſtronger when the hole is made in the upper ſide than when made in the under, provided a piece of wood is driven hard in to fill up the hole.

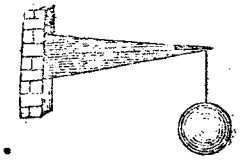
If a piece is to be ſpliced upon the end of a beam, to be ſupported at both ends; it will be the ſtronger when ſpliced on the under ſide of a beam: but if the piece is ſupported only at one end, to bear a weight on the other; it is ſtronger when ſpliced on the upper ſide.

When a ſmall lever, &c, is nailed to a body, to move it or ſuſpend it by; the ſtrain is greater upon the nail neareſt the hand, or point where the power is applied.

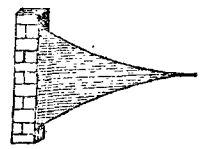
If a beam be ſupported at both ends; and the two ends reach over the props, and be fixed down immoveable; it will bear twice as much weight, as when the ends only lie looſe or free upon the ſupporters.

When a ſlender cylinder is to be ſupported by two pieces; the diſtance of the pins ought to be nearly $\frac{3}{4}$ of the length of the cylinder, and the pins equidiſtant from its ends; and then the cylinder will endure the leaſt bending or ſtrain by its weight.

A beam fixed at one end, and bearing a weight at the other; if it be cut in the form of a wedge, and placed with its parallel ſides parallel to the horizon; it will be equally ſtrong every where; and no ſooner break in one place than another.



When a beam has all its ſides cut in form of a concave parabola, having the vertex at the end, and its abſciſs perpendicular to the axis of the ſolid, and the baſe a ſquare, or a circle, or any regular polygon; ſuch a beam fixed horizontally, at one end, is equally ſtrong throughout for ſupporting its own weight.

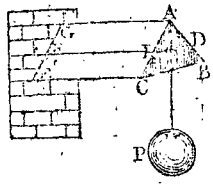


Alſo when a wall faces the wind, and if the vertical ſection of it be a right-angled triangle; or if the fore part next the wind &c be perpendicular to the horizon, and the back part a ſloping plane; ſuch a wall will be equally ſtrong in all its parts to reſiſt the wind, if the parts of the wall cohere ſtrongly together; but when it is built of looſe materials, it is better to be convex on the back part in form of a parabola.

When a wall is to ſupport a bank of earth or any fluid body, it ought to be built concave in form of a ſemicubical parabola, whoſe vertex is at the top of the wall, provided the parts of the wall adhere firmly together. But if the parts be looſe, then a right line or ſloping plane ought to be its figure. Such walls will be equally ſtrong throughout

All ſpires of churches in the form of cones or pyramids, are equally ſtrong in all parts to reſiſt the wind. But when the parts do not cohere together, then they ought to be parabolic conoids, to be equally ſtrong throughout.

Likewiſe if there be a pillar erected in form of the logarithmic curve, the aſymptote being the axis; it cannot be cruſhed to pieces in one part ſooner than in another, by its own weight. And if ſuch a pillar be turned upſide down, and ſuſpended by the thick end, it will not be more liable to ſeparate in one part than another, by its own weight.



Moreover, if AE be a beam in form of a triangular prism; and if AD = $\frac{1}{3}$AB, and AI = $\frac{1}{3}$ AC, and the edge or ſmall ſimilar priſm ADIF be cut away parallel to the baſe; the remaining beam DIBEF will bear a greater weight P, than the whole ABCEG, or the part will be ſtronger than the whole; which is a paradox in Mechanics.

As to the Strength of ſeveral ſorts of wood, drawn from experiments, he ſays, On a medium, a piece of good oak, an inch ſquare, and a yard long, ſupported at both ends, will bear in the middle, for a very ſhort time, about 330lb averdupois, but will break with more than that weight. But ſuch a piece of wood ſhould not, in practice, be truſted for any length of time, with more than a third or a fourth part of that weight. And the proportion of the Strength of ſeveral ſorts of wood, he found to be as follows:

Box, oak, plumbtree, yew	11
Aſh, elm	$8\frac{1}{2}$
Thorn, walnut	$7\frac{1}{2}$
Apple tree, elder, red fir, holly, plane	7
Beech, cherry, hazle	$6\frac{2}{3}$
Alder, aſp, Birch, white-fir, willow	6
Iron	107
Braſs	50
Bone	22
Lead	$6\frac{1}{2}$
Fine free ſtone	1

As to the Strength of bodies in direction of the fibres, he obſerves, A cylindric rod of good clean fir, of an inch circumference, drawn in length, will bear at extremity 400lb; and a ſpear of fir 2 inches diameter, will bear about 7 ton.—A rod of good iron, of an inch circumference, will bear near 3 ton weight. And a good hempen rope of an inch circumference, will bear 1000lb. at extremity.

All this ſuppoſes theſe bodies to be ſound and good throughout; but none of them ſhould be put to bear more than a third or a fourth part of that weight, eſpecially for any length of time. From what has been ſaid; if a ſpear of fir, or a rope, or a ſpear of iron, of *d* inches diameter, were to lift $\frac{1}{4}$ the extreme weight; then

The fir would bear $8\frac{1}{4}dd$ hundred weight.
The rope would bear $22dd$ hundred weight.
The iron would bear $6\frac{3}{4}dd$ ton weight.

As to Animals; Men may apply their Strength ſeveral ways, in working a machine. A man of ordinary Strength turning a roller by the handle, can act for a whole day againſt a reſiſtance equal to 30 lb. weight; and if he works 10 hours a day, he will raiſe a weight of 30lb. through $3\frac{1}{2}$ feet in a ſecond of time; or if the weight be greater, he will raiſe it ſo much leſs in proportion. But a man may act, for a ſmall time, againſt a reſiſtance of 50lb. or more.

If two men work at a windlaſs, or roller, they can more eaſily draw up 70lb, than one man can 30lb, provided the elbow of one of the handles be at right angles to that of the other. And with a fly, or heavy wheel, applied to it, a man may do $\frac{1}{3}$ part more work; and for a little while he can act with a force, or overcome a continual reſiſtance, of 80l; and work a whole day when the reſiſtance is but 40lb.

Men uſed to bear loads, ſuch as porters, will carry, ſome 150lb, others 200 or 250lb. according to their Strength.

A man can draw but about 70 or 80lb. horizontally; for he can but apply about half his weight.

If the weight of a man be 140lb, he can act with no greater a force in thruſting horizontally, at the height of his ſhoulders, than 27lb.

As to Horſes: A horſe is, generally ſpeaking, as ſtrong as 5 men. A horſe will carry 240 or 270lb. A horſe draws to greateſt advantage, when the line of direction is a little elevated above the horizon, and the power acts againſt his breaſt: and he can draw 200lb. for 8 hours a day, at $2\frac{1}{2}$ miles an hour. If he draw 240lb, he can work but 6 hours, and not go quite ſo faſt. And in both caſes, if he carries ſome weight, he will draw the better for it. And this is the weight a horſe is ſuppoſed to be able to draw over a pulley out of a well. But in a cart, a horſe may draw 1000lb, or even double that weight, or a ton weight, or more.

As the moſt force a horſe can exert, is when he draws a little above the horizontal poſition: ſo the worſt way of applying the ſtrength of a horſe, is to make him carry or draw uphill: And three men in a ſteep hill, carrying each 100lb, will climb up faſter than a horſe with 300l. Alſo, though a horſe may draw in a round walk of 18 feet diameter; yet ſuch a walk ſhould not be leſs than 25 or 30 feet diameter. Emerſon's Mechan. pa. 111 and 177.

STRIKE, or STRYKE, a meaſure, containing 4 buſhels, or half a quarter.

STRIKING-*wheel*, in a clock, the ſame as that by ſome called the *pin-wheel*, becauſe of the pins which are placed on the round or rim, the number of which is the quotient of the pinion divided by the pinion of the detent-wheel. In ſixteen-day clocks, the firſt or great wheel is uſually the pin-wheel; but in ſuch as go 8 days, the ſecond wheel is the pin-wheel, or ſtriking-wheel.

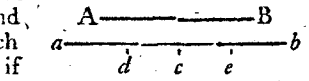
STRING, in Muſic. See CHORD.

If two Strings or chords of a muſical inſtrument only differ in length; their tones, or the number of vibrations they make in the ſame time, are in the inverſe ratio of their lengths. If they differ only in thickneſs, their tones are in the inverſe ratio of their diameters.

As to the tenſion of Strings, to meaſure it regularly, they muſt be conceived ſtretched or drawn by weights; and then, cæteris paribus, the tones of two Strings are in a direct ratio of the ſquare roots of the weights that ſtretch them; that is, ex. gr. the tone of a String ſtretched by a weight 4, is an octave above the tone of a String ſtretched by the weight 1.

It is an obſervation of very old ſtanding, that if a viol or lute-ſtring be touched with the bow, or the hand, another String on the ſame inſtrument, or even on another, not far from it, if in uniſon with it, or in octave, or the like, will at the ſame time tremble of its

its own accord. But it is now found, that it is not the whole of that other String that thus trembles, but only the parts, ſeverally, according as they are uniſons to the whole, or the parts, of the String ſo ſtruck. Thus, ſuppoſing AB to be an upper octave to *ab*, and therefore an uniſon to each half of it, ſtopped at *c*; if while *ab* is open, AB be ſtruck, the two halves of this other, that is, *ac*, and *cb*, will both tremble; but the middle point will be at reſt; as will be eaſily perceived, by wrapping a bit of paper lightly about the ſtring *ab*, and moving it ſucceſſively from one end of the ſtring to the other. In like manner, if AB were an upper 12th to *ab*, and conſequently an uniſon to its three parts *ad*, *de*, *eb*; then, *ab* being open, if AB be ſtruck, the three parts of the other, *ad*, *de*, *eb* will ſeverally tremble; but the points *d* and *e* remain at reſt.



This, Dr. Wallis tells us, was firſt diſcovered by Mr. William Noble of Merton college; and after him by Mr. T. Pigot of Wadham college, without knowing that Mr. Noble had obſerved it before. To which may be added, that M. Sauveur, long afterwards, propoſed it to the Royal Academy at Paris, as his own diſcovery, which in reality it might be; but upon his being informed, by ſome of the members then preſent, that Dr. Wallis had publiſhed it before, he immediately reſigned all the honour of it. Philoſ. Tranſ. Abridg. vol. I, pa. 606.

STURM, Sturmius (John Christopher), a noted German mathematician and philoſpher, was born at Hippolſtein in 1635. He became profeſſor of philoſophy and mathematics at Altdorf, where he died in 1703, at 68 years of age.

He was author of ſeveral uſeful works on mathematics and philoſophy, the moſt eſteemed of which are,

1. His *Matheſis enucleata*, in 1 vol. 8vo.

2. *Matheſis Juvenilis*, in 2 large volumes 8vo.

3. *Collegium Experimentale, ſive Curioſum, in quo primaria Seculi ſuperioris Inventa & Experimenta Phyſico-Mathematica, Speciatim Campanæ Urinatoriæ, Cameræ obſcuræ, Tubi Torricelliani, ſeu Baroſcopii, Antliæ Pneumaticæ, Thermometrorum Phænomena & Effecta; partim ac aliis jampridem exhibita, partim noviter iſtis ſuperaddita, &c.* in one large vol. 4to, Norimberg, 1701.

This is a very curious work, containing a multitude of intereſting experiments, neatly illuſtrated by copper-plate figures printed upon almoſt every page, by the ſide of the letter-preſs. Of theſe, the 10th experiment is an improvement on father Lana's project for navigating a ſmall veſſel ſuſpended in the atmoſphere by ſeveral globes exhauſted of air.

STYLE, in Chronology, a particular manner of counting time; as the *Old Style*, the *New Style*. See Calendar.

Old Style, is the Julian manner of computing, as inſtituted by Julius Cæſar, in which the mean year conſiſts of 365¼ days.

New Style, is the Gregorian manner of computation, inſtituted by pope Gregory the 13th, in the year 1582, and is uſed by moſt catholic countries, and many other ſtates of Europe.

The Gregorian, or new Style, agrees with the true ſolar year, which contains only 365 days 5 hours 49 minutes. In the year of Chriſt 200, there was no difference of Styles. In the year 1582, when the new Style was firſt introduced, there was a difference of 10 days. At preſent there is 11 days difference, and accordingly at the diet of Ratiſbon, in the year 1700, it was decreed by the body of proteſtants of the empire, that 11 days ſhould be retrenched from the old Style, to accommodate it for the future to the new. And the ſame regulation has ſince paſſed into Sweden, Denmark, and into England, where it was eſtabliſhed in the year 1752, when it was enacted, that in all dominions belonging to the crown of Great Britain, the ſupputation, according to which the year of our lord begins on the 25th day of March, ſhall not be uſed from and after the laſt day of December 1751; and that from thenceforth, the 1ſt day of January every year ſhall be reckoned to be the firſt day of the year: and that the natural day next immediately following the 2d day of September 1752, ſhall be accounted the 14th day of September, omitting the 11 intermediate nominal days of the common calendar. It is farther enacted, that all kinds of writings, &c, ſhall bear date according to the new method of computation, and that all courts and meetings &c, feaſts, faſts, &c, ſhall be held and obſerved accordingly. And for preſerving the calendar in the ſame regular courſe for the future, it is enacted, that the ſeveral years of our lord 1800, 1900, 2100, 2200, 2300, &c, except only every 400th year, of which the year 2000 ſhall be the firſt, ſhall be common years of 365 days, and that the years 2000, 2400, 2800, &c, and every other 400th year from the year 2000 incluſive, ſhall be leap years, conſiſting of 366 days. See Bissextile and Calendar.

The following table ſhews by what number of days the new ſtyle differs from the old, from 5900 years before the birth of Chriſt, to 5900 years after it. The days under the ſign — (viz from 6000 years before to 200 years after Chriſt) are to be ſubtracted from the old Style, to reduce it to the new; and the days under the ſign + (viz from 200 to 5900 years after Chriſt) are to be added to the old Style, to reduce it to the new.—N.B. All the years mentioned in the table are leap years in the old Style; but thoſe only that are marked with an L are leap years in the new.

Years before Christ. New Style.	Days diff. —	Years after Christ. New Style.	Days diff. ∓

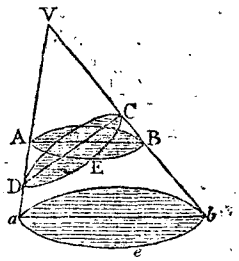
The French nation has lately commenced another new Style, or computation of time, viz, in the year 1792; according to which, the year commences usually on our 22d of September. The year is divided into 12 months of 30 days each; and each month into 3 decades of 10 days each. For the names and computations of which, see the article CALENDAR.

STYLE, in Dialling, denotes the cock or gnomon, raised above the plane of the dial, to project a Shadow. —The edge of the Style, which by its shadow marks the hours on the face of the dial, is to be set according to the latitude, always parallel to the axis of the world.

STYLOBATA, or STYLOBATON, in Architecture, the same with the pedestal of a column. It is sometimes taken for the trunk of the pedestal, between the cornice and the base, and is then called *truncus*. It is also otherwise named *abacus*.

SUBCONTRARY position, in Geometry, is when two equiangular triangles, as VAB and VCD are so placed as to have one common angle V at the vertex, and yet their bases not parallel. Consequently the angles at the bases are equal, but on the contrary sides; viz, the ∠A = ∠C, and the ∠B = ∠D.



If the oblique cone VAB or V*ab*, having the circular base AEB, or *aeb*, be so cut by a plane DEC, that the angle D be = the ∠B, or the ∠C = ∠A, then the cone is said to be cut, by this plane, in a Subcontrary position to the base AEB, or *aeb*; and in this case the section DEC is always a circle, as well as the base AEB or *aeb*.

SUBDUCTION, in Arithmetic, the same as Subtraction.

SUBDUPLE *Ratio*, is when any number or quantity is the half of another, or contained twice in it. Thus, 3 is said to be subduple of 6, as 3 is the half of 6, or is twice contained in it.

SUBDUPLICATE *Ratio*, of any two quantities, is the ratio of their square roots, being the opposite to duplicate ratio, which is the ratio of the squares. Thus, of the quantities, *a* and *b*, the subduplicate ratio is that of $\sqrt{a}$ to $\sqrt{b}$ or $a^{\frac{1}{2}}$ to $b^{\frac{1}{2}}$, as the duplicate ratio is that of a^2 to b^2.

SUBLIME *Geometry*, the higher geometry, or that of curve lines. See GEOMETRY.

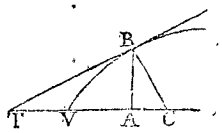
SUBLUNARY, is said of all things below the moon; as all things on the earth, or in its atmosphere, &c.

SUBMULTIPLE, the contrary of a multiple, being a number or quantity which is contained exactly a certain number of times in another of the same kind; or it is the same as an aliquot part of it. Thus, 3 is a Submultiple of 21, or an aliquot part of it, because 21 is a multiple of 3.

SUBMULTIPLE *Ratio*, is the ratio of a Submultiple or aliquot part, to its multiple; as the ratio of 3 to 21.

SUBNORMAL, in Geometry, is the subperpendicular AC, or line under the perpendicular to the curve BC, a term used in curve lines to denote the distance AC in the axis, between the ordinate AB, and the perpendicular

pendicular BC to the curve or to the tangent. And the ſaid perpendicular BC is the normal.



In all curves, the Subnormal AC is a 3d proportional to the ſubtangent TA and the ordinate AB; and in the parabola, it is equal to half the parameter of the axis.

SUBSTITUTION, in Algebra, is the putting and uſing, in an equation, one quantity inſtead of another which is equal to it, but expreſſed after another manner. See REDUCTION of Equations.

SUBSTRACTION, or SUBTRACTION, in Arithmetic, is the taking of one number or quantity from another, to find the remainder or difference between them; and is uſually made the ſecond rule in arithmetic.

The greater number or quantity is called the *minuend*, the leſs is the *ſubtrahend*, and the *remainder* is the *difference*. Alſo the ſign of Subtraction is —, or minus.

SUBTRACTION *of Whole Numbers*, is performed by ſetting the leſs number below the greater, as in addition, units under units, tens under tens, &c; and then, proceeding from the right hand towards the left, ſubtract or take each lower figure from that juſt above, and ſet down the ſeveral remainders or differences underneath; and theſe will compoſe the whole remainder or difference of the two given numbers. But when any one of the figures of the under number is greater than that of the upper, from which it is to be taken, you muſt add 10 (in your mind) to that upper figure, then take the under one from this ſum, and ſet the difference underneath, carrying or adding 1 to the next under figure to be ſubtracted. Thus, for example, to ſubtract 2904821 from 37409732

Minuend	37409732
Subtrahend	2904821
Difference	34504911
Proof	37409732

To prove Subtraction: Add the remainder or difference to the leſs number, and the ſum will be equal to the greater when the work is right.

SUBTRACTION *of Decimals*, is performed in the ſame manner as in whole numbers, by obſerving only to ſet the figures or places of the ſame kind under each other. Thus:

From	351·04	·479	27
Take	72·71	·0573	0·936
Diff.	278·33	·4217	26·064

To Subtract Vulgar Fractions. Reduce the two fractions to a common denominator, if they have different ones; then take the leſs numerator from the greater, and ſet the remainder over the common denominator, for the difference ſought.—N. B. It is beſt to ſet the leſs fraction after the greater, with the ſign (—) of ſubtraction between them, and the mark of equality (=) after them.

Thus, $\frac{7}{9} - \frac{2}{9} = \frac{5}{9}$.

And $\frac{3}{5} - \frac{4}{7} = \frac{21}{35} - \frac{20}{35} = \frac{1}{35}$.

SUBTRACTION, *in Algebra*, is performed by changing the ſigns of all the terms of the ſubtrahend, to their contrary ſigns, viz, + into —, and — into +; and then uniting the terms with thoſe of the minuend after the manner of addition of Algebra.

Ex. From $+ 6a$
Take $+ 2a$
Rem. $6a - 2a = 4a$.

From $+ 6a$
Take $- 2a$
Rem. $6a + 2a = 8a$.

From $- 6a$
Take $+ 2a$
Rem. $- 6a - 2a = - 8a$.

From $- 6a$
Take $- 4a$
Rem. $- 6a + 4a = - 2a$.

From $2a - 3x + 5z - 6$
Take $6a + 4x + 5z + 4$
Rem. $-4a - 7x \quad 0 \quad - 10$

SUBSTILE, or SUBSTILAR *Line*, in Dialling, a right line upon which the ſtile or gnomon of a dial is erected, being the common ſection of the face of the dial and a plane perpendicular to it paſſing through the ſtile.

The angle included between this line and the ſtile, is called the elevation or height of the ſtile.

In polar, horizontal, meridional, and northern dials, the Subſtilar line is the meridional line, or line of 12 o'clock; or the interſection of the plane of the dial with that of the meridian.—In all declining dials, the Subſtile makes an angle with the hour line of 12, and this angle is called the diſtance of the Subſtile from the meridian.—In eaſterly and weſterly dials, the ſubſtilar line is the line of 6 o'clock, or the interſection of the dial plane with the prime vertical.

SUBSUPERPARTICULAR. } See RATIO.
SUBSUPERPARTICUS. }

SUBTANGENT *of a curve*, is the line TA in the axis below the tangent TB, or limited between the tangent and ordinate to the point of contact. (See the laſt figure above).

The tangent, ſubtangent, and ordinate, make a right-angled triangle.

In all paraboliform and hyperboliform figures, the Subtangent is equal to the abſciſs multiplied by the exponent of the power of the ordinate in the equation of the curve. Thus, in the common parabola, whoſe property or equation is $px = y^2$, the Subtangent is equal to $2x$, double the abſciſs. And if $ax^2 = y^3$, or

$px =$

$py = y^{\frac{3}{2}}$, then the Subtangent is $= \frac{3}{2}x$. Alſo if $a^{m}x^{n} = y^{m+n}$, or $px = y^{\frac{m+n}{n}}$, the Subtangent is $= \frac{m+n}{n}x$. See *Method of* TANGENTS.

SUBTENSE, in Geometry, of an arc, is the ſame as the chord of the arc; but of an angle, it is a line drawn acroſs from the one leg of the angle to the other, or between the two extremes of the arc that meaſures the angle.

SUBTRACTION. See SUBSTRACTION.

SUBTRIPLE, is when one quantity is the 3d part of another; as 2 is Subtriple of 6. And SUBTRIPLE *Ratio*, is the ratio of 1 to 3.

SUBTRIPLICATE *Ratio*, is the ratio of the cube roots. So the Subtriplicate ratio of a to b, is the ratio of $\sqrt[3]{a}$ to $\sqrt[3]{b}$, or of $a^{\frac{1}{3}}$ to $b^{\frac{1}{3}}$.

SUCCESSION *of Signs*, in Aſtronomy, is the order in which they are reckoned, or follow one another, and according to which the ſun enters them; called alſo *conſequentia*. As Aries, Taurus, Gemini, Cancer, &c.

When a planet goes according to the order and ſucceſſion of the ſigns, or *in conſequentia*, it is ſaid to be direct; but retrograde when contrary to the ſucceſſion of the ſigns, or *in antecedentia*, as from Gemini to Taurus, then to Aries, &c.

SUCCULA, in Mechanics, a bare axis or cylinder with ſtaves in it to move it round; but without any tympanum, or peritrochium.

SUCKER, in Mechanics, a name by which ſometimes is called the piſton or bucket, in a ſucking pump; and ſometimes the pump itſelf is ſo called.

SUCKING-*Pump*, the common pump, working by two valves opening upwards. See PUMP.

SUMMER, the name of one of the ſeaſons of the year, being one of the quarters when the year is divided into 4 quarters, or one half when the year is divided only into two, Summer and winter. In the former caſe, Summer is the quarter during which, in northern climates, the ſun is paſſing through the three ſigns Cancer, Leo, Virgo, or from the time of the greateſt declination, till the ſun come to the equinoctial again, or have no declination; which is from about the 21ſt of June, till about the 22d of September. In the latter caſe, Summer contains the 6 warmer months, while the ſun is on one ſide of the equinoctial; and winter the other 6 months, when the ſun is on the other ſide of it.

It is ſaid, that a froſty winter produces a dry Summer; and a mild winter, a wet Summer. See Philoſ. Tranſ. no. 458, ſect. 10.

SUMMER *Solſtice*, the time or point when the ſun comes to his greateſt declination, and neareſt the zenith of the place. See SOLSTICE.

SUM, the quantity produced by addition, or by adding two or more numbers or quantities together. So the Sum of 6 and 4 is 10, and the Sum of a and b is $a + b$.

SUN, SOL, ☉, in Aſtronomy, the great luminary which enlightens the world, and by his preſence conſtitutes day.

The Sun, which was reckoned among the planets in the infancy of aſtronomy, ſhould rather be counted among the fixed ſtars. He only appears brighter and larger than they do, becauſe we keep conſtantly near the Sun; whereas we are immenſely farther from the ſtars. But a ſpectator, placed as near to any ſtar as we are to the Sun, would probably ſee that ſtar a body as large and as bright as the Sun appears to us; and, on the other hand, a ſpectator as far diſtant from the Sun as we are from the ſtars, would ſee the Sun as ſmall as we ſee a ſtar, diveſted of all his circumvolving planets; and he would reckon it one of the ſtars in numbering them.

According to the Pythagorean and Copernican hypotheſis, which is now generally received, and has been demonſtrated to be the true ſyſtem, the Sun is the common centre of all the planetary and cometary ſyſtem; around which all the planets and comets, and our earth among the reſt, revolve, in different periods, according to their different diſtances from the Sun.

But the Sun, though thus eaſed of that prodigious motion by which the Ancients imagined he revolved daily round our earth, yet is he not a perfectly quieſcent body. For, from the phenomena of his maculæ or ſpots, it evidently appears, that he has a rotation round his axis, like that of the earth by which our natural day is meaſured, but only ſlower. For, ſome of theſe ſpots have made their firſt appearance near the edge or margin of the Sun, from thence they have ſeemed gradually to paſs over the Sun's face to the oppoſite edge, then diſappear; and hence, after an abſence of about 14 days, they have reappeared in their firſt place, and have taken the ſame courſe over again; finiſhing their entire circuit in 27 days 12^h 20^m; which is hence inferred to be the period of the Sun's rotation round his axis: and therefore the periodical time of the Sun's revolution to a fixed ſtar is 25^d 15^h 16^m; becauſe in 27^d 12^h 20^m of the month of May, when the obſervations were made, the earth deſcribes an angle about the Sun's centre of 26° 22′, and therefore as the angular motion

$360° + 26° 22′ : 360° :: 27^d 12^h 20^m : 25^d 15^h 16^m$.

This motion of the ſpots is from weſt to eaſt: whence we conclude the motion of the Sun, to which the other is owing, to be from eaſt to weſt.

Beſide this motion round his axis, the Sun, on account of the various attractions of the ſurrounding planets, is agitated by a ſmall motion round the centre of gravity of the ſyſtem.—Whether the Sun and ſtars have any proper motion of their own in the immenſity of ſpace, however ſmall, is not abſolutely certain. Though ſome very accurate obſervers have intimated conjectures of this kind, and have made ſuch a general motion not improbable. See STARS.

As for the apparent annual motion of the SUN *round the earth*; it is eaſily ſhewn, by aſtronomers, that the real annual motion of the earth, about the Sun, will cauſe ſuch an appearance. A ſpectator in the Sun would ſee the earth move from weſt to eaſt, for the ſame reaſon as we ſee the Sun move from eaſt to weſt: and all the phenomena reſulting from this annual motion in whichſoever of the bodies it be, will appear the ſame

from either. And hence arises that apparent motion of the Sun, by which he is seen to advance insensibly towards the eastern stars; in so much that, if any star, near the ecliptic, rise at any time with the Sun; after a few days the Sun will be got more to the east of the star, and the star will rise and set before him.

Nature, Properties, Figure, &c, of the SUN.

Those who have maintained that the substance of the Sun is fire, argue in the following manner: The Sun shines, and his rays, collected by concave mirrors, or convex lenses, do burn, consume, and melt the most solid bodies, or else convert them into ashes, or glass: therefore, as the force of the solar rays is diminished, by their divergency, in a duplicate ratio of the distances reciprocally taken; it is evident that their force and effect are the same, when collected by a burning lens, or mirror, as if we were at such distance from the sun, where they were equally dense. The Sun's rays therefore, in the neighbourhood of the Sun, produce the same effects, as might be expected from the most vehement fire: consequently the Sun is of a fiery substance.

Hence it follows, that its surface is probably every where fluid; that being the condition of flame. Indeed, whether the whole body of the Sun be fluid, as some think; or solid, as others; they do not presume to determine: but as there are no other marks, by which to distinguish fire from other bodies, but light, heat, a power of burning, consuming, melting, calcining, and vitrifying; they do not see what should hinder but that the Sun may be a globe of fire, like our fires, invested with flame: and, supposing that the maculæ are formed out of the solar exhalations, they infer that the Sun is not pure fire; but that there are heterogeneous parts mixed along with it.

Philosophers have been much divided in opinion with respect to the nature of fire, light, and heat, and the causes that produce them: and they have given very different accounts of the agency of the Sun, with which, whether we consider them as substances or qualities, they are intimately connected, and on which they seem primarily to depend. Some, among whom we may reckon Sir Isaac Newton, consider the rays of light as composed of small particles, which are emitted from shining bodies, and move with uniform velocities in uniform mediums, but with variable velocities in mediums of variable densities. These particles, say they, act upon the minute constituent parts of bodies, not by impact, but at some indefinitely small distance; they attract and are attracted; and in being reflected or refracted, they excite a vibratory motion in the component particles. This motion increases the distance between the particles, and thus occasions an augmentation of bulk, or an expansion in every dimension, which is the most certain characteristic of fire. This expansion, which is the beginning of a disunion of the parts, being increased by the increasing magnitude of the vibrations proceeding from the continued agency of light, it may easily be apprehended, that the particles will at length vibrate beyond their sphere of mutual attraction, and thus the texture of the body will be altered or destroyed; from solid it may become fluid, as in melted gold; or from being fluid, it may be dispersed in vapour, as in boiling water.

Others, as Boerhaave, represent fire as a substance *sui generis*, unalterable in its nature, and incapable of being produced or destroyed; naturally existing in equal quantities in all places, imperceptible to our senses, and only discoverable by its effects, when, by various causes, it is collected for a time into a less space than that which it would otherwise occupy. The matter of this fire is not in any wise supposed to be derived from the Sun: the solar rays, whether direct or reflected, are of use only as they impel the particles of fire in parallel directions: that parallelism being destroyed, by intercepting the solar rays, the fire instantly assumes its natural state of uniform diffusion. According to this explication, which attributes heat to the matter of fire, when driven in parallel directions, a much greater degree must be given it when the quantity, so collected, is amassed into a focus; and yet the focus of the largest speculum does not heat the air or medium in which it is is found, but only bodies of densities different from that medium.

M. de Luc (Lettres Physiques) is of opinion, that the solar rays are the principal cause of heat; but that they heat such bodies only as do not allow them a free passage. In this remark he agrees with Newton; but then he differs totally from him, as well as from Boerhaave, concerning the nature of the rays of the Sun. He does not admit the emanation of any luminous corpuscles from the Sun, or other self-shining substances, but supposes all space to be filled with an ether of great elasticity and small density, and that light consists in the vibrations of this ether, as sound consists in the vibrations of the air. "Upon Newton's supposition, says an excellent writer, the cause by which the particles of light, and the corpuscles constituting other bodies are mutually attracted and repelled, is uncertain. The reason of the uniform diffusion of fire, of its vibration, and repercussion, as stated in Boerhaave's opinion, is equally inexplicable. And in the last mentioned hypothesis, we may add to the other difficulties attending the supposition of an universal ether, the want of a first mover to make the Sun vibrate. Of these several opinions concerning elementary fire, it may be said, as Cicero remarked upon the opinions of philosophers concerning the nature of the soul: *Harum sententiarum quæ vera sit, Deus aliquis viderit; quæ verisimillima, magna quæstio est.*" Watson's Chem. Ess. vol. 1, pa. 164.

As to the Figure of the SUN; this, like the planets, is not perfectly globular, but spheroidical, being higher about the equator than at the poles. The reason of which is this: the Sun has a motion about his own axis; and therefore the solar matter will have an endeavour to recede from the axis, and that with the greater force as their distances from it, or the circles they move in, are greater: but the equator is the greatest circle; and the rest, towards the poles, continually decrease; therefore the solar matter, though at first in a spherical form, will endeavour to recede from the centre of the equator farther than from the centres of the parallels. Consequently, since the gravity, by which it is retained in its place, is supposed to be uniform throughout the whole Sun, it will really recede from the centre more at

the

the equator, than at any of the parallels; and hence the Sun's diameter will be greater through the equator, than through the poles; that is, the Sun's figure is not perfectly ſpherical, but ſpheroidical.

Several particulars of the Sun, related by Newton, in his Principia, are as follow:

1. That the denſity of the Sun's heat, which is proportional to his light, is 7 times as great at Mercury as with us; and therefore our water there would be all carried off, and boil away: for he found by experiments of the tharmometer, that a heat but 7 times greater than that of the Sun beams in ſummer, will ſerve to make water boil.

2. That the quantity of matter in the Sun is to that in Jupiter, nearly as 1100 to 1; and that the diſtance of that planet from the Sun, is in the ſame ratio to the Sun's ſemidiameter.

3. That the matter in the Sun is to that in Saturn, as 2360 to 1; and the diſtance of Saturn from the Sun is in a ratio but little leſs than that of the Sun's ſemidiameter. And hence, that the common centre of gravity of the Sun and Jupiter is nearly in the ſuperficies of the Sun; of the Sun and Saturn, a little within it.

4. And by the ſame mode of calculation it will be found, that the common centre of gravity of all the planets, cannot be more than the length of the ſolar diameter diſtant from the centre of the Sun. This common centre of gravity he proves is at reſt; and therefore though the Sun, by reaſon of the various poſitions of the planets, may be moved every way, yet it cannot recede far from the common centre of gravity, and this, he thinks, ought to be accounted the centre of our world. Book 3, prop. 12.

5. By means of the ſolar ſpots it hath been diſcovered, that the Sun revolves round his own axis, without moving conſiderably out of his place, in about 25 days, and that the axis of this motion is inclined to the ecliptic in an angle of 87° 30′ nearly. The Sun's apparent diameter being ſenſibly longer in December than in June, the Sun muſt be proportionably nearer to the earth in winter than in Summer; in the former of which ſeaſons therefore will be the perihelion, in the latter the aphelion: and this is alſo confirmed by the earth's motion being quicker in December than in June, as it is by about $\frac{1}{15}$ part. For ſince the earth always deſcribes equal areas in equal times, whenever it moves ſwifter, it muſt needs be nearer to the Sun: and for this reaſon there are about 8 days more from the ſun's vernal equinox to the autumnal, than from the autumnal to the vernal.

6. That the Sun's diameter is equal to 100 diameters of the earth; and therefore the body of the Sun muſt be 1000000 times greater than that of the earth.—Mr. Azout aſſures us, that he obſerved, by a very exact method, the Sun's diameter to be no leſs than 21′ 45″ in his apogee, and not greater than 32′ 45″ in his perigee.

7. According to Newton, in his theory of the moon, the mean apparent diameter of the Sun is 32′ 12″.—The Sun's horizontal parallax is now fixed at $8''\frac{5}{10}$.

8. If you divide 360 degrees (the whole ecliptic) by the quantity of the ſolar year, it will give 59′ 8″ &c, which therefore is the medium quantity of the Sun's daily motion: and if this 59′ 8″ be divided by 24, you have the Sun's horary motion equal to 2′ 28″: and if this laſt be divided by 60, it will give his motion in a minute, &c. And in this way are the tables of the Sun's mean motion conſtructed, as placed in books of Aſtronomical tables and calculations.

SUNDAY, the firſt day of the week; thus called by our idolatrous anceſtors, becauſe ſet apart for the worſhip of the ſun.

It is ſometimes called the *Lord's Day*, becauſe kept as a feaſt in memory of our Lord's reſurrection on this day: and alſo *Sabbath-day*, becauſe ſubſtituted under the new law inſtead of the Sabbath in the old law.

It was Conſtantine the Great who firſt made a law for the proper obſervation of Sunday; and who, according to Euſebius, appointed that it ſhould be regularly celebrated throughout the Roman empire.

SUNDAY *Letter*. See DOMINICAL *Letter*.

SUPERFICIAL, relating to Superficies.

SUPERFICIES, or SURFACE, in Geometry, the outſide or exterior face of any body. This is conſidered as having the two dimenſions of length and breadth only, but no thickneſs; and therefore it makes no part of the ſubſtance or ſolid content or matter of the body.

The terms or bounds or extremities of a Superficies, are lines; and Superficies may be conſidered as generated by the motions of lines.

Superficies are either rectilinear, curvilinear, plane, concave, or convex. A

Rectilinear SUPERFICIES, is that which is bounded by right lines.

Curvilinear SUPERFICIES, is bounded by curve lines.

Plane SUPERFICIES is that which has no inequality in it, nor riſings, nor ſinkings, but lies evenly and ſtraight throughout, ſo that a right line may wholly coincide with it in all parts and directions.

Convex SUPERFICIES, is that which is curved and riſes outwards.

Concave SUPERFICIES, is curved and ſinks inward.

The meaſure or quantity of a Surface, is called the *area* of it. And the finding of this meaſure or area, is ſometimes called the *quadrature* of it, meaning the reducing it to an equal ſquare, or to a certain number of ſmaller ſquares. For all plane figures, and the Surfaces of all bodies, are meaſured by ſquares; as ſquare inches, or ſquare feet, or ſquare yards, &c; that is, ſquares whoſe ſides are inches, or feet, or yards, &c. Our leaſt ſuperficial meaſure is the ſquare inch, and other ſquares are taken from it according to the proportion in the following Table of ſuperficial or ſquare meaſure.

Table of Superficial or Square Meaſure.

144	ſquare inches	= 1 ſquare foot
9	ſquare feet	= 1 ſquare yard
$30\frac{1}{4}$	ſquare yards	= 1 ſquare pole
16	ſquare poles	= 1 ſquare chain
10	ſquare chains	= 1 acre
640	acres - -	= 1 ſquare mile.

The Superficial meaſure of all bodies and figures depends entirely on that of a rectangle; and this is found by drawing or multiplying the length by the breadth of

it; as is proved from plane geometry only, in my Menſuration, pt. 2, ſect. 1, prob. 1. From the area of the rectangle we obtain that of any oblique parallelogram, which, by geometry, is equal to a rectangle of equal baſe and altitude; thence a triangle, which is the half of ſuch a parallelogram or rectangle; and hence, by compoſition, we obtain the Superficies of all other figures whatever, as theſe may be conſidered as made up of triangles only.

Beſide this way of deriving the Superficies of all figures, which is the moſt ſimple and natural, as proceeding on common geometry alone, there are certain other methods; ſuch as the methods of exhauſtions, of fluxions, &c. See theſe articles in their places, as alſo QUADRATURES.

Line of SUPERFICIES, a line uſually found on the ſector, and Gunter's ſcale. The deſcription and uſe of which, ſee under SECTOR and GUNTER'S *Scale*.

SUPERPARTICULAR *Proportion*, or *Ratio*, is that in which the greater term exceeds the leſs by unit or 1. As the ratio of 1 to 2, or 2 to 3, or 3 to 4, &c.

SUPERPARTIENT *Proportion*, or *Ratio*, is when the greater term contains the leſs term, once, and leaves ſome number greater than 1 remaining. As the ratio

of 3 to 5, which is equal to that of 1 to $1\frac{2}{3}$;
of 7 to 10, which is equal to that of 1 to $1\frac{3}{7}$; &c.

SUPPLEMENT, of an arch, or angle, in Geometry or Trigonometry, is what it wants of a ſemicircle, or of 180 degrees; as the *complement* is what it wants of a quadrant, or of 90 degrees. So, the Supplement of 50° is 130°; as the complement of it is 40°.

SURD, in Arithmetic, denotes a number or quantity that is incommenſurate to unity; or that is inexpreſſible in rational numbers by any known way of notation, otherwiſe than by its radical ſign or index.—This is otherwiſe called an *irrational* or *incommenſurable number*, as alſo an *imperfect power*.

Theſe Surds ariſe in this manner: when it is propoſed to extract a certain root of ſome number or quantity, which is not a complete power or a true figurate number of that kind; as, if its ſquare root be demanded, and it is not a true ſquare; or if its cube root be required, and it is not a true cube, &c; then it is impoſſible to aſſign, either in whole numbers, or in fractions, the exact root of ſuch propoſed number. And whenever this happens, it is uſual to denote the root by ſetting before it the proper mark of radicality, which is $\surd$, and placing above this radical ſign the number that ſhews what kind of root is required. Thus, $\surd^2 2$ or $\surd 2$ ſignifies the ſquare root of 2, and $\sqrt[3]{10}$ ſignifies the cube root of 10; which roots, becauſe it is impoſſible to expreſs them in numbers exactly, are properly called *Surd roots*.

There is alſo another way of notation, now much in uſe, by which roots are expreſſed by fractional indices, without the radical ſign: thus, like as x^2, x^3, x^4, &c, denote the ſquare, cube, 4th power, &c, of x; ſo $x^{\frac{1}{2}}$, $x^{\frac{1}{3}}$, $x^{\frac{1}{4}}$, &c, denote the ſquare root, cube root, 4th root, &c, of the ſame quantity x.—The reaſon of this is plain enough; for ſince $\surd x$ is a geometrical mean proportional between 1 and x, ſo $\frac{1}{2}$ is an arithmetical mean between 0 and 1; and therefore, as 2 is the index of the ſquare of x, $\frac{1}{2}$ will be the proper index of its ſquare root, &c.

It may be obſerved that, for convenience, or the ſake of brevity, quantities which are not naturally Surds, are often expreſſed in the form of Surd roots. Thus $\surd 4$, $\surd \frac{9}{4}$, $\surd 27$, are the ſame as 2, $\frac{3}{2}$, 3.

Surds are either *ſimple* or *compound*.

Simple SURDS, are ſuch as are expreſſed by one ſingle term; as $\surd 2$, or $\sqrt[3]{a}$, &c.

Compound SURDS, are ſuch as conſiſt of two or more ſimple Surds connected together by the ſigns + or −; as $\surd 3 + \surd 2$, or $\surd 3 - \surd 2$, or $\sqrt[3]{5 + \surd 2}$: which laſt is called an *univerſal* root, and denotes the cubic root of the ſum ariſing by adding 5 and the root of 2 together.

Of certain Operations by Surds.

1. Such Surds as $\surd 2$, $\surd 3$, $\surd 5$, &c. though they are themſelves incommenſurable with unity, according to the definition, are commenſurable in power with it, becauſe their powers are integers, which are multiples of unity. They may alſo be ſometimes commenſurable with one another; as $\surd 8$ and $\surd 2$, which are to one another as 2 to 1, as is found by dividing them by their greateſt common meaſure, which is $\surd 2$, for then thoſe two become $\surd 4 = 2$, and 1 the ratio.

2. *To reduce Rational Quantities to the form of any propoſed Surd Roots.*—Involve the rational quantity according to the index of the power of the Surd, and then prefix before that power the propoſed radical ſign.

Thus, $a = \surd a^2 = \sqrt[3]{a^3} = \sqrt[4]{a^4} = \sqrt[n]{a^n}$, &c.
and $4 = \surd 16 = \sqrt[3]{64} = \sqrt[4]{256} = \sqrt[n]{4^n}$, &c.

And in this way may a ſimple Surd fraction, whoſe radical ſign refers to only one of its terms, be changed into another, which ſhall include both numerator and denominator. Thus, $\frac{\surd 2}{5}$ is reduced to $\surd \frac{2}{25}$, and $\frac{5}{\sqrt[3]{4}}$ to $\sqrt[3]{\frac{125}{4}}$: thus alſo the quantity a reduced to the form of $x^{\frac{1}{n}}$ or $\sqrt[n]{x}$, is $\overline{a^n}^{\frac{1}{n}}$ or $\sqrt[n]{a^n}$. And thus may roots with rational coefficients be reduced ſo as to be wholly affected by the radical ſign; as $a\sqrt[n]{x} = \sqrt[n]{a^n x}$.

3. *To reduce Simple Surds, having different radical ſigns (which are called heterogeneal Surds) to others that may have one common radical ſign, or which are homogeneal: Or to reduce roots of different names to roots of the ſame name.*—Involve the powers reciprocally, each according to the index of the other, for new powers; and multiply their indices together, for the common index. Otherwiſe, as Surds may be conſidered as powers with fractional exponents, reduce theſe fractional exponents to fractions having the ſame value and a common denominator.

Thus, by the 1ſt way,

$\sqrt[n]{a}$ and $\sqrt[m]{x}$ become $\sqrt[mn]{a^m}$ and $\sqrt[mn]{x^n}$;

and,

and, by the 2d way,

$a^{\frac{1}{n}}$ and $x^{\frac{1}{m}}$ become $\overline{a^m}^{\frac{1}{mn}}$ and $\overline{x^n}^{\frac{1}{mn}}$.

Alſo $\sqrt{3}$ and $\sqrt[3]{2}$ are reduced to $\sqrt[6]{27}$ and $\sqrt[6]{4}$, which are equal to them, and have a common radical ſign.

4. *To reduce Surds to their moſt ſimple expreſſions, or to the loweſt terms poſſible.*—Divide the Surd by the greateſt power, of the ſame name with that of the root, which you can diſcover is contained in it, and which will meaſure or divide it without a remainder; then extract the root of that power, and place it before the quotient or Surd ſo divided; this will produce a new Surd of the ſame value with the former, but in more ſimple terms. Thus, $\sqrt{16a^2x}$, by dividing by $16a^2$, and prefixing its root $4a$, before the quotient $\sqrt{x}$, becomes $4a\sqrt{x}$; in like manner, $\sqrt{12}$ or $\sqrt{4 \times 3}$, becomes $2\sqrt{3}$;

And $\sqrt[3]{ab^3x}$ reduces to $b\sqrt[3]{ax}$.

Alſo $\sqrt[3]{81} = \sqrt[3]{27 \times 3} = \sqrt[3]{3^3 \times 3} = 3\sqrt[3]{3}$.

And $\sqrt{288} = \sqrt[3]{144 \times 2} = 12\sqrt{2}$.

5. *To Add and Subtract Surds.*—When they are reduced to their loweſt terms, if they have the ſame irrational part, add or ſubtract their rational coefficients, and to the ſum or difference ſubjoin the common irrational part.

Thus, $\sqrt{75} + \sqrt{48} = 5\sqrt{3} + 4\sqrt{3} = 9\sqrt{3}$;
and $\sqrt{150} - \sqrt{54} = 5\sqrt{6} - 3\sqrt{6} = 2\sqrt{6}$;
alſo $\sqrt{a^2x} + \sqrt{c^2x} = a\sqrt{x} + c\sqrt{x} = \overline{a+c}.\sqrt{x}$.

Or ſuch Surds may be added and ſubtracted, by firſt ſquaring them (by uniting the ſquare of each part with double their product), and then extracting the root univerſal of the whole. Thus, for the firſt example above,

$$\sqrt{75} + \sqrt{48} = \sqrt{75 + 48 + 2\sqrt{75 \times 48}} = \sqrt{123 + 2\sqrt{3600}} = \sqrt{123 + 120} = \sqrt{243} = 9\sqrt{3}.$$

If the quantities cannot be reduced to the ſame irrational part, they may juſt be connected by the ſigns + or −.

6. *To Multiply and Divide Surds.*—If the terms have the ſame radical, they will be multiplied and divided like powers, viz, by adding their indices for multiplication, and ſubtracting them for diviſion.

Thus,

$\sqrt{a} \times \sqrt[3]{a} = a^{\frac{1}{2}} \times a^{\frac{1}{3}} = a^{\frac{3}{6}} \times a^{\frac{2}{6}} = a^{\frac{5}{6}} = \sqrt[6]{a^5}$;

and $\sqrt{2} \times \sqrt[3]{2} = 2^{\frac{5}{6}} = \sqrt[6]{2^5} = \sqrt[6]{32}$;

alſo $\sqrt{a} \div \sqrt[3]{a} = a^{\frac{1}{2}} \div a^{\frac{1}{3}} = a^{\frac{1}{6}} = \sqrt[6]{a}$;

and $\sqrt{2} \div \sqrt[3]{2} = 2^{\frac{1}{6}} = \sqrt[6]{2}$.

If the quantities be different, but under the ſame radical ſign; multiply or divide the quantities, and place the radical ſign to the product or quotient.

Thus, $\sqrt{2} \times \sqrt{5} = \sqrt{10}$;
and $\sqrt[3]{a^2} \times \sqrt[3]{c} = \sqrt[3]{a^2c}$;
alſo $\sqrt[3]{20} \div \sqrt[3]{4} = \sqrt[3]{5}$.

But if the Surds have not the ſame radical ſign, reduce them to ſuch as ſhall have the ſame radical ſign, and proceed as before.

Thus, $\sqrt[m]{a} \times \sqrt[n]{b} = \sqrt[mn]{a^n} \times \sqrt[mn]{b^m} = \sqrt[mn]{a^n b^m}$;
and $\sqrt{2} \times \sqrt[3]{4} = \sqrt[6]{2^3} \times \sqrt[6]{4^2} = \sqrt[6]{8 \times 16} = \sqrt[6]{128}$.

If the Surds have any rational coefficients, their product or quotient muſt be prefixed.

Thus, $5\sqrt{6} \times 2\sqrt{3} = 10\sqrt{18} = 30\sqrt{2}$;
and $8\sqrt{5} \div 2\sqrt{6} = 4\sqrt{\frac{5}{6}}$.

7. *Involution and Evolution of Surds.*——Surds are involved, or raiſed to any power, by multiplying their indices by the index of the power; and they are evolved or extracted, by dividing their indices by the index of the root.

Thus, the ſquare of $\sqrt[3]{2}$ or of $2^{\frac{1}{3}}$, is $2^{\frac{2}{3}} = \sqrt[3]{4}$;

and the cube of $\sqrt{5}$ or of $5^{\frac{1}{2}}$, is $5^{\frac{3}{2}} = \sqrt{125}$;

alſo the ſquare root of $\sqrt[3]{4}$ or $4^{\frac{1}{3}}$, is $4^{\frac{1}{6}} = 2^{\frac{1}{3}} = \sqrt[3]{2}$.

Or thus: involve or extract the quantity under the radical ſign according to the power or root required, continuing the ſame radical ſign.

So the ſquare of $\sqrt[3]{2}$ is $\sqrt[3]{4}$;
and the ſquare root of $\sqrt[3]{4}$, is $\sqrt[3]{2}$.

Unleſs the index of the power is equal to the name of the Surd, or a multiple of it, for in that caſe the power of the Surd becomes rational. Thus, the ſquare of $\sqrt{3}$ is 3, and the cube of $\sqrt[3]{a^2}$ is a^2.

Simple Surds are commenſurable in power, and by being multiplied by themſelves give, at length, rationals quantities: but compound Surds, multiplied by themſelves, commonly give irrational products. Yet, in this caſe, when any compound Surd is propoſed, there is another compound Surd, which, multiplied by it, gives a rational product.

Thus, $\sqrt{a} + \sqrt{b}$ multiplied by $\sqrt{a} - \sqrt{b}$ gives $a - b$; and $\sqrt[3]{a} - \sqrt[3]{b}$ mult. by $\sqrt[3]{a^2} + \sqrt[3]{ab} + \sqrt[3]{b^2}$ gives $a - b$. The finding of ſuch a Surd as multiplying the propoſed Surd gives a rational product, is made eaſy by three theorems, delivered by Maclaurin, in his Algebra, pa. 109 &c.

This operation is of uſe in reducing Surd expreſſions to more ſimple forms. Thus, ſuppoſe a binomial Surd divided by another, as $\sqrt{20} + \sqrt{12}$ by $\sqrt{5} - \sqrt{3}$, the quotient might be expreſſed by

$$\frac{\sqrt{20} + \sqrt{12}}{\sqrt{5} - \sqrt{3}} = \frac{2\sqrt{5} + 2\sqrt{3}}{\sqrt{5} - \sqrt{3}};$$

but this will be expreſſed in a more ſimple form, by multiplying both numerator and denominator by ſuch a Surd as makes the product of the denominator become a rational quantity: thus, multiplying them by $\sqrt{5} + \sqrt{3}$, the fraction or quotient becomes

$$2 \times \frac{\sqrt{5} + \sqrt{3}}{\sqrt{5} - \sqrt{3}} \times \frac{\sqrt{5} + \sqrt{3}}{\sqrt{5} + \sqrt{3}} = 2 \times \frac{\overline{\sqrt{5} + \sqrt{3}}^2}{5 - 3} = 2 \times \overline{\sqrt{5} + \sqrt{3}}^2 = 8 + 2\sqrt{15}.$$

To do this generally, ſee Maclaurin's Alg. p. 113.

When the ſquare root of a Surd is required, it may be found nearly, by extracting the root of a rational quantity that approximates to its value. Thus, to find the

ſquare.

square root of $3 + 2\sqrt{2}$; first calculate $\sqrt{2} = 1{\cdot}41421$; hence $3 + 2\sqrt{2} = 5{\cdot}82842$, the root of which is nearly $2{\cdot}41421$.

In like manner we may proceed with any other propoſed root. And if the index of the root be very high, a table of logarithms may be uſed to advantage: thus, to extract the root $\sqrt[7]{5 + \sqrt[13]{17}}$; take the logarithm of 17, divide it by 13, find the number anſwering to the quotient, add this number to 5, find the log. of the ſum, and divide it by 7, and the number anſwering to this quotient will be nearly equal to $\sqrt[7]{5 + \sqrt[13]{17}}$.

But it is ſometimes requiſite to expreſs the roots of Surds exactly by other Surds. Thus, in the firſt example, the ſquare root of $3 + 2\sqrt{2}$ is $1 + \sqrt{2}$, for $\overline{1 + \sqrt{2}}^2 = 1 + 2\sqrt{2} + 2 = 3 + \sqrt{2}$. For the method of performing this, the curious may conſult Maclaurin's Algeb. p. 115, where alſo rules for trinomials &c may be found. See alſo the article BINOMIAL *Roots*, in this Dictionary.

For extracting the higher roots of a binomial, whoſe two members when ſquared are commenſurable numbers, we have a rule in Newton's Arith. pa. 59, but without demonſtration. This is ſupplied by Maclaurin, in his Alg. p. 120: as alſo by Graveſande, in his Matheſeos Univerſ. Elem. p. 211.

It ſometimes happens, in the reſolution of cubic equations, that binomials of this form $a \pm b\sqrt{-1}$ occur, the cube roots of which muſt be found; and to theſe Newton's rule cannot always be applied, becauſe of the impoſſible or imaginary factor $\sqrt{-1}$; yet if the root be expreſſible in rational numbers, the rule will often yield to it in a ſhort way, not merely tentative, the trials being confined to known limits. See Maclaurin's Alg. p. 127. It may be farther obſerved, that ſuch roots, whether expreſſible in rational numbers or not, may be found by evolving the quantity $a + b\sqrt{-1}$ by Newton's binomial theorem, and ſumming up the alternate terms. Maclaurin, p. 130.

Thoſe who are deſirous of a general and elegant ſolution of the problem, *to extract any root of an impoſſible binomial* $a + b\sqrt{-1}$, *or of a poſſible binomial* $a + \sqrt{b}$, may have recourſe to the appendix to Saunderſon's Algebra, and to the Philoſ. Tranſ. number 451, or Abridg. vol. 8, p. 1. On the management of Surds, ſee alſo the numerous authors upon Algebra.

SURDESOLID. See SURSOLID.

SURFACE, in Geometry. See SUPERFICIES.

A *mathematical* SURFACE is the mere exterior face of a body, but is not any part of it, being of no thickneſs, but only the bare figure or termination of the body.

A *Phyſical* SURFACE is conſidered as of ſome very ſmall thickneſs.

SURSOLID, or SURDESOLID, in Arithmetic, the 5th power of a number, conſidered as a root. The number 2, for inſtance, conſidered as a root, produces the powers thus:

$2 = 2$ the root or 1ſt power,
$2 \times 2 = 4$ the ſquare or 2d power,
$2 \times 4 = 8$ the cube or 3d power,
$2 \times 8 = 16$ the biquadratic or 4th power,
$2 \times 16 = 32$ the Surſolid or 5th power.

SURSOLID PROBLEM, is that which cannot be reſolved but by curves of a higher kind than the conic ſections.

SURVEYING, the art, or act, of meaſuring land. This compriſes the three following parts; viz, taking the dimenſions of any tract or piece of ground; the delineating or laying the ſame down in a map or draught; and finding the ſuperficial content or area of the ſame; beſide the dividing and laying out of lands.

The firſt of theſe is what is properly called *Surveying*; the ſecond is called *plotting*, or *protracting*, or *mapping*; and the third *caſting up*, or *computing the contents*.

The firſt again conſiſts of two parts, the making of obſervations for the angles, and the taking of lineal meaſures for the diſtances.

The former of theſe is performed by ſome of the following inſtruments; the theodolite, circumferentor, ſemicircle, plain-table, or compaſs, or even by the chain itſelf: the latter is performed by means either of the chain, or the perambulator. The deſcription and manner of uſing each of theſe, ſee under its reſpective article or name.

It is uſeful in Surveying, to take the angles which the bounding lines form with the magnetic needle, in order to check the angles of the figure, and to plot them conveniently afterwards. But, as the difference between the true and magnetic meridian perpetually varies in all places, and at all times; it is impoſſible to compare two ſurveys of the ſame place, taken at diſtant times, by magnetic inſtruments, without making due allowance for this variation. See obſervations on this ſubject, by Mr. Molineux, Philoſ. Tranſ. number 230, p. 625, or Abr. vol. 1, p. 125.

The ſecond branch of Surveying is performed by means of the protractor, and plotting ſcale. The deſcription of which, ſee under their proper names.

If the lands in the ſurvey are hilly, and not in any one plane, the meaſured lines cannot be truly laid down on paper, till they are reduced to one plane, which muſt be the horizontal one, becauſe angles are taken in that plane. And in this caſe, when obſerving diſtant objects, for their elevation or depreſſion, the following table ſhews the links or parts to be ſubtracted from each chain in the hypothenuſal line, when the angle is the correſponding number of degrees.

A TABLE *of the links to be ſubtracted out of every chain in hypothenuſal lines, of ſeveral degrees of altitude or depreſſion, for reducing them to horizontal.*

	links		links
4° 3′	¼	19° 57′	6
5 44	½	21 34	7
7 1	¾	23 4	8
8 7	1	24 30	9
11 29	2	24 50	10
14 4	3	27 8	11
16 16	4	28 22	12
18 12	5	29 32	13

For example, if a ſtation line meaſure 1250 links, or 12½ chains, on an aſcent, or a deſcent, of 11°; here it is after the rate of almoſt two links per chain, and it will be exact enough to take only the 12 chains at that rate, which make 24 links in all, to be deducted from 1250, which leaves 1226 links, for the length to be laid down.

Practical ſurveyors ſay, it is beſt to make this deduction at the end of every chain-length while meaſuring, by drawing the chain forward every time as much as the deduction is; viz, in the preſent inſtance, drawing the chain on 2 links at each chain-length.

The third branch of Surveying, namely computing or caſting-up, is performed by reducing the ſeveral incloſures and diviſions into triangles, trapeziums, and parallelograms, but eſpecially the two former; then finding the areas or contents of theſe ſeveral figures, and adding them all together.

The Practice of Surveying.

1. Land is meaſured with a chain, called Gunter's chain, of 4 poles or 22 yards in length, which conſiſts of 100 equal links, each link being $\frac{2}{100}$ of a yard, or $\frac{66}{100}$ of a foot, or 7·92 inches long, that is nearly 8 inches or $\frac{2}{3}$ of a foot.

An acre of land is equal to 10 ſquare chains, that is, 10 chains in length and 1 chain in breadth.

Or it is 40 × 4 or 160 ſquare poles.
Or it is 220 × 22 or 4840 ſquare yards.
Or it is 1000 × 100 or 100000 ſquare links.

Theſe being all the ſame quantity.

Alſo, an acre is divided into 4 parts called roods, and a rood into 40 parts called perches, which are ſquare poles, or the ſquare of a pole of 5½ yards long, or the ſquare of $\frac{1}{4}$ of a chain, or of 25 links, which is 625 ſquare links. So that the diviſions of land meaſure will be thus:

625 ſq. links = 1 pole or perch
40 perches = 1 rood
4 roods = 1 acre

The length of lines, meaſured with a chain, are ſet down in links as integers, every chain in length being 100 links; and not in chains and decimals. Therefore, after the content is found, it will be in ſquare links; then cut off five of the figures on the right-hand for decimals, and the reſt will be acres. Thoſe decimals are then multiplied by 4 for roods, and the decimals of theſe again by 40 for perches.

Ex. Suppoſe the length of a rectangular piece of ground be 792 links, and its breadth 385: to find the area in acres, roods, and perches.

2. Among the various inſtruments for ſurveying, the plain-table is the eaſieſt and moſt generally uſeful, eſpecially in crooked difficult places, as in a town among houſes, &c. But although the plain-table be the moſt generally uſeful inſtrument, it is not *always* ſo; there being many caſes in which ſometimes one inſtrument is the propereſt, and ſometimes another; nor is that ſurveyor maſter of his buſineſs who cannot in any caſe diſtinguiſh which is the fitteſt inſtrument or method, and uſe it accordingly: nay, ſometimes no inſtrument at all, but barely the chain itſelf, is the beſt method, particularly in regular open fields lying together; and even when you are uſing the plain-table, it is often of advantage to meaſure ſuch large open parts with the chain only, and from thoſe meaſures lay them down upon the table.

The perambulator is uſed for meaſuring roads, and other great diſtances on level ground, and by the ſides of rivers. It has a wheel of 8½ feet, or half a pole, in circumference, upon which the machine turns; and the diſtance meaſured is pointed out by an index, which is moved round by clock work.

Levels, with teleſcopic or other ſights, are uſed to find the level between place and place, or how much one place is higher or lower than another.

An offset-ſtaff is a very uſeful and neceſſary inſtrument, for meaſuring the offsets and other ſhort diſtances. It is 10 links in length, being divided and marked at each of the 10 links.

Ten ſmall arrows, or rods of iron or wood, are uſed to mark the end of every chain length, in meaſuring lines. And ſometimes pickets, or ſtaves with flags, are ſet up as marks or objects of direction.

Various ſcales are alſo uſed in protracting and meaſuring on the plan or paper; ſuch as plane ſcales, line of chords, protractor, compaſſes, reducing ſcales, parallel and perpendicular rulers, &c. Of plane ſcales, there ſhould be ſeveral ſizes, as a chain in 1 inch, a chain in $\frac{3}{4}$ of an inch, a chain in $\frac{1}{2}$ of an inch, &c. And of theſe, the beſt for uſe are thoſe that are laid on the very edges of the ivory ſcale, to prick off diſtances by, without compaſſes.

3. *The Field Book.*

In ſurveying with the plain-table, a field-book is not uſed, as every thing is drawn on the table immediately when it is meaſured. But in ſurveying with the theodolite, or any other inſtrument, ſome ſort of a field-book muſt be uſed, to write down in it a regiſter or account of all that is done and occurs relative to the ſurvey in hand.

This book every one contrives and rules as he thinks fitteſt for himſelf. The following is a ſpecimen of a form that has formerly been much uſed. It is ruled into 3 columns: the middle, or principal column, is for the ſtations, angles, bearings, diſtances meaſured, &c; and thoſe on the right and left are for the offsets on the right and left, which are ſet againſt their correſponding diſtances in the middle column; as alſo for ſuch remarks as may occur, and be proper to note for drawing the plan, &c.

Here ⊙ 1 is the firſt ſtation, where the angle or bearing is 105° 25′. On the left, at 73 links in the diſtance

diſtance or principal line, is an offset of 92; and at 610 an offset of 24 to a croſs hedge. On the right, at 0, or the beginning, an offset 25 to the corner of the field; at 248 Brown's boundary hedge commences; at 610 an offset 35; and at 954, the end of the firſt line, the 0 denotes its terminating in the hedge. And ſo on for the other ſtations.

Draw a line under the work, at the end of every ſtation line, to prevent confuſion.

Offsets and Remarks on the left.	Stations, Bearings, and Diſtances.	Offsets and Remarks on the right.
	⊙1	
	105°25′	
	00	25 corner
92	73	
	248	Brown's hedge
croſs a hedge 24	610	35
	954	00
	⊙2	
	53°10′	
	00	00
houſe corner 51	25	21
	120	29 a tree
34	734	40 a ſtile
	⊙3	
	67°20′	
	61	35
a brook 30	248	
	639	16 a ſpring
foot path 16	810	
croſs hedge 18	973	20 a pond

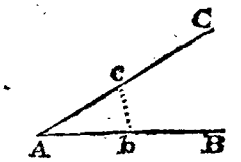
But a few ſkilful ſurveyers now make uſe of a different method for the field book, namely, beginning at the bottom of the page and writing upwards; by which they ſketch a neat boundary on either hand, as they paſs it; an example of which will be given below, with the plan of the ground to accompany it.

In ſmaller ſurveys and meaſurements, a very good way of ſetting down the work, is, to draw, by the eye, on a piece of paper, a figure reſembling that which is to be meaſured; and ſo write the dimenſions, as they are found, againſt the correſponding parts of the figure. And this method may be practiſed to a conſiderable extent, even in the larger ſurveys.

4. *To meaſure a line on the ground with the chain:* Having provided a chain, with 10 ſmall arrows, or rods, to ſtick one into the ground, as a mark, at the end of every chain; two perſons take hold of the chain, one at each end of it, and all the 10 arrows are taken by one of them who goes foremoſt, and is called the leader; the other being called the follower, for diſtinction's ſake.

A picket, or ſtation ſtaff, being ſet up in the direction of the line to be meaſured, if there do not appear ſome marks naturally in that direction; the follower ſtands at the beginning of the line, holding the ring at the end of the chain in his hand, while the leader drags forward the chain by the other end of it, till it is ſtretched ſtraight, and laid or held level, and the leader directed, by the follower waving his hand, to the right or left, till the follower ſee him exactly in a line with the mark or direction to be meaſured to; then both of them ſtretching the chain ſtraight, and ſtooping and holding it level, the leader having the head of one of his arrows in the ſame hand by which he holds the end of the chain, he there ſticks one of them down with it, while he holds the chain ſtretched. This done, he leaves the arrow in the ground, as a mark for the follower to come to, and advances another chain forward, being directed in his poſition by the follower ſtanding at the arrow, as before; as alſo by himſelf now, and at every ſucceeding chain's length, by moving himſelf from ſide to ſide, till he brings the follower and the back mark into a line. Having then ſtretched the chain, and ſtuck down an arrow, as before, the follower takes up his arrow, and they advance again in the ſame manner another chain length. And thus they proceed till all the 10 arrows are employed, and are in the hands of the follower; and the leader, without an arrow, is arrived at the end of the 11th chain length. The follower then ſends or brings the 10 arrows to the leader, who puts one of them down at the end of his chain, and advances with the chain as before. And thus the arrows are changed from the one to the other at every 10 chains' length, till the whole line is finiſhed; the number of changes of the arrows ſhews the number of tens, to which the follower adds the arrows he holds in his hand, and the number of links of another chain over to the mark or end of the line. So if there have been 3 changes of the arrows, and the follower hold 6 arrows, and the end of the line cut off 45 links more, the whole length of the line is ſet down in links thus, 3645.

5. *To take Angles and Bearings.*



Let B and C be two objects, or two pickets ſet up perpendicular; and let it be required to take their bearings, or the angle formed between them at any ſtation A.

1ſt. *With the Plain Table.* The table being covered with a paper, and fixed on its ſtand; plant it at the ſtation A, and fix a fine pin, or a point of the compaſſes, in a proper part of the paper, to repreſent the point A: Cloſe by the ſide of this pin lay the fiducial edge of the index, and turn it about, ſtill touching the pin, till one object B can be ſeen through the ſights: then by the fiducial edge of the index draw a line. In the very ſame manner draw another line in the direction of the other object C. And it is done.

2d. *With the Theodolite, &c.* Direct the fixed ſights along one of the lines, as AB, by turning the inſtrument about till you ſee the mark B through theſe ſights; and there ſcrew the inſtrument faſt. Then

turn

turn the moveable index about till, through its ſights, you ſee the other mark C. Then the degrees cut by the index, upon the graduated limb or ring of the inſtrument, ſhew the quantity of the angle.

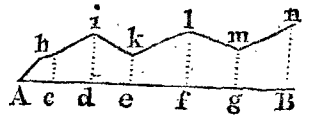
3*d*. *With the Magnetic Needle and Compaſs.* Turn the inſtrument, or compaſs, ſo, that the north end of the needle point to the flower-de-luce. Then direct the ſights to one mark, as B, and note the degrees cut by the needle. Then direct the ſights to the other mark C, and note again the degrees cut by the needle. Then their ſum or difference, as the caſe is, will give the quantity of the angle BAC.

4*th*. *By Meaſurement with the Chain, &c.* Meaſure one chain length, or any other length, along both directions, as to b and c. Then meaſure the diſtance b c, and it is done.—This is eaſily transferred to paper, by making a triangle A b c with theſe three lengths, and then meaſuring the angle A as in Practical Geometry.

6. *To Meaſure the Offsets.*

A h i k l m n being a crooked hedge, or river, &c. From A meaſure in a ſtraight direction along the ſide of it to B. And in meaſuring along this line AB obſerve when you are directly oppoſite any bends or corners of the hedge, as at c d, e, &c; and from thence meaſure the perpendicular offsets, ch, di, &c, with the offset-ſtaff, if they are not very large, otherwiſe with the chain itſelf; and the work is done. And the regiſter, or field-book, may be as follows:

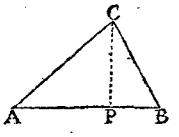
Offs. left.	Baſe line AB
o	⊙ A
ch 62	45 Ac
di 84	220 Ad
ek 70	340 Ae
fl 98	510 Af
gm 57	634 Ag
Bn 91	785 AB



7. *To Survey a triangular Field* ABC.

1ſt. By the Chain.

AP	794
AB	1321
PC	826



Having ſet up marks at the corners, which is to be done in all caſes where there are not marks naturally; meaſure with the chain from A to P, where a perpendicular would fall from the angle C, and there meaſure from P to C; then complete the diſtance AB by meaſuring from P to B; ſetting down each of theſe meaſured diſtances. And thus, having the baſe and perpendicular, the area from them is eaſily found. Or having the place P of the perpendicular, the triangle is eaſily conſtructed.

Or, meaſure all the three ſides with the chain, and note them down. From which the content is eaſily found, or the figure conſtructed.

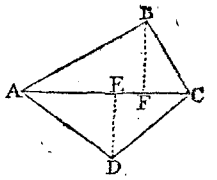
2d. By taking one or more of the Angles.

Meaſure two ſides AB, AC, and the angle A between them. Or meaſure one ſide AB, and the two adjacent angles A and B. From either of theſe ways the figure is eaſily planned: then by meaſuring the perpendicular CP on the plan, and multiplying it by half AB, you have the content.

8. *To meaſure a Four-ſided Field.*

1ſt. By the Chain.

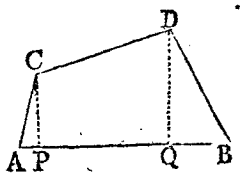
AE	214	210 DE
AF	362	306 BF
AC	592	



Meaſure along either of the diagonals, as AC; and either the two perpendiculars DE, BF, as in the laſt problem; or elſe the ſides AB, BC, CD, DA. From either of which the figure may be planned and computed as before directed.

Otherwiſe by the Chain.

AP	110	352 PC
AQ	74	595 QD
AB	1110	



Meaſure on the longeſt ſide, the diſtances AP, AQ, AB; and the perpendiculars PC, QD.

2d. By taking one or more of the Angles.

Meaſure the diagonal AC (ſee the firſt fig. above), and the angles CAB, CAD, ACB, ACD.—Or meaſure the four ſides, and any one of the angles as BAD.

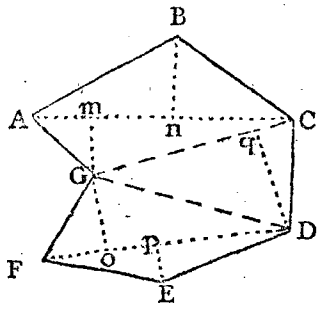
Thus		Or thus	
AC	591	AB	486
CAB	37°20′	BC	394
CAD	41. 15	CD	410
ACB	72 25	DA	462
ACD	54 40	BAD	78°35′

9. *To Survey any Field by the Chain only.*

Having ſet up marks at the corners, where neceſſary, of the propoſed field ABCDEFG. Walk over the ground, and conſider how it can beſt be divided into triangles and trapeziums; and meaſure them ſeparately as in the laſt two problems. And in this way it will be proper to divide it into as few ſeparate triangles, and as many trapeziums as may be, by drawing diago-

nals from corner to corner: and ſo, as that all the perpendiculars may fall within the figure. Thus, the following figure is divided into the two trapeziums ABCG, GDEF, and the triangle GCD. Then, in the firſt, beginning at A, meaſure the diagonal AC, and the two perpendiculars Gm, Bn. Then the baſe GC and the perpendicular Dq. Laſtly the diagonal DF, and the two perpendiculars pE, oG. All which meaſures write againſt the correſponding parts of a rough figure drawn to reſemble the figure to be ſurveyed, or ſet them down in any other form you chooſe.

Am	135	130 mG
An	410	180 nB
Ac	550	
Cq	152	230 qD
CG	440	
FO	206	120 oG
FP	288	80 pE
FD	520	



Or thus:

Meaſure all the ſides AB, BC, CD, DE, EF, FG, and GA; and the diagonals AC, CG, GD, DF.

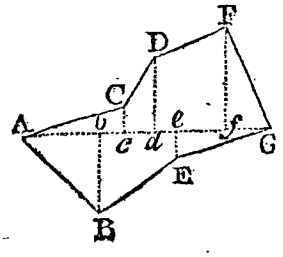
Otherwiſe,

Many pieces of land may be very well ſurveyed, by meaſuring any baſe line, either within or without them, together with the perpendiculars let fall upon it from every corner of them. For they are by theſe means divided into ſeveral triangles and trapezoids, all whoſe parallel ſides are perpendicular to the baſe line; and the ſum of theſe triangles and trapeziums will be equal to the figure propoſed if the baſe line fall within it; if not, the ſum of the parts which are without being taken from the ſum of the whole which are both within and without, will leave the area of the figure propoſed.

In pieces that are not very large, it will be ſufficiently exact to find the points, in the baſe line, where the ſeveral perpendiculars will fall, by means of the *croſs*, and from thence meaſuring to the corners for the lengths of the perpendiculars.—And it will be moſt convenient to draw the line ſo as that all the perpendiculars may fall within the figure.

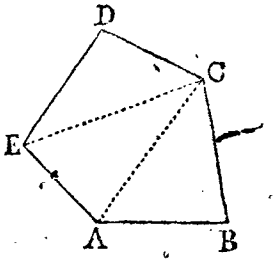
Thus, in the following figure, beginning at A, and meaſuring along the line AG, the diſtances and perpendiculars, on the right and left, are as below.

Ab	315	350 bB
Ac	440	70 cC
Ad	585	320 dD
Ae	610	50 eE
Af	990	470 fF
AG	1020	0



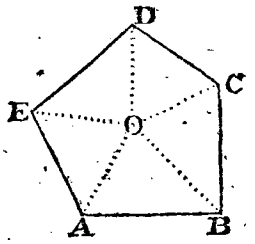
16. *To Survey any Field with the Plain Table.*

1ſt. From one Station.



Plant the table at any angle, as C, from whence all the other angles, or marks ſet up, can be ſeen; and turn the table about till the needle point to the flower-de-luce: and there ſcrew it faſt. Make a point for C on the paper on the table, and lay the edge of the index to C, turning it about there till through the ſights you ſee the mark D; and by the edge of the index draw a dry or obſcure line: then meaſure the diſtance CD, and lay that diſtance down on the line CD. Then turn the index about the point C, till the mark E be ſeen through the ſights, by which draw a line, and meaſure the diſtance to E, laying it on the line from C to E. In like manner determine the poſitions of CA and CB, by turning the ſights ſucceſſively to A and B; and lay the lengths of thoſe lines down. Then connect the points with the boundaries of the field, by drawing the black lines CD, DE, EA, AB, BC.

2d. From a Station within the Field.



When all the other parts cannot be ſeen from one angle, chooſe ſome place O within; or even without, if more convenient, from whence the other parts can be ſeen. Plant the table at O, then fix it with the needle north, and mark the point O upon it. Apply the index ſucceſſively to O, turning it round with the ſights to each angle A, B, C, D, E, drawing dry lines to them by the edge of the index, then meaſuring the diſtances OA, OB, &c, and laying them down upon thoſe lines. Laſtly draw the boundaries AB, BC, CD, DE, EA.

3d. By going round the Figure.

When the figure is a wood or water, or from ſome other obſtruction you cannot meaſure lines acroſs it; begin at any point A, and meaſure round it, either within or without the figure, and draw the directions of all the ſides thus: Plant the table at A, turn it with the needle to the north or flower-de-luce, fix it and mark the point A. Apply the index to A, turning it till you can ſee the point E, there draw a line; and then the point B, and there draw a line: then meaſure theſe lines, and lay them down from A to E and B. Next move the table to B, lay the index along the line AB, and turn the table about till you can ſee the mark A, and ſcrew faſt the table; in which poſition alſo the needle will again point to the flower-de-luce, as it will

do.

do indeed at every ſtation when the table is in the right poſition. Here turn the index about B till through the ſights you ſee the mark C; there draw a line, meaſure BC, and lay the diſtance upon that line after you have ſet down the table at C. Turn it then again into its proper poſition, and in like manner find the next line CD. And ſo on quite round by E to A again. Then the proof of the work will be the joining at A: for if the work is all right, the laſt direction EA on the ground, will paſs exactly through the point A on the paper; and the meaſured diſtance will alſo reach exactly to A. If theſe do not coincide, or nearly ſo, ſome error has been committed, and the work muſt be examined over again.

11. *To Survey a Field with the Theodolite, &c.*

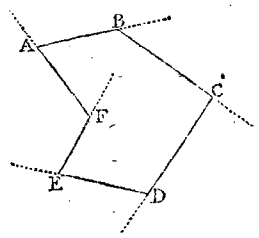
1ſt. From one Point or Station.

When all the angles can be ſeen from one point, as the angle C (laſt fig. but one), place the inſtrument at C, and turn it about till, through the fixed ſights, you ſee the mark B, and there fix it. Then turn the moveable index about till the mark A is ſeen through the ſights, and note the degrees cut on the inſtrument. Next turn the index ſucceſſively to E and D, noting the degrees cut off at each; which gives all the angles BCA, BCE, BCD. Laſtly, meaſure the lines CB, CA, CE, CD; and enter the meaſures in a field-book, or rather againſt the correſponding parts of a rough figure drawn by gueſs to reſemble the field.

2d. From a Point within or without.

Plant the inſtrument at O, (laſt fig.) and turn it about till the fixed ſights point to any object, as A; and there ſcrew it faſt. Then turn the moveable index round till the ſights point ſucceſſively to the other points E, D, C, B, noting the degrees cut off at each of them; which gives all the angles round the point O. Laſtly, meaſure the diſtances OA, OB, OC, OD, OE, noting them down as before, and the work is done.

3d. By going round the Field.



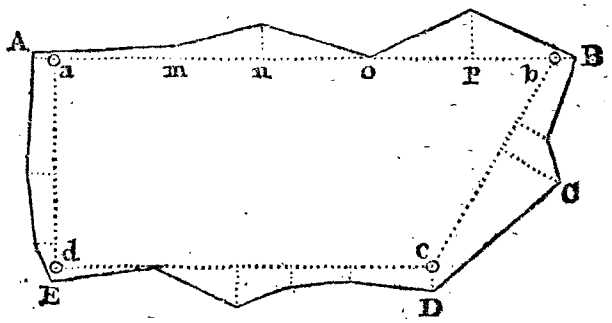
By meaſuring round, either within or without the field, proceed thus. Having ſet up marks at B, C, &c. near the corners as uſual, plant the inſtrument at any point A, and turn it till the fixed index be in the direction AB, and there ſcrew it faſt: then turn the moveable index to the direction AF; and the degrees cut off will be the angle A. Meaſure the line AB, and plant the inſtrument at B, and there in the ſame manner obſerve the angle A. Then meaſure BC, and obſerve the angle C. Then meaſure the diſtance CD, and take the angle D. Then meaſure DE, and take the angle E. Then meaſure EF, and take the angle F. And laſtly meaſure the diſtance FA.

To prove the work; add all the inward angles, A, B, C, &c, together, and when the work is right, their ſum will be equal to twice as many right angles as the figure has ſides, wanting 4 right angles. And when there is an angle, as F, that bends inwards, and you meaſure the external angle, which is leſs than two right angles, ſubtract it from 4 right angles, or 360 degrees, to give the internal angle greater than a ſemicircle or 180 degrees.

Otherwiſe. Inſtead of obſerving the internal angles, you may take the external angles, formed without the figure by producing the ſides further out. And in this caſe, when the work is right, their ſum altogether will be equal to 360 degrees. But when one of them, as F, runs inwards, ſubtract it from the ſum of the reſt, to leave 360 degrees.

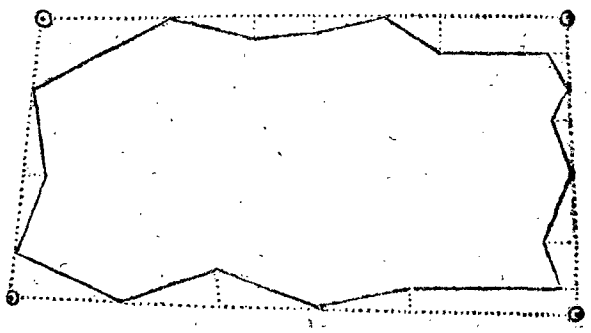
12. *To Survey a Field with crooked Hedges, &c.*

With any of the inſtruments meaſure the lengths and poſitions of imaginary lines running as near the ſides of the field as you can; and in going along them meaſure the offsets in the manner before taught; and you will have the plan on the paper in uſing the plain table, drawing the crooked hedges through the ends of the offsets; but in ſurveying with the theodolite, or other inſtrument, ſet down the meaſures properly in a field-book, or memorandum-book, and plan them after returning from the field, by laying down all the lines and angles.



So, in ſurveying the piece ABCDE, ſet up marks a, b, c, d, dividing it into as few ſides as may be. Then begin at any ſtation a, and meaſure the lines ab, bc, cd, da, and take their poſitions, or the angles a, b, c, d; and in going along the lines meaſure all the offsets, as at m, n, o, p, &c, along every ſtation line.

And this is done either within the field, or without, as may be moſt convenient. When there are obſtructions within, as wood, water, hills, &c; then meaſure without, as in the figure here below.

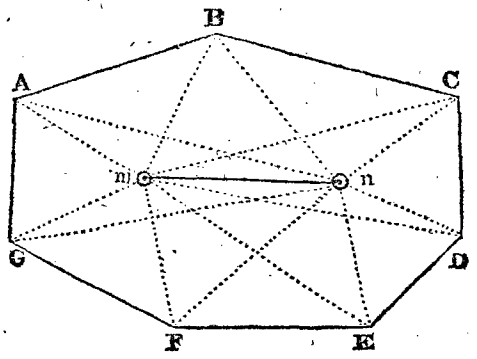


13. *To Survey a Field or any other Thing, by Two Stations.*

This is performed by chooſing two ſtations, from whence all the marks and objects can be ſeen, then meaſuring the diſtance between the ſtations, and at each ſtation taking the angles formed by every object, from the ſtation line or diſtance.

The two ſtations may be taken either within the bounds, or in one of the ſides, or in the direction of two of the objects, or quite at a diſtance, and without the bounds of the objects, or part to be ſurveyed.

In this manner, not only grounds may be ſurveyed, without even entering them, but a map may be taken of the principal parts of a country, or the chief places of a town, or any part of a river or coaſt ſurveyed, or any other inacceſſible objects; by taking two ſtations, on two towers, or two hills, or ſuch like.



When the plain table is uſed; plant it at one ſtation m, draw a line m n on it, along which lay the edge of the index, and turn the table about till the ſights point directly to the other ſtation; and there ſcrew it faſt. Then turn the ſights round m ſucceſſively to all the objects ABC, &c, drawing a dry line by the edge of the index at each, as mA, mB, mC, &c. Then meaſure the diſtance to the other ſtation, there plant the table, and lay that diſtance down on the ſtation line from m to n. Next lay the index by the line nm, and turn the table about till the ſights point to the other ſtation m, and there ſcrew it faſt. Then direct the ſights ſucceſſively to all the objects A, B, C, &c, as before, drawing lines each time, as nA, nB, nC, &c: and their interſection with the former lines will give the places of all the objects, or corners, A, B, C, &c.

When the theodolite, or any other inſtrument for taking angles, is uſed; proceed in the ſame way, meaſuring the ſtation diſtance mn, planting the inſtrument firſt at one ſtation, and then at another; then placing the fixed ſights in the direction mn, and directing the moveable ſights to every object, noting the degrees cut off at each time. Then, theſe obſervations being planned, the interſections of the lines will give the objects as before.

When all the objects, to be ſurveyed, cannot be ſeen from two ſtations; then three ſtations may be uſed, or four, or as many as is neceſſary; meaſuring always the diſtance from one ſtation to another; placing the inſtrument in the ſame poſition at every ſtation, by means deſcribed before; and from each ſtation obſerving or ſetting every object that can be ſeen from it, by taking its direction or angular poſition, till every object be determined by the interſection of two or more lines of direction, the more the better. And thus may very extenſive ſurveys be taken, as of large commons, rivers, coaſts, countries, hilly grounds, and ſuch like.

14. *To Survey a Large Eſtate.*

If the eſtate be very large, and contain a great number of fields, it cannot well be done by ſurveying all the fields ſingly, and then putting them together; nor can it be done by taking all the angles and boundaries that incloſe it. For in theſe caſes, any ſmall errors will be ſo multiplied, as to render it very much diſtorted.

1ſt. Walk over the eſtate two or three times, in order to get a perfect idea of it, and till you can carry the map of it tolerably in your head. And to help your memory, draw an eye draught of it on paper, or at leaſt, of the principal parts of it, to guide you.

2d. Chooſe two or more eminent places in the eſtate, for your ſtations, from whence you can ſee all the principal parts of it: and let theſe ſtations be as far diſtant from one another as poſſible; as the fewer ſtations you have to command the whole, the more exact your work will be: and they will be fitter for your purpoſe, if theſe ſtation lines be in or near the boundaries of the ground, and eſpecially if two or more lines proceed from one ſtation.

3d. Take angles, between the ſtations, ſuch as you think neceſſary, and meaſure the diſtances from ſtation to ſtation, always in a right line: theſe things muſt be done, till you get as many angles and lines as are ſufficient for determining all your points of ſtation. And in meaſuring any of theſe ſtation diſtances, mark accurately where theſe lines meet with any hedges, ditches, roads, lanes, paths, rivulets, &c, and where any remarkable object is placed, by meaſuring its diſtance from the ſtation line, and where a perpendicular from it cuts that line; and always mind, in any of theſe obſervations, that you be in a right line, which you will know by taking backſight and foreſight, along your ſtation line. And thus as you go along any main ſtation line, take offsets to the ends of all hedges, and to any pond, houſe, mill, bridge, &c, omitting nothing that is remarkable. And all theſe things muſt be noted down; for theſe are your data, by which the places of ſuch objects are to be determined upon your plan. And be ſure to ſet marks up at the interſections of all hedges with the ſtation line, that you may know where to meaſure from; when you come to ſurvey theſe particular fields, which muſt immediately be done, as ſoon as you have meaſured that ſtation line, whilſt they are freſh in memory. In this way all your ſtation lines are to be meaſured, and the ſituation of all places adjoining to them determined, which is the firſt grand point to be obtained. It will be proper for you to lay down your work upon paper every night, when you go home, that you may ſee how you go on.

4th. As to the inner parts of the eſtate, they muſt be deter-

determined in like manner, by new ſtation lines: for, after the main ſtations are determined, and every thing adjoining to them, then the eſtate muſt be ſubdivided into two or three parts by new ſtation lines; taking inner ſtations at proper places, where you can have the beſt view. Meaſure theſe ſtation lines as you did the firſt, and all their interſections with hedges, and all offsets to ſuch objects as appear. Then you may proceed to ſurvey the adjoining fields, by taking the angles that the ſides make with the ſtation line, at the interſections, and meaſuring the diſtances to each corner, from the interſections. For every ſtation line will be a baſis to all the future operations; the ſituation of all parts being entirely dependant upon them; and therefore they ſhould be taken of as great a length as poſſible; and it is beſt for them to run along ſome of the hedges or boundaries of one or more fields, or to paſs through ſome of their angles. All things being determined for theſe ſtations, you muſt take more inner ones, and ſo continue to divide and ſubdivide, till at laſt you come to ſingle fields; repeating the ſame work for the inner ſtations, as for the outer ones, till all be done: and cloſe the work as often as you can, and in as few lines as poſſible. And that you may chooſe ſtations the moſt conveniently, ſo as to cauſe the leaſt labour, let the ſtation lines run as far as you can along ſome hedges, and through as many corners of the fields, and other remarkable points, as you can. And take notice how one field lies by another; that you may not miſplace them in the draught.

5th. An eſtate may be ſo ſituated, that the whole cannot be ſurveyed together; becauſe one part of the eſtate cannot be ſeen from another. In this caſe, you may divide it into three or four parts, and ſurvey the parts ſeparately, as if they were lands belonging to different perſons; and at laſt join them together.

6th. As it is neceſſary to protract or lay down your work as you proceed in it, you muſt have a ſcale of a due length to do it by. To get ſuch a ſcale, you muſt meaſure the whole length of the eſtate in chains; then you muſt conſider how many inches in length the map is to be; and from theſe you will know how many chains you muſt have in an inch; then make your ſcale, or chooſe one already made, accordingly.

7th. The trees in every hedge row muſt be placed in their proper ſituation, which is ſoon done by the plain table; but may be done by the eye without an inſtrument; and being thus taken by gueſs, in a rough draught, they will be exact enough, being only to look at; except it be ſuch as are at any remarkable places, as at the ends of hedges, at ſtiles, gates, &c, and theſe muſt be meaſured. But all this need not be done till the draught is finiſhed. And obſerve in all the hedges, what ſide the gutter or ditch is on, and conſequently to whom the fences belong.

8th. When you have long ſtations, you ought to have a good inſtrument to take angles with; and the plain table may very properly be made uſe of, to take the ſeveral ſmall internal parts, and ſuch as cannot be taken from the main ſtations, as it is a very quick and ready inſtrument.

15. Inſtead of the foregoing method, an ingenious friend (Mr. Abraham Crocker), after mentioning the new and improved method of keeping the field book by writing from bottom to top of the pages, obſerves that "In the former method of meaſuring a large eſtate, the accuracy of it depends on the correctneſs of the inſtruments uſed in taking the angles. To avoid the errors incident to ſuch a multitude of angles, other methods have of late years been uſed by ſome few ſkilful ſurveyors; the moſt practical, expeditious, and correct, ſeems to be the following.

"As was adviſed in the foregoing method, ſo in this, chooſe two or more eminences, as grand ſtations, and meaſure a principal baſe line from one ſtation to the other, noting every hedge, brook, or other remarkable object as you paſs by it; meaſuring alſo ſuch ſhort perpendicular lines to ſuch bends of hedges as may be near at hand. From the extremities of this baſe line, or from any convenient parts of the ſame, go off with other lines to ſome remarkable object ſituated towards the ſides of the eſtate, without regarding the angles they make with the baſe line or with one another; ſtill remembering to note every hedge, brook or other object that you paſs by. Theſe lines, when laid down by interſections, will with the baſe line form a grand triangle upon the eſtate; ſeveral of which, if need be, being thus laid down, you may proceed to form other ſmaller triangles and trapezoids on the ſides of the former: and ſo on, until you finiſh with the encloſures individually.

"To illuſtrate this excellent method, let us take AB (in the plan of an eſtate, fig. 1, pl. 28) for the principal baſe line. From B go off to the tree at C; noting down, in the field-book, every croſs hedge, as you meaſure on; and from C meaſure back to the firſt ſtation at A, noting down every thing as before directed.

"This grand triangle being completed, and laid down on the rough-plan paper, the parts, exterior as well as interior, are to be completed by ſmaller triangles and trapezoids.

"When the whole plan is laid down on paper, the contents of each field might be calculated by the methods laid down below, at article 20.

"In countries where the lands are encloſed with high hedges, and where many lanes paſs through an eſtate, a theodolite may be uſed to advantage, in meaſuring the angles of ſuch lands; by which means, a kind of ſkeleton of the eſtate may be obtained, and the lane-lines ſerve as the baſes of ſuch triangles and trapezoids as are neceſſary to fill up the interior parts."

The method of meaſuring the other croſs lines, offſets and interior parts and encloſures, appears in the plan, fig. 1, laſt referred to.

16. Another ingenious correſpondent (Mr. John Rodham of Richmond, Yorkſhire) has alſo communicated the following example of the new method of ſurveying, accompanied by the field-book, and its correſponding plan. His account of the method is as follows.

The field-book is ruled into three columns. In the middle one are ſet down the diſtances on the chain line at which any mark, offset, or other obſervation is made; and in the right and left hand columns are entered, the offsets and obſervations made on the right and left hand reſpectively of the chain line.

It is of great advantage, both for brevity and perſpicuity,

ſpicuity, to begin at the bottom of the leaf and write upwards; denoting the croſſing of fences, by lines drawn acroſs the middle column, or only a part of ſuch a line on the right and left oppoſite the figures, to avoid confuſion, and the corners of fields, and other remarkable turns in the fences where offsets are taken to, by lines joining in the manner the fences do, as will be beſt ſeen by comparing the book with the plan annexed, fig. 2, pl. 28.

The marks called, *a*, *b*, *c*, &c, are beſt made in the fields, by making a ſmall hole with a ſpade, and a chip or ſmall bit of wood, with the particular letter upon it, may be put in, to prevent one mark being taken for another, on any return to it. But in general, the name of a mark is very eaſily had by referring in the book to the line it was made in. After the ſmall alphabet is gone through, the capitals may be next, the print letters afterwards, and ſo on, which anſwer the purpoſe of ſo many different letters; or the marks may be numbered.

The letter in the left hand corner at the beginning of every line, is the mark or place meaſured *from*; and, that at the right hand corner at the end, is the mark meaſured *to*: But when it is not convenient to go exactly from a mark, the place meaſured from, is deſcribed *ſuch a diſtance* from *one mark* towards *another*; and where a mark is not meaſured to, the exact place is aſcertained by ſaying, turn to the right or left hand, *ſuch a diſtance* to *ſuch a mark*, it being always underſtood that thoſe diſtances are taken in the chain line.

The characters uſed, are ⌐ for *turn to the right hand*, ¬ for turn to the left hand, and ^ placed over an offset, to ſhew that it is not taken at right angles with the chain line, but in the line with ſome ſtraight fence; being chiefly uſed when croſſing their directions, and is a better way of obtaining their true places than by offsets at right angles.

When a line is meaſured whoſe poſition is determined, either by former work (as in the caſe of producing a given line or meaſuring from one known place or mark to another) or by itſelf (as in the third ſide of a triangle) it is called a *faſt line*, and a double line acroſs the book is drawn at the concluſion of it; but if its poſition is not determined (as in the ſecond ſide of a triangle) it is called a *looſe line*, and a ſingle line is drawn acroſs the book. When a line becomes determined in poſition, and is afterwards continued, a double line half through the book is drawn.

When a looſe line is meaſured, it becomes abſolutely neceſſary to meaſure ſome line that will determine its poſition. Thus, the firſt line *ab*, being the baſe of a triangle, is always determined; but the poſition of the ſecond ſide *bj*, does not become determined, till the third ſide *jb* is meaſured; then the triangle may be conſtructed, and the poſition of both is determined.

At the beginning of a line, to fix a looſe line to the mark or place meaſured from, the ſign of turning to the right or left hand muſt be added (as at *j* in the third line); otherwiſe a ſtranger, when laying down the work may as eaſily conſtruct the triangle *hjb* on the wrong ſide of the line *ab*, as on the right one: but this error cannot be fallen into, if the ſign above named be carefully obſerved.

In chooſing a line to fix a looſe one, care muſt be taken that it does not make a very acute or obtuſe angle; as in the triangle *p*B*r*, by the angle at B being very obtuſe, a ſmall deviation from truth, even the breadth of a point at *p* or *r*, would make the error at B when conſtructed very conſiderable; but by conſtructing the triangle *p*B*q*, ſuch a deviation is of no conſequence.

Where the words *leave off* are written in the field-book, it is to ſignify that the taking of offsets is from thence diſcontinued; and of courſe ſomething is wanting between that and the next offset.

The field-book above referred to, is engraved on plate 29, in parts, repreſenting ſo many pages, each of which is ſuppoſed to begin at the bottom, and end at top. And the map or plan belonging to it, in fig. 2, pl. 28.

17. *To Survey a County, or Large Tract of Land.*

1ſt. Chooſe two, three, or four eminent places for ſtations; ſuch as the tops of high hills or mountains, towers, or church ſteeples, which may be ſeen from one another; and from which moſt of the towns, and other places of note, may alſo be ſeen. And let them be as far diſtant from one another as poſſible. Upon theſe place raiſe beacons, or long poles, with flags of different colours flying at them; ſo as to be viſible from all the other ſtations.

2d. At all the places, which you would ſet down in the map, plant long poles with flags at them of ſeveral colours, to diſtinguiſh the places from one another; fixing them upon the tops of church ſteeples, or the tops of houſes, or in the centres of leſſer towns.

But you need not have theſe marks at many places at once, as ſuppoſe half a ſcore at a time. For when the angles have been taken, at the two ſtations, to all theſe places, the marks may be moved to new ones; and ſo ſucceſſively to all the places you want. Theſe marks then being ſet up at a convenient number of places, and ſuch as may be ſeen from both ſtations; go to one of theſe ſtations, and with an inſtrument to take angles, ſtanding at that ſtation, take all the angles between the other ſtation, and each of theſe marks, obſerving which is blue, which red, &c, and which hand they lie on; and ſet all down with their colours. Then go to the other ſtation, and take all the angles between the firſt ſtation, and each of the former marks, and ſet them down with the others, each againſt his fellow with the ſame colour. You may, if you can, alſo take the angles at ſome third ſtation, which may ſerve to prove the work, if the three lines interſect in that point, where any mark ſtands. The marks muſt ſtand till the obſervations are finiſhed at both ſtations; and then they muſt be taken down, and ſet up at freſh places. And the ſame operations muſt be performed, at both ſtations, for theſe freſh places; and the like for others. Your inſtrument for taking angles muſt be an exceeding good one, made on purpoſe with teleſcopic ſights; and of three, four, or five feet radius. A circumferentor is reckoned a good inſtrument for this purpoſe.

3d. And though it is not abſolutely neceſſary to meaſure any diſtance, becauſe a ſtationary line being laid down from any ſcale, all the other lines will be proportional

proportional to it; yet it is better to measure some of the lines, to ascertain the distances of places in miles; and to know how many geometrical miles there are in any length; and from thence to make a scale to measure any distance in miles. In measuring any distance, it will not be exact enough to go along the high roads; by reason of their turnings and windings, and hardly ever lying in a right line between the stations, which would cause endless reductions, and create trouble to make it a right line; for which reason it can never be exact. But a better way is to measure in a right line with a chain, between station and station, over hills and dales or level fields, and all obstacles. Only in case of water, woods, towns, rocks, banks, &c, where one cannot pass, such parts of the line must be measured by the methods of inaccessible distances; and besides, allowing for ascents and descents, when we meet with them. And a good compass that shews the bearing of the two stations, will always direct you to go straight, when you do not see the two stations; and in your progress, if you can go straight, you may take offsets to any remarkable places, likewise noting the intersection of the stationary line with all roads, rivers, &c.

4th. And from all the stations, and in the whole progress, be very particular in observing sea coasts, river mouths, towns, castles, houses, churches, windmills, watermills, trees, rocks, sands, roads, bridges, fords, ferries, woods, hills, mountains, rills, brooks, parks, beacons, sluices, floodgates, locks, &c; and in general all things that are remarkable.

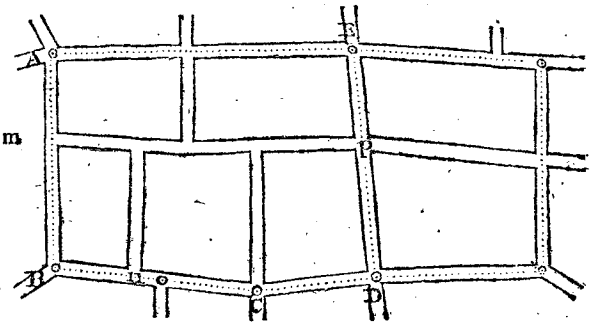
5th. After you have done with the first and main station lines, which command the whole county; you must then take inner stations, at some places already determined; which will divide the whole into several partitions: and from these stations you must determine the places of as many of the remaining towns as you can. And if any remain in that part, you must take more stations, at some places already determined; from which you may determine the rest. And thus proceed through all the parts of the country, taking station after station, till we have determined all we want. And in general the station distances must always pass through such remarkable points as have been determined before, by the former stations.

6th. Lastly, the position of the station line you measure, or the point of the compass it lies on, must be determined by astronomical observation. Hang up a thread and plummet in the sun, over some part of the station line, and observe when the shadow runs along that line, and at that moment take the sun's altitude; then having his declination, and the latitude, the azimuth will be found by spherical trigonometry. And the azimuth is the angle the station line makes with the meridian; and therefore a meridian may easily be drawn through the map: Or a meridian may be drawn through it by hanging up two threads in a line with the pole star, when he is just north, which may be known from astronomical tables. Or thus; observe the star Alioth, or that in the rump of the great bear, being that next the square; or else Cassiopeia's hip; I say, observe by a line and plummet when either of these stars and the pole star come into a perpendicular; and at that time they are due north. Therefore two perpendicular lines being fixed at that moment, towards these two stars, will give the position of the meridian.

18. *To Survey a Town or City.*

This may be done with any of the instruments for taking angles, but best of all with the plain table, where every minute part is drawn while in sight. It is proper also to have a chain of 50 feet long, divided into 50 links, and an offset-staff of 10 feet long.

Begin at the meeting of two or more of the principal streets, through which you can have the longest prospects, to get the longest station lines. There having fixed the instrument, draw lines of direction along those streets, using two men as marks, or poles set in wooden pedestals, or perhaps some remarkable places in the houses at the farther ends, as windows, doors, corners, &c. Measure these lines with the chain, taking offsets with the staff, at all corners of streets, bendings, or windings, and to all remarkable things, as churches, markets, halls, colleges, eminent houses, &c. Then remove the instrument to another station along one of these lines; and there repeat the same process as before. And so on till the whole is finished.



Thus, fix the instrument at A, and draw lines in the direction of all the streets meeting there; and measure AB, noting the street on the left at m. At the second station B, draw the directions of the streets meeting there; measure from B to C, noting the places of the streets at n and o as you pass by them. At the 3d station C, take the direction of all the streets meeting there, and measure CD. At D do the same, and measure DE, noting the place of the cross streets at p. And in this manner go through all the principal streets. This done, proceed to the smaller and intermediate streets; and lastly to the lanes, alleys, courts, yards, and every part that it may be thought proper to represent.

Of Planning, Computing, and Dividing.

19. *To Lay down the Plan of any Survey.*

If the survey was taken with a plain table, you have a rough plan of it already on the paper which covered the

the table. But if the ſurvey was with any other inſtrument, a plan of it is to be drawn from the meaſures that were taken in the ſurvey, and firſt of all a rough plan upon paper.

To do this, you muſt have a ſet of proper inſtruments, for laying down both lines and angles, &c; as ſcales of various ſizes, the more of them, and the more accurate, the better; ſcales of chords, protractors, perpendicular and parallel rulers, &c. Diagonal ſcales are beſt for the lines, becauſe they extend to three figures, or chains and links, which are hundredth parts of chains. And in uſing the diagonal ſcale, a pair of compaſſes muſt be employed to take off the lengths of the principal lines very accurately. But a ſcale with a thin edge divided, is much readier for laying down the perpendicular offsets to crooked hedges, and for marking the places of thoſe offsets upon the ſtation line; which is done at only one application of the edge of the ſcale to that line, and then pricking off all at once the diſtances along it. Angles are to be laid down either with a good ſcale of chords, which is perhaps the moſt accurate way; or with a large protractor, which is much readier when many angles are to be laid down at one point, as they are pricked off all at once round the edge of the protractor.

Very particular directions for laying down all ſorts of figures cannot be neceſſary in this place, to any perſon who has learned practical geometry, or the conſtruction of figures, and the uſe of his inſtruments. It may therefore be ſufficient to obſerve, that all lines and angles muſt be laid down on the plan in the ſame order in which they were meaſured in the field, and in which they are written in the field-book; laying down firſt the angles for the poſition of lines, then the lengths of the lines, with the places of the offsets, and then the lengths of the offsets themſelves, all with dry or obſcure lines; then a black line drawn through the extremities of all the offsets, will be the hedge or bounding line of the field, &c. After the principal bounds and lines are laid down, and made to fit or cloſe properly, proceed next to the ſmaller objects, till you have entered every thing that ought to appear in the plan, as houſes, brooks, trees, hills, gates, ſtiles, roads, lanes, mills, bridges, woodlands, &c, &c.

The north ſide of a map or plan is commonly placed uppermoſt, and a meridian ſomewhere drawn, with the compaſs or flower-de-luce pointing north. Alſo, in a vacant place, a ſcale of equal parts or chains is drawn, and the title of the map in conſpicuous characters, and embelliſhed with a compartment. All hills muſt be ſhadowed, to diſtinguiſh them in the map. Colour the hedges with different colours; repreſent hilly grounds by broken hills and valleys; draw ſingle dotted lines for foot-paths, and double ones for horſe or carriage roads. Write the name of each field and remarkable place within it, and, if you chooſe, its content in acres, roods, and perches.

In a very large eſtate, or a county, draw vertical and horizontal lines through the map, denoting the ſpaces between them by letters, placed at the top, and bottom, and ſides, for readily finding any field or other object, mentioned in a table.

In mapping counties, and eſtates that have uneven grounds of hills and valleys, reduce all oblique lines, meaſured up hill and down hill, to horizontal ſtraight lines, if that was not done during the ſurvey, before they were entered in the field-book, by making a proper allowance to ſhorten them. For which purpoſe, there is commonly a ſmall table engraven on ſome of the inſtruments for Surveying.

20. *To Compute the Contents of Fields.*

1ſt. Compute the contents of the figures, whether triangles, or trapeziums, &c, by the proper rules for the ſeveral figures laid down in meaſuring; multiplying the lengths by the breadths, both in links: the product is acres after you have cut off five figures on the right, for decimals; then bring theſe decimals to roods and perches, by multiplying firſt by 4, and then by 40. An example of which was given in the deſcription of the chain, art. 1.

2d. In ſmall and ſeparate pieces, it is uſual to caſt up their contents from the meaſures of the lines taken in ſurveying them, without making a correct plan of them.

Thus, in the triangle in art. 7, where we had AP = 794, and AB = 1321
PC = 826

3d. In pieces bounded by very crooked and winding hedges, meaſured by offſets, all the parts between the offſets are moſt accurately meaſured ſeparately as ſmall trapezoids. Thus, for the example to art. 6, where

Ac 45	62 ch
Ad 220	84 di
Ae 340	70 ek
Af 510	98 fl
Ag 634	57 gm
AB 785	91 Bn

Then

4th. Sometimes ſuch pieces as that above, are computed by finding a mean breadth, by dividing the ſum of the offſets by the number of them, accounting that for one of them where the boundary meets the ſtation line, as at A; then multiply the length AB by that mean breadth.

Thus:

00	785	AB
62	66	mean breadth
84		
70	4710	ac r p
98	4710	Content 0 2 2 by this method,
57		which is 10 perches too little.
91	·51810	
	4	
7) 462		
66	2·07240	
	40	
	2·89600	

But this method is always erroneous, except when the offſets ſtand at equal diſtances from one another.

5th. But in larger pieces, and whole eſtates, conſiſting of many fields, it is the common practice to make a rough plan of the whole, and from it compute the contents quite independent of the meaſures of the lines and angles that were taken in Surveying. For then new lines are drawn in the fields in the plan, ſo as to divide them into trapeziums and triangles, the baſes and perpendiculars of which are meaſured on the plan by means of the ſcale from which it was drawn, and ſo multiplied together for the contents. In this way the work is very expeditiouſly done, and ſufficiently correct; for ſuch dimenſions are taken, as afford the moſt eaſy method of calculation; and, among a number of parts, thus taken and applied to a ſcale, it is likely that ſome of the parts will be taken a ſmall matter too little, and others too great; ſo that they will, upon the whole, in all probability, very nearly balance one another. After all the fields, and particular parts, are thus computed ſeparately, and added all together into one ſum, calculate the whole eſtate independent of the fields, by dividing it into large and arbitrary triangles and trapeziums, and add theſe alſo together. Then if this ſum be equal to the former, or nearly ſo, the work is right; but if the ſums have any conſiderable difference, it is wrong, and they muſt be examined, and recomputed, till they nearly agree.

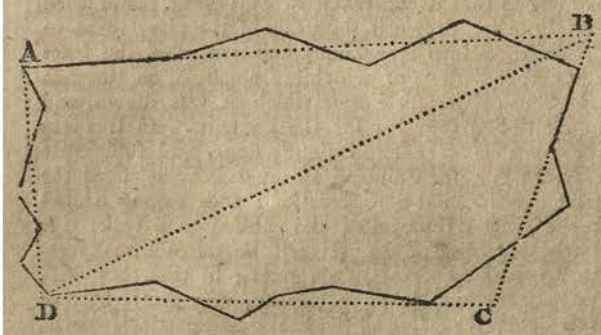
A ſpecimen of dividing into one triangle, or one trapezium, which will do for moſt ſingle fields, may be ſeen in the examples to the laſt article; and a ſpecimen of dividing a large tract into ſeveral ſuch trapeziums and triangles, in article 9, where a piece is ſo divided, and its dimenſions taken and ſet down; and again in articles 15, 16.

6th. But the chief ſecret in caſting up, conſiſts in finding the contents of pieces bounded by curved, or very irregular lines, or in reducing ſuch crooked ſides of fields or boundaries to ſtraight lines, that ſhall incloſe the ſame or equal area with thoſe crooked ſides, and ſo obtain the area of the curved figure by means of the right-lined one, which will commonly be a trapezium.

-zium. Now this reducing the crooked ſides to ſtraight ones, is very eaſily and accurately performed thus: Apply the ſtraight edge of a thin, clear piece of lanthorn-horn to the crooked line, which is to be reduced, in ſuch a manner, that the ſmall parts cut off from the crooked figure by it, may be equal to thoſe which are taken in: which equality of the parts included and excluded, you will preſently be able to judge of very nicely by a little practice; then with a pencil draw a line by the ſtraight edge of the horn. Do the ſame by the other ſides of the field or figure. So ſhall you have a ſtraight-ſided figure equal to the curved one; the contents of which, being computed as before directed, will be the content of the curved figure propoſed.

Or, inſtead of the ſtraight edge of the horn, a horſe-hair may be applied acroſs the crooked ſides in the ſame manner; and the eaſieſt way of uſing the hair, is to ſtring a ſmall ſlender bow with it, either of wire, or cane, or whale-bone, or ſuch like ſlender ſpringy matter; for, the bow keeping it always ſtretched, it can be eaſily and neatly applied with one hand, while the other is at liberty to make two marks by the ſide of it, to draw the ſtraight line by.

Ex. Thus, let it be required to find the contents of the ſame figure as in art. 12, to a ſcale of 4 chains to an inch.



Draw the four dotted ſtraight lines AB, BC, CD, DA, cutting off equal quantities on both ſides of them, which they do as near as the eye can judge: ſo is the crooked figure reduced to an equivalent right-lined one of four ſides ABCD. Then draw the diagonal BD, which, by applying a proper ſcale to it, meaſures 1256. Alſo the perpendicular, or neareſt diſtance, from A to this diagonal, meaſures 456; and the diſtance of C from it, is 428. Then

456	2) 11·10304
428	5·55152
884	4
1256	2·20608
5024	40
10048	8·24320
10048	
1110304	

And thus the content of the trapezium, and conſequently of the irregular figure, to which it is equal, is eaſily found to be 5 acres, 2 roods, 8 perches.

21. *To Tranſfer a Plan to another Paper, &c.*

After the rough plan is completed, and a fair one is wanted; this may be done, either on paper or vellum, by any of the following Methods.

Firſt Method.—Lay the rough plan upon the clean paper, and keep them always preſſed flat and cloſe together, by weights laid upon them. Then, with a the point of a fine pin or pricker, prick through all the corners of the plan to be copied. Take them aſunder, and connect the pricked points on the clean paper, with lines; and it is done. This method is only to be practiſed in plans of ſuch figures as are ſmall and tolerably regular, or bounded by right lines.

Second Method.—Rub the back of the rough plan over with black lead powder; and lay the ſaid black part upon the clean paper, upon which the plan is to be copied, and in the proper poſition. Then, with the blunt point of ſome hard ſubſtance, as braſs, or ſuch like, trace over the lines of the whole plan; preſſing the tracer ſo much as that the black lead under the lines may be tranſferred to the clean paper; after which take off the rough plan, and trace over the leaden marks with common ink, or with Indian ink, &c.—Or, inſtead of blacking the rough plan, you may keep conſtantly a blacked paper to lay between the plans.

Third Method.—Another way of copying plans, is by means of ſquares. This is performed by dividing both ends and ſides of the plan, which is to be copied, into any convenient number of equal parts, and connecting the correſponding points of diviſion with lines; which will divide the plan into a number of ſmall ſquares. Then divide the paper, upon which the plan is to be copied, into the ſame number of ſquares, each equal to the former when the plan is to be copied of the ſame ſize, but greater or leſs than the others, in the proportion in which the plan is to be increaſed or diminiſhed, when of a different ſize. Laſtly, copy into the clean ſquares, the parts contained in the correſponding ſquares of the old plan; and you will have the copy either of the ſame ſize, or greater or leſs in any proportion.

Fourth Method.—A fourth way is by the inſtrument called a pentagraph, which alſo copies the plan in any ſize required.

Fifth Method.—But the neateſt method of any is this. Procure a copying frame or glaſs, made in this manner; namely, a large ſquare of the beſt window glaſs, ſet in a broad frame of wood, which can be raiſed up to any angle, when the lower ſide of it reſts on a table. Set this frame up to any angle before you, facing a ſtrong light; fix the old plan and clean paper together with ſeveral pins quite around, to keep them together, the clean paper being laid uppermoſt, and upon

upon the face of the plan to be copied. Lay them, with the back of the old plan, upon the glaſs, namely, that part which you intend to begin at to copy firſt; and, by means of the light ſhining through the papers, you will very diſtinctly perceive every line of the plan through the clean paper. In this ſtate then trace all the lines on the paper with a pencil. Having drawn that part which covers the glaſs, ſlide another part over the glaſs, and copy it in the ſame manner. And then another part. And ſo on till the whole be copied.

Then, take them aſunder, and trace all the pencil-lines over with a fine pen and Indian ink, or with common ink.

And thus you may copy the fineſt plan, without injuring it in the leaſt.

When the lines, &c, are copied upon the clean paper or vellum, the next buſineſs is to write ſuch names, remarks, or explanations as may be judged neceſſary; laying down the ſcale for taking the lengths of any parts, a flower-de-luce to point out the direction, and the proper title ornamented with a compartment; and illuſtrating or colouring every part in ſuch manner as ſhall ſeem moſt natural, ſuch as ſhading rivers or brooks with crooked lines, drawing the repreſentations of trees, buſhes, hills, woods, hedges, houſes, gates, roads, &c, in their proper places; running a ſingle dotted line for a foot path, and a double one for a carriage road; and either repreſenting the baſes or the elevations of buildings, &c.

22. *Of the Diviſion of Lands.*

In the diviſion of commons, after the whole is ſurveyed and caſt up, and the proper quantities to be allowed for roads, &c, deducted, divide the net quantity remaining among the ſeveral proprietors, by the rule of Fellowſhip, in proportion to the real value of their eſtates, and you will thereby obtain their proportional quantities of the land. But as this diviſion ſuppoſes the land, which is to be divided, to be all of an equal goodneſs, you muſt obſerve that if the part in which any one's ſhare is to be marked off, be better or worſe than the general mean quality of the land, then you muſt diminiſh or augment the quantity of his ſhare in the ſame proportion.

Or, which comes to the ſame thing, divide the ground among the claimants in the direct ratio of the value of their claims, and the inverſe ratio of the quality of the ground allotted to each; that is, in proportion to the quotients ariſing from the diviſion of the value of each perſon's eſtate, by the number which expreſſes the quality of the ground in his ſhare.

But theſe regular methods cannot always be put in practice; ſo that, in the diviſion of commons, the uſual way is, to meaſure ſeparately all the land that is of different values, and add into two ſums the contents and the values; then, the value of every claimant's ſhare is found, by dividing the whole value among them in proportion to their eſtates; and, laſtly, by the 24th article, a quantity is laid out for each perſon, that ſhall be of the value of his ſhare before found.

23. *It is required to divide any given Quantity of Ground, or its Value, into any given Number of Parts, and in Proportion as any given Numbers.*

Divide the given piece, or its value, as in the rule of Fellowſhip, by dividing the whole content or value by the ſum of the numbers expreſſing the proportions of the ſeveral ſhares, and multiplying the quotient ſeverally by the ſaid proportional numbers for the reſpective ſhares required, when the land is all of the ſame quality. But if the ſhares be of different qualities, then divide the numbers expreſſing the proportions or values of the ſhares, by the numbers which expreſs the qualities of the land in each ſhare; and uſe the quotients inſtead of the former proportional numbers.

Ex. 1. If the total value of a common be 2500 pounds, it is required to determine the values of the ſhares of the three claimants A, B, C, whoſe eſtates are of theſe values, 10000, and 15000, and 25000 pounds.

The eſtates being in proportion as the numbers 2, 3, 5, whoſe ſum is 10, we ſhall have $2500 \div 10 = 250$; which being ſeverally multiplied by 2, 3, 5, the products 500, 750, 1250, are the values of the ſhares required.

Ex. 2. It is required to divide 300 acres of land among A, B, C, D, E, F, G, and H, whoſe claims upon it are reſpectively in proportion as the numbers 1, 2, 3, 5, 8, 10, 15, 20.

The ſum of theſe proportional numbers is 64, by which dividing 300, the quotient is 4 ac. 2 r. 30 p. which being multiplied by each of the numbers, 1, 2, 3, 5, &c, we obtain for the ſeveral ſhares as below:

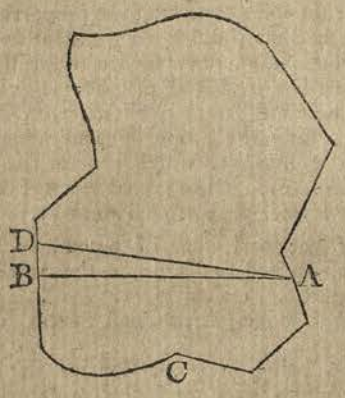
	Ac.	R.	P.
A =	4	2	30
B =	9	1	20
C =	14	0	10
D =	23	1	30
E =	37	2	00
F =	46	3	20
G =	70	1	10
H =	93	3	00
Sum =	300	0	00

Ex. 3. It is required to divide 780 acres among A, B, and C, whoſe eſtates are 1000, 3000, and 4000 pounds a year; the ground in their ſhares being worth 5, 8, and 10 ſhillings the acre reſpectively.

Here their claims are as 1, 3, 4; and the qualities of their land are as 5, 8, 10; therefore their quantities muſt be as $\frac{1}{5}$, $\frac{3}{8}$, $\frac{2}{5}$, or, by reduction, as 8, 15, 16. Now the ſum of theſe numbers is 39; by which dividing the 780 acres, the quotient is 20; which being multiplied ſeverally by the three numbers 8, 15, 16, the three products are 160, 300, 320, for the ſhares of A, B, C, reſpectively.

24. *To Cut off from a Plan a Given Number of Acres, &c, by a Line drawn from any Point in the Side of it.*

Let A be the given point in the annexed plan, from which a line is to be drawn cutting off ſuppoſe 5 ac. 2 r. 14 p.



Draw AB cutting off the part ABC as near as can be judged equal to the quantity propoſed; and let the true quantity of ABC, when calculated, be only 4 ac. 3 r. 20 p. which is leſs than 5 ac. 2 r. 14 p. the true quantity, by 0 ac. 2 r. 34 p. or 71250 ſquare links. Then meaſure AB, which ſuppoſe = 1234 links, and divide 71250, by 617 the half of it, and the quotient 115 links will be the altitude of the triangle to be added, and whoſe baſe is AB. Therefore if upon the centre B, with the radius 115, an arc be deſcribed; and a line be drawn parallel to AB, touching the arc, and cutting BD in D; and if AD be drawn, it will be the line cutting off the required quantity ADCA.

Note. If the firſt piece had been too much, then D muſt have been ſet below B.

In this manner the ſeveral ſhares of commons, to be divided, may be laid down upon the plan, and transferred from thence to the ground itſelf.

Alſo for the greater eaſe and perfection in this buſineſs, the following problems may be added.

25. *From an Angle in a Given Triangle, to draw Lines to the oppoſite Side, dividing the Triangle into any Number of Parts, which ſhall be in any aſſigned Proportion to each other.*

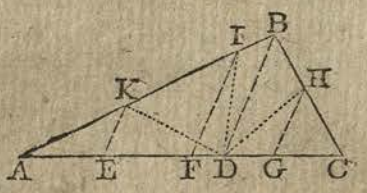
Divide the baſe into the ſame number of parts, and in the ſame proportion, by article 22; then from the ſeveral points of diviſion draw lines to the propoſed angle, and they will divide the triangle as required.—For, the ſeveral parts are triangles of the ſame altitude, and which therefore are as their baſes, which baſes are taken in the aſſigned proportion.

Ex. Let the triangle ABC, of 20 acres, be divided into five parts, which ſhall be in proportion to the numbers 1, 2, 3, 5, 9; the lines of diviſion to be drawn from A to CB, whoſe length is 1600 links.

Here 1 + 2 + 3 + 5 + 9 = 20, and 1600 ÷ 20 = 80, which being multiplied by each of the proportional numbers, we have 80, 160, 240, 400, and 720; therefore make Ca = 80, *ab* = 160, *bc* = 240, *cd* = 400, and *d*B = 720; then by drawing the lines A*a*, A*b*, A*c*, A*d*, the triangle is divided as required.

26. *From any Point in one ſide of a Given Triangle, to draw Lines to the other two Sides, dividing the Triangle into any Number of Parts which ſhall be in any aſſigned Ratio.*

From the given point D, draw DB to the angle oppoſite the ſide AC in which the point is taken; then divide the ſame ſide AC into as many parts AE, EF, FG, GC, and in the ſame proportion with the required parts of the triangle, like as was done in the laſt problem; and from the points of diviſion draw lines EK, FI, GH, parallel to the line BD, and meeting the other ſides of the triangle in K, I, H; laſtly, draw KD, ID, HD, ſo ſhall ADK, KDI, IDHB, HDC be the parts required.—The example to this will be done exactly as the laſt.



For, the triangles ADK, KDI, IDB, being of the ſame height, are as their baſes AK, KI, IB; which, by means of the parallels EK, FI, DB, are as AE, EF, FD; in like manner, the triangles CDH, HDB, are to each other as CG, GD: but the two triangles IDB, BDH, having the ſame baſe BD, are to each other as the diſtances of I and H from BD, or as FD to DG; conſequently the parts DAK, DKI, DIBH, DHC, are to each other as AE, EF, FG, GC.

Surveying of Harbours.

The method of Surveying harbours, and of forming maps of them, as alſo of the adjacent coaſts, ſands, &c, depends on the ſame principles, and is chiefly conducted like that of common Surveying. The operation is indeed more complicated and laborious; as it is neceſſary to erect a number of ſignals, and to mark a variety of objects along the coaſt, with different bearings from one another, and the ſeveral parts of the harbour; and likewiſe to meaſure a great number of angles

at

at different ſtations, whether on the land or the water. For this purpoſe the beſt inſtrument is Hadley's quadrant, as all theſe operations may be performed by it, not only with greater eaſe, but alſo with much more preciſion, than can be hoped for by any other means; as it is the only inſtrument in uſe, in which neither the exactneſs of the obſervations, nor the eaſe with which they may be made, are ſenſibly affected by the motion of a veſſel: and hence a ſingle obſerver, in a boat, may generally determine the ſituation of any place at pleaſure, with a ſufficient degree of exactneſs, by taking the angles ſubtended by ſeveral pairs of objects properly choſen upon ſhore round about him; but it will be ſtill better to have two obſervers, or the ſame obſerver at different ſtations, to take the like angles to the ſeveral objects, and alſo to the ſtations. By this means, two angles and one ſide are given, in every triangle, from whence the ſituation of every part of them will be known. By ſuch obſervations, when carefully made with good inſtruments, the ſituation of places may be eaſily determined to 20 or 30 feet, or leſs, upon every 3 or 4 miles. See Philoſ. Tranſ. vol. 55, pa. 70; alſo Mackenzie's Maritime Surveying.

SURVEYING *Croſs*. See CROSS.

SURVEYING *Quadrant*. See QUADRANT.

SURVEYING *Scale*, the ſame with Reducing Scale.

SURVEYING *Wheel*. See PERAMBULATOR.

SURVIVORSHIP, the doctrine of reverſionary payments that depend upon certain contingencies, or contingent circumſtances.

Payments which are not to be made till ſome future period, are termed *reverſions*, to diſtinguiſh them from payments that are to be made immediately.

Reverſions are either *certain* or *contingent*. Of the former ſort, are all ſums or annuities, payable certainly or abſolutely at the expiration of any terms, or on the extinction of any lives. And of the latter ſort, are all ſuch reverſions as depend on any contingency; and particularly the Survivorſhip of any lives beyond or after other lives. An account of the former may be found under the articles Aſſurance, Annuities, and Life-annuities. But the latter form the moſt intricate and difficult part of the doctrine of reverſions and life-annuities; and the books in which this ſubject is treated moſt at large, and at the ſame time with the moſt preciſion, are Mr. Simpſon's Select Exerciſes; Dr. Price's Reverſionary Payments; and Mr. Morgan's Annuities and Aſſurances on Lives and Survivorſhips. The whole likewiſe of the 3d volume of Dodſon's Mathematical Repoſitory is on this ſubject; but his inveſtigations are founded on De Moivre's falſe hypotheſis, viz of an equal decrement of life through all its ſtages, and which is explained under Life-annuities: but as this hypotheſis does not agree near enough to fact and experience, the rules deduced from it cannot be ſufficiently correct. For this reaſon, Dr. Price, and alſo the ingenious Mr. Maſeres, curſitor baron of the exchequer (in two volumes lately publiſhed, entitled the Principles of the Doctrine of Life Annuities), have diſcarded the valuations of lives grounded upon it; and the former in particular, in order to obviate all occaſion for uſing them, has ſubſtituted in their ſtead, a great variety of new tables of the probabilities and values of lives, at every age and in every ſituation; calculated, not upon any hypotheſis, but in ſtrict conformity to the beſt obſervations. Theſe tables, added to other new tables of the ſame kind, in Mr. Baron Maſeres's work juſt mentioned, form a complete ſet of tables, by which all queſtions relating to annuities on lives, and Survivorſhips, may be anſwered with as much correctneſs as the nature of the ſubject allows.

Rules for calculating correctly, in moſt caſes, the values of reverſions depending on Survivorſhips, may be found in the three treatiſes juſt mentioned. Mr. Morgan, in particular, has gone a good way towards exhauſting this ſubject, as far as any queſtions can include in them any Survivorſhips between two or three lives, either for terms, or the whole duration of the lives.

There is, however, one circumſtance neceſſary to be attended to in calculating ſuch values, to which no regard could be paid till lately. This circumſtance is the ſhorter duration of the lives of males than of females; and the conſequent advantage in favour of females in all caſes of Survivorſhip. In the 4th edition of Dr. Price's Treatiſe on Reverſionary Payments, this fact is not only aſcertained, but ſeparate tables of the duration and values of lives are given for males and females.

SUSPENSION, in Mechanics, as in a balance, are thoſe points in the axis or beam where the weights are applied, or from which they are ſuſpended.

SUTTON's *Quadrant*. See QUADRANT.

SWAN, in Aſtronomy. See CYGNUS.

SWALLOW's-TAIL, in Fortification, is a ſingle Tenaille, which is narrower towards the place than towards the country.

SWING-*Wheel*, in a royal pendulum, is that wheel which drives the pendulum. In a watch, or balance clock, it is called the *crown-wheel*.

SYDEREAL *Day*, or *Year*. See SIDEREAL.

SYMMETRY, the relation of parity, both in reſpect of length, breadth, and height, of the parts neceſſary to compoſe a beautiful whole.

Symmetry ariſes from that proportion which the Greeks call *analogy*, which is the relation of conformity of all the parts of a building, and of the whole, to ſome certain meaſure; upon which depends the nature of Symmetry.

According to Vitruvius, Symmetry conſiſts in the union and conformity of the ſeveral members of a work to their whole, and of the beauty of each of the ſeparate parts to that of the intire work; regard being had to ſome certain meaſure: ſo the body, for inſtance, is framed with Symmetry, by the due relation which the arm, elbow, hand, fingers, &c, have to each other, and to their whole.

SYMPHONY, is a conſonance or concert of ſeveral ſounds agreeable to the ear; whether they be vocal or inſtrumental, or both; called alſo *harmony*.

The Symphony of the Ancients went no farther than to two or more voices or inſtruments ſet to uniſon; for they had no ſuch thing as muſic in parts; as is very well proved by Perrault: at leaſt, if ever they knew ſuch a thing, it muſt have been early loſt.

It is to Guido Aretine, about the year 1022, that moſt writers agree in aſcribing the invention of compoſition: it was he, they ſay, who firſt joined in one harmony ſeveral diſtinct melodies; and brought it even to the-

the length of 4 parts, viz. baſs, tenor, counter-tenor, and treble.

The term Symphony is now applied to inſtrumental muſic, both that of pieces deſigned only for inſtruments, as ſonatas and concertos, and that in which the inſtruments are accompanied with the voice, as in operas, &c.

A piece is ſaid to be in grand Symphony, when, beſides the baſs and treble, it has alſo two other inſtrumental parts, viz, tenor and 5th of the violin.

SYNCHRONISM, the being or happening of ſeveral things together, at or in the ſame time.

The happening or performing of ſeveral things in equal times, as the vibrations of pendulums, &c, is more properly called *iſochroniſm:* though ſome authors confound the two.

SYNCOPATION, in Muſic, denotes a ſtriking or breaking of the time; by which the diſtinctneſs of the ſeveral times or parts of the meaſure is interrupted.

SYNCOPATION, or SYNCOPE, is more particularly uſed for the connecting the laſt note of one meaſure or bar with the firſt of the following meaſure; ſo as to make only one note of both.

SYNCOPATION is alſo uſed when a note of one part ends on the middle of a note of the other part. This is otherwiſe called *binding*.

SYNODICAL *Month*, is the period or interval of time in which the moon paſſes from one conjunction with the ſun to another. This period is alſo called a *Lunation*, ſince in this period the moon puts on all her phaſes, or appearances, as to increaſe and decreaſe. —Kepler found the quantity of the mean Synodical month to be 29 days, 12 hrs, 44 min. 3 ſec. 11 thirds.

SYNTHESIS denotes a method of compoſition, as oppoſed to analyſis.

In the Syntheſis, or ſynthetic method, we purſue the truth by reaſons drawn from principles before eſtabliſhed, or aſſumed, and propoſitions formerly proved; thus proceeding by a regular chain till we come to the concluſion; and hence called alſo the *direct* method, and *compoſition*, in oppoſition to analyſis or reſolution.

Such is the method in Euclid's Elements, and moſt demonſtrations of the ancient mathematicians, which proceed from definitions and axioms, to prove theorems &c, and from thoſe theorems proved, to demonſtrate others. See ANALYSIS.

SYNTHETICAL *Method*, the method by Syntheſis, or compoſition, or the direct method. See SYNTHESIS.

SYPHON. See SIPHON.

SYRINGE, in Hydraulics, a ſmall ſimple machine, ſerving firſt to imbibe or ſuck in a quantity of water, or other fluid, and then to ſquirt or expel the ſame with violence in a ſmall jet.

The Syringe is juſt a ſmall ſingle ſucking pump, without a valve, the water aſcending in it on the ſame principle. It conſiſts, like the pump, of a ſmall cylinder, with an embolus or ſucker, moving up and down in it by means of a handle, and fitting it very cloſe within. At the lower end is either a ſmall hole, or a ſmaller tube fixed to it than the body of the inſtrument, through which the fluid or the water is drawn up, and ſquirted out again.

Thus, the embolus being firſt puſhed quite down, introduce the lower end of the pipe into the fluid, then draw up, by the handle, the ſucker, and the fluid will immediately follow, ſo as to fill the whole cave of the Syringe, and will remain there, even when the pipe is taken out of the fluid; but by thruſting forward the embolus, it will drive the water before it; and, being partly impeded by the ſmallneſs of the hole, or pipe, it will hence be expelled in a ſmart jet or ſquirt, and to the greater diſtance, as the ſucker is puſhed down with the greater force, or the greater velocity.

This aſcent of the water the Antients, who ſuppoſed a plenum, attributed to Nature's abhorrence of a vacuum; but the Moderns, more [illegible] as more intelligibly, attribute it to the preſſure of the atmoſphere on the exterior ſurface of the fluid. For, by drawing up the embolus, the cavity of the cylinder would become a vacuum, or the air left there extremely rarefied; ſo that being no longer a counterbalance to the air incumbent on the ſurface of the fluid, this prevails, and forces the water through the little tube, or hole, up into the body of the Syringe.

SYSTEM, in a general Senſe, denotes an aſſemblage or chain of principles and concluſions: or the whole of any doctrine, the ſeveral parts of which are bound together, and follow or depend on each other. As a Syſtem of aſtronomy, a Syſtem of planets, a Syſtem of philoſophy, a Syſtem of motion, &c.

SYSTEM, in Aſtronomy, denotes an hypotheſis or a ſuppoſition of a certain order and arrangement of the ſeveral parts of the univerſe; by which aſtronomers explain all the phenomena or appearances of the heavenly bodies, their motions, changes, &c.

This is more peculiarly called the *Syſtem of the world*, and ſometimes the *Solar Syſtem*.

Syſtem and hypotheſis have much the ſame ſignification; unleſs perhaps hypotheſis be a more particular Syſtem, and Syſtem a more general hypotheſis.

Some late authors indeed make another diſtinction: an hypotheſis, ſay they, is a mere ſuppoſition or fiction, founded rather on imagination than reaſon; while a Syſtem is built on the firmeſt ground, and raiſed by the ſevereſt rules; it is founded on aſtronomical obſervations, and phyſical cauſes, and confirmed by geometrical demonſtrations.

The moſt celebrated Syſtems of the world, are the Ptolomaic, the Copernican or Pythagorean, and the Tychonic: the economy of each of which is as follows.

Ptolomaic SYSTEM is ſo called from the celebrated aſtronomer Ptolomy. In this Syſtem, the earth is placed at reſt, in the centre of the univerſe, while the heavens are conſidered as revolving about it, from eaſt to weſt, and carrying along with them all the heavenly bodies, the ſtars and planets, in the ſpace of 24 hours.

The principal aſſertors of this Syſtem, are Ariſtotle, Hipparchus, Ptolomy, and many of the old philoſophers, followed by the whole world, for a great number of ages, and long adhered to in many univerſities, and other places. But the late improvements in philoſophy and reaſoning, have utterly exploded this erroneous Syſtem from the place it ſo long held in the minds of men.

Copernican SYSTEM, is that Syſtem of the world which

which places the Sun at reſt, in the centre of the world, and the earth and planets all revolving round him, in their ſeveral orbits. See this more particularly explained under the article COPERNICAN *Syſtem*.

Solar or *Planetary* SYSTEM, is uſually confined to narrower bounds; the ſtars, by their immenſe diſtance, and the little relation they ſeem to bear to us, being accounted no part of it. It is highly probable that each fixed ſtar is itſelf a Sun, and the centre of a particular ſyſtem, ſurrounded with a company of planets &c, which, in different periods, and at different diſtances, perform their courſes round their reſpective ſun, which enlightens, warms, and cheriſhes them. Hence we have a very magnificent idea of the world, and the immenſity of it. Hence alſo ariſes a kind of Syſtem of Syſtems.

The Planetary Syſtem, deſcribed under the article COPERNICAN, is the moſt ancient in the world. It was firſt of all, as far as we know, introduced into Greece and Italy by Pythagoras; from whom it was called the Pythagorean Syſtem. It was followed by Philolaus, Plato, Archimedes, &c: but it was loſt under the reign of the Peripatetic philoſophy; till happily retrieved about the year 1500 by Nic. Copernicus.

Tychonic SYSTEM, was taught by Tycho, a Dane; who was born An. Dom. 1546. It ſuppoſes that the earth is fixed in the centre of the univerſe or firmament of ſtars, and that all the ſtars and planets revolve round the earth in 24 hours; but it differs from the Ptolomaic Syſtem, as it not only allows a menſtrual motion to the moon round the earth, and that of the ſatellites about Jupiter and Saturn, in their proper periods, but it makes the ſun to be the centre of the orbits of the primary planets Mercury, Venus, Mars, Jupiter, &c, in which they are carried round the ſun in their reſpective years, as the ſun revolves round the earth in a ſolar year; and all theſe planets, together with the ſun, are ſuppoſed to revolve round the earth in 24 hours. This hypotheſis was ſo embarraſſed and perplexed, that very few perſons embraced it. It was afterwards altered by Longomontanus and others, who allowed the diurnal motion of the earth on its own axis, but denied its annual motion round the ſun. This hypotheſis, partly true and partly falſe, is called the *Semi-Tychonic Syſtem*. See the figure and economy of theſe Syſtems, in plates 30, 31, 32, 33.

SYSTEM, in Muſic, denotes a compound interval; or an interval compoſed, or conceived to be compoſed of ſeveral leſs intervals. Such is the octave, &c.

SYSTYLE, in Architecture, the manner of placing columns, where the ſpace between the two fuſts conſiſts of 2 diameters, or 4 modules.

SYZYGY, a term equally uſed for the conjunction and oppoſition of a planet with the ſun.

On the phenomena and circumſtances of the Syzygies, a great part of the lunar theory depends. See MOON. For,

1. It is ſhewn in the phyſical aſtronomy, that the force which diminiſhes the gravity of the moon in the Syzygies, is double that which increaſes it in the quadratures; ſo that, in the Syzygies, the gravity of the moon is diminiſhed by a part which is to the whole gravity, as 1 to 89·36; for in the quadratures, the addition of gravity is to the whole gravity, as 1 to 178·73.

2. In the Syzygies, the diſturbing force is directly as the diſtance of the moon from the earth, and inverſely as the cube of the diſtance of the earth from the ſun. And at the Syzygies, the gravity of the moon towards the earth receding from its centre, is more diminiſhed than according to the inverſe ratio of the ſquare of the diſtance from that centre.—Hence, in the moon's motion from the Syzygies to the quadratures, the gravity of the moon towards the earth is continually increaſed, and the moon is continually retarded in her motion; but in the moon's motion from the quadratures to the Syzygies, her gravity is continually diminiſhed, and the motion in her orbit is accelerated.

3. Farther, in the Syzygies, the moon's orbit, or circuit round the earth, is more convex than in the quadratures; for which reaſon ſhe is leſs diſtant from the earth at the former than the latter.—Alſo, when the moon is in the Syzygies, her apſes go backward, or are retrograde.—Moreover, when the moon is in the Syzygies, the nodes move in antecedentia faſteſt; then ſlower and ſlower, till they become at reſt when the moon is in the quadratures.—Laſtly, when the nodes are come to the Syzygies, the inclination of the plane of the orbit is the leaſt of all.

However, theſe ſeveral irregularities are not equal in each Syzygy, being all ſomewhat greater in the conjunction than in the oppoſition.

T.

TAB

TABLE, in Architecture, a ſmooth, ſimple member or ornament, of various forms, but moſt commonly in that of a parallelogram.

TABLE, in Perſpective, is ſometimes uſed for the perſpective plane, or the tranſparent plane upon which the objects are formed in their reſpective appearance.

TABLE *of Pythagoras*, is the ſame as the MULTIPLICATION

CATION Table; which ſee; as alſo PYTHAGORAS's Table.

TABLES *of Houſes*, among aſtrologers, are certain Tables, ready drawn up, for the aſſiſtance of practitioners in that art, for the erecting or drawing of figures or ſchemes. See HOUSE.

TABLES, in Mathematics, are ſyſtems or ſeries of numbers, calculated to be ready at hand for expediting any ſort of calculations in the various branches of mathematics.

Aſtronomical TABLES, are computations of the motions, places, and other phenomena of the planets, both primary and ſecondary.

The oldeſt aſtronomical Tables, now extant, are thoſe of Ptolomy, found in his Almageſt. Theſe however are not now of much uſe, as they no longer agree with the motions of the heavens.

In 1252, Alphonſo XI, king of Caſtile, undertook the correcting of them, chiefly by the aſſiſtance of Iſaac Hazen, a learned Jew; and ſpent 400,000 crowns on the buſineſs. Thus aroſe the *Alphonſine Tables*, to which that prince himſelf prefixed a preface. But the deficiency of theſe alſo was ſoon perceived by Purbach and Muller, or Regiomontanus; upon which the latter, and after him Walther Warner, applied themſelves to celeſtial obſervations, for farther improving them; but death, or various difficulties, prevented the effect of theſe good deſigns.

Copernicus, in his books of the celeſtial revolutions, gives other Tables, calculated by himſelf, partly from his own obſervations, and partly from the Alphonſine Tables.

From Copernicus's obſervations and theorems, Eraſmus Reinhold afterwards compiled the *Prutenic Tables*, which have been printed ſeveral times, and in ſeveral places.

Tycho Brahe, even in his youth, became ſenſible of the deficiency of the Prutenic Tables: which determined him to apply himſelf with ſo much vigour to celeſtial obſervations. From theſe he adjuſted the motions of the ſun and moon; and Longomontanus, from the ſame obſervations, made out Tables of the motions of the planets, which he added to the Theories of the ſame, publiſhed in his Aſtronomia Danica; thoſe being called the *Daniſh Tables*. And Kepler alſo, from the ſame obſervations, publiſhed in 1627 his *Rudolphine Tables*, which are much eſteemed.

Theſe were afterwards, viz in 1650, changed into another form, by Maria Cunitia, whoſe Aſtronomical Tables, comprehending the effect of Kepler's phyſical hypotheſis, are very eaſy, ſatisfying all the phenomena without any mention of logarithms, and with little or no trouble of calculation. So that the Rudolphine calculus is here greatly improved.

Mercator made a like attempt in his Aſtronomical Inſtitution, publiſhed in 1676. And the like did J. Bap. Morini, whoſe abridgment of the Rudolphine Tables was prefixed to a Latin verſion of Street's Aſtronomia Carolina, publiſhed in 1705.

Lanſbergius indeed endeavoured to diſcredit the Rudolphine Tables, and framed *Perpetual Tables*, as he calls them, of the heavenly motions. But his attempt was never much regarded by the aſtronomers; and our countryman Horrox warmly attacked him, in his defence of the Keplerian aſtronomy.

Since the Rudolphine Tables, many others have been framed, and publiſhed: as the *Philolaic Tables* of Bulliald; the *Britannic Tables* of Vincent Wing, calculated on Bulliald's hypotheſis; the *Britannic Tables* of Newton; the French ones of the Count Pagan, the *Caroline Tables* of Street, all calculated on Ward's hypotheſis; and the *Novæ Mediceæ Tables* of Riccioli. Among theſe, however, the Philolaic and Caroline Tables are eſteemed the beſt; inſomuch that Mr. Whiſton, by the advice of Mr. Flamſteed, thought fit to adapt the Caroline Tables to his aſtronomical lectures.

The *Ludovician Tables*, publiſhed [illegible] De la Hire, were conſtructed wholly from his own obſervations, and without the aſſiſtance of any hypotheſis; which, before the invention of the micrometer teleſcope and the pendulum clock, was held impoſſible.

Dr. Halley alſo long laboured to perfect another ſet of Tables; which were printed in 1719, but not publiſhed till 1752.

M. Monnier, in 1746, publiſhed, in his Inſtitutions Aſtronomiques, Tables of the motions of the ſun and moon, with the ſatellites, as alſo of refractions, and the places of the fixed ſtars. La Hire alſo publiſhed Tables of the planets, and La Caille Tables of the ſun: Gael Morris publiſhed Tables of the ſun and moon, and Mayer conſtructed Tables of the moon, which were publiſhed by the Board of Longitude. Tables of the ſame have alſo been computed by Charles Maſon, from the principles of the Newtonian philoſophy, which are found to be very accurate, and are employed in computing the Nautical Ephemeris. Many other ſets of aſtronomical Tables have alſo been publiſhed by various perſons and academies; and divers ſets of them may be found in the modern books of aſtronomy, navigation, &c, of which thoſe are eſteemed the beſt and moſt complete, that are printed in Lalande's Aſtronomy. For an account of ſeveral, and eſpecially of thoſe publiſhed annually under the direction of the Commiſſioners of Longitude, ſee ALMANAC, EPHEMERIS, and LONGITUDE.

For TABLES *of the Stars*, ſee CATALOGUE.

TABLES of *Sines*, *Tangents*, and *Secants*, uſed in trigonometry, &c, are uſually called CANONS. See SINE.

TABLES *of Logarithms*, *Rhumbs*, *&c*, uſed in geometry, navigation, &c, ſee LOGARITHM, and RHUMB.

TABLES, *Loxodromic*, and *of Difference of Latitude and Departure*, are Tables uſed in computing the way and reckoning of a ſhip on a voyage, and are publiſhed in moſt books of navigation.

TACQUET (ANDREW), a Jeſuit of Antwerp, who died in 1660. He was a moſt laborious and voluminous writer in mathematics. His works were collected, and printed at Antwerp in one large volume in folio, 1669.

TACTION, in Geometry, the ſame as tangency, or touching. See TANGENT.

TALUS, or TALUD, in Architecture, the inclination or ſlope of a work; as of the outſide of a wall, when its thickneſs is diminiſhed by degrees, as it riſes in height, to make it the firmer.

TALUS,

TALUS, in Fortification, means alſo the ſlope of a work, whether of earth or maſonry.

The *Exterior Talus* of a work, is its ſlope on the ſide outwards or towards the country; which is always made as little as poſſible, to prevent the enemy's eſcalade, unleſs the earth be bad, for then it is neceſſary to allow a conſiderable Talus for its parapet, and ſometimes to ſupport the earth with a ſlight wall, called a revetement.

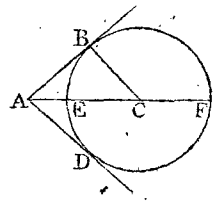
The *Interior Talus* of a work, is its ſlope on the inſide, towards the place. This is larger than the former, and it has, at the angles of the gorge, and ſometimes in the middle of the curtains, ramps, or ſloping roads for mounting upon the terreplain of the rampart.

Superior TALUS *of the Parapet*, is a ſlope on the top of the parapet, that allows of the ſoldiers defending the covert-way with ſmall-ſhot, which they could not do if it were level.

TAMBOUR, in Architecture, a term applied to the Corinthian and Compoſite capitals, as bearing ſome reſemblance to a tambour or drum.

TAMUZ, in Chronology, the 4th month of the Jewiſh eccleſiaſtical year, anſwering to part of our June and July. The 17th day of this month is obſerved by the Jews as a faſt, in memory of the deſtruction of Jeruſalem by Nebuchadnezzar, in the 11th year of Zedekiah, and the 588th before Chriſt.

TANGENT, in Geometry, is a line that touches a curve, &c, that is, which meets it in a point without cutting it there, though it be produced both ways; as the Tangent AB of the circle BD. The point B, where the Tangent touches the curve, is called the *point of contact*.



The direction of a curve at the point of contact, is the ſame as the direction of the Tangent.

It is demonſtrated in Geometry;

1. That a Tangent to a circle, as AB, is perpendicular to the radius BC drawn to the point of contact.

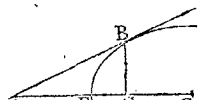
2. The Tangent AB is a mean proportional between AF and AE, the whole ſecant and the external part of it; and the ſame for any other ſecant drawn from the ſame point A.

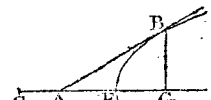
3. The two Tangents AB and AD, drawn from the ſame point A, are always equal to one another. And therefore alſo, if a number of Tangents be drawn to different points of the curve quite around, and an equal length BA be ſet off upon each of them from the points of contact, the locus of all the points A will be a circle having the ſame centre C.

4. The angle of contact ABE, formed at the point of contact, between the Tangent AB and the arc BE, is leſs than any rectilineal angle.

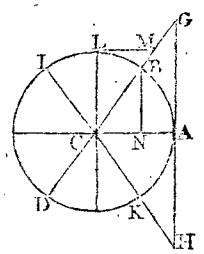
5. The Tangent of an arc is the right line that limits the poſition of all the ſecants that can paſs through the point of contact; though ſtrictly ſpeaking it is not one of the ſecants, but only the limit of them.

6. As a right line is the Tangent of a circle, when it touches the circle ſo cloſely, that no right line can be drawn through the point of contact between it and the arc, or within the angle of contact that is formed by them; ſo, in general, when any right line touches an arc of any curve, in ſuch a manner, that no right line can be drawn through the point of contact, between the right line and the arc, or within the angle of contact that is formed by them, then is that line the Tangent of the curve at the ſaid point; as AB.





7. In all the conic ſections; if C be the centre of the figure, and BG an ordinate drawn from the point of contact and perpendicular to the axis; then is CG : CE :: CE : CA, or the ſemiaxis CE is a mean proportional between CG and CA.



TANGENT, in Trigonometry. A TANGENT *of an arc*, is a right line drawn touching one extremity of the arc, and limited by a ſecant or line drawn through the centre and the other extremity of the arc.

So, AG is the Tangent of the arc AB, or of the arc ABD; and AH is the Tangent of the arc AI, or of the arc AIDK.

The ſame are alſo the Tangents of the angles that are ſubtended or meaſured by the arcs.

Hence, 1. The Tangents in the 1ſt and 3d quadrants are poſitive, in the 2d and 4th negative, or drawn the contrary way. But of 0 or 180° the ſemicircle, the Tangent is 0 or nothing; while thoſe of 90° or a quadrant, and 270° or 3 quadrants, are both infinite; the former infinitely poſitive, and the latter infinitely negative. That is,

Between 0 and 90°, or bet. 180° and 270°, the Tangents are poſitive.
Bet. 90° and 180°, or bet. 270° and 360°, the Tangents are negative.

2. The Tangent of an arc and the Tangent of its ſupplement, are equal, but of contrary affections, the one being poſitive, and the other negative;

as of a and $180° - a$, where a is any arc.

Alſo $180° + a$ and a have the ſame Tangent, and of the ſame affection.

Or $180° + a$ and $180° - a$ have the ſame Tangent, but of different affections.

3. The Tangent of an arc is a 4th proportional to the coſine the ſine and the radius; that is, CN : NB :: CA : AG. Hence, a canon of ſines being made or given, the canon of Tangents is eaſily conſtructed from them.

Co-TANGENT, contracted from complement-tangent, is the Tangent of the complement of the arc or angle, or of what it wants of a quadrant or 90°. So LM is the Cotangent of the arc AB, being the Tangent of its complement BL.

The Tangent is reciprocally as the cotangent; or the

Tangent and cotangent are reciprocally proportional with the radius. That is Tang. is as $\frac{1}{\text{cotan.}}$, or Tang. : radius :: radius : cotan. And the rectangle of the Tangent and cotangent is equal to the ſquare of the radius; that is, Tan. × cot. = radius^2.

Artificial TANGENTS, or *logarithmic* TANGENTS, are the logarithms of the tangents of arcs; ſo called, in contradiſtinction from the natural Tangents, or the Tangents expreſſed by the natural numbers.

Line of TANGENTS, is a line uſually placed on the ſector, and Gunter's ſcale; the deſcription and uſes of which ſee under the article SECTOR.

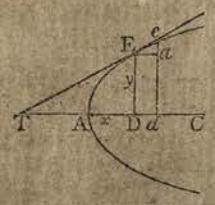
Sub-TANGENT, a line lying beneath the Tangent, being the part of the axis intercepted by the Tangent and the ordinate to the point of contact; as the line AG in the 2d and 3d figures above.

Method of TANGENTS, is a method of determining the quantity of the Tangent and ſubtangent of any algebraic curve; the equation of the curve being given.

This method is one of the great reſults of the doctrine of fluxions. It is of great uſe in Geometry; becauſe that in determining the Tangents of curves, we determine at the ſame time the quadrature of the curvilinear ſpaces: on which account it deſerves to be here particularly treated on.

To Draw the Tangent, or to find the Subtangent, of a curve.

If AE be any curve, and E any point in it, to which it is required to draw a Tangent TE. Draw the ordinate DE: then if we can determine the ſubtangent TD, by joining the points T and E, the line TE will be the Tangent ſought.



Let *dae* be another ordinate indefinitely near to DE, meeting the curve, or Tangent produced, in *e*; and let E*a* be parallel to the axis AD. Then is the elementary triangle E*ae* ſimilar to the triangle TDE;

and therefore - $ea : aE :: ED : DS$;
but - - - - - - - $ea : aE ::$ flux. ED : flux. AD;
therefore - - - - flux. ED : flux. AD :: DE : DT;

that is - - - - - $\dot{y} : \dot{x} :: y : \frac{y\dot{x}}{\dot{y}} = DT$,

which is therefore the value of the ſubtangent ſought; where x is the abſciſs AD, and y the ordinate DE.

Hence we have this general rule: By means of the given equation of the curve, find the value either of $\dot{x}$ or $\dot{y}$, or of $\frac{\dot{x}}{\dot{y}}$, which value ſubſtitute for it in the expreſſion $DT = \frac{y\dot{x}}{\dot{y}}$, and, when reduced to its ſimpleſt terms, it will be the value of the ſubtangent ſought. This we may illuſtrate in the following examples.

Ex. 1. The equation defining a circle is $2ax - xx = y^2$, where a is the radius; and the fluxion of this is $2a\dot{x} - 2x\dot{x} = 2y\dot{y}$; hence $\frac{\dot{x}}{\dot{y}} = \frac{y}{a-x}$; this multiplied by y, gives $\frac{y\dot{x}}{\dot{y}} = \frac{y^2}{a-x} = \frac{DE^2}{CD} =$ the ſubtangent TD, or CD : DE :: DE : TD, which is a property of the circle we alſo know from common geometry.

Ex. 2. The equation defining the common parabola is $ax = y^2$, a being the parameter, and x and y the abſciſs and ordinate in all caſes. The fluxion of this is $a\dot{x} = 2y\dot{y}$; hence $\frac{\dot{x}}{\dot{y}} = \frac{2y}{a}$; conſeq. $\frac{y\dot{x}}{\dot{y}} = \frac{2y^2}{a} = \frac{2ax}{a} = 2x =$ TD; that is, the ſubtangent TD is double the abſciſs AD, or TA is = AD, which is a well-known property of the parabola.

Ex. 3. The equation defining an ellipſis is $c^2.2ax - x^2 = a^2y^2$, where a and c are the ſemiaxes. The fluxion of it is $c^2.2a\dot{x} - 2x\dot{x} = 2a^2y\dot{y}$; hence

$$\frac{y\dot{x}}{\dot{y}} = \frac{a^2y^2}{c^2(a-x)} = \frac{c^2(2ax-x^2)}{c^2(a-x)} = \frac{2a-x}{a-x}x = TD$$

the ſubtangent; or by adding CD which is $= a-x$, it becomes $CT = \frac{2ax-x^2}{a-x} + a - x = \frac{a^2}{a-x} = \frac{CA^2}{CD}$, or CD : CA :: CA : CT, a well-known property of the ellipſe.

Ex. 4. The equation defining the hyperbola is $c^2.2ax + x^2 = a^2y^2$, which is ſimilar to that for the ellipſe, having only $+x^2$ for $-x^2$; hence the concluſion is exactly ſimilar alſo, viz,

$\frac{2a+x}{a+x}x$ or $\frac{2ax+xx}{a+x} = TD$, which taken from CD or $a+x$, gives $CT = \frac{CA^2}{CD}$, or CD : CA :: CA : CT.

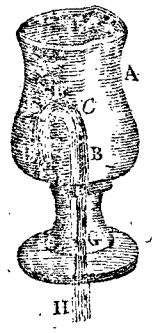
And ſo on, for the Tangents to other curves.

The Inverſe Method of TANGENTS. This is the reverſe of the foregoing, and conſiſts in finding the nature of the curve that has a given ſubtangent. The method of ſolution is to put the given ſubtangent equal to the general expreſſion $\frac{y\dot{x}}{\dot{y}}$, which ſerves for all ſorts of curves; then the equation reduced, and the fluents taken, will give the fluential equation of the curve ſought.

Ex. 1. To find the curve line whoſe ſubtangent is $= \frac{2y^2}{a}$. Here $\frac{2y^2}{a} = \frac{y\dot{x}}{\dot{y}}$; hence $2y\dot{y} = a\dot{x}$, and the fluents of this give $y^2 = ax$, the equation to a parabola, which therefore is the curve ſought.

Ex. 2. To find the curve whoſe ſubtangent is $= \frac{yy}{2a-x}$, or a third proportional to $2a-x$ and y. Here $\frac{yy}{2a-x} = \frac{y\dot{x}}{\dot{y}}$; hence $y\dot{y} = 2a\dot{x} - x\dot{x}$, the fluents of which give $y^2 = ax - x^2$, the equation to a circle, which therefore is the curve ſought.

TANTALUS's *Cup*, in Hydraulics, is a cup, as



A, with a hole in the bottom, and the longer leg of a ſyphon BCED cemented into the hole; ſo that the end D of the ſhorter leg DE may always touch the bottom of the cup within. Then, if water be poured into this cup, it will riſe in the ſhorter leg by its upward preſſure, extruding the air before it through the longer leg, and, when the cup is filled above the bend of the ſyphon at E, the preſſure of the water in the cup will force it over the bend; from whence it will deſcend in the longer leg EB, and through the bottom at G, till the cup be quite emptied. The legs of this ſyphon are almoſt cloſe together, and it is ſometimes concealed by a ſmall hollow ſtatue, or figure of a man placed over it; the bend E being within the neck of the figure as high as the chin. So that poor thirſty Tantalus ſtands up to the chin in water, according to the fable, imagining it will riſe a little higher, as more water is poured in, and he may drink; but inſtead of that, when the water comes up to his chin, it immediately begins to deſcend, and therefore, as he cannot ſtoop to follow it, he is left as much tormented with thirſt as ever. Ferguſon's Lect. p. 72, 4to.

TARRANTIUS (Lucius), ſurnamed *Firmanus*, becauſe he was a native of Firmum, a town in Italy, flouriſhed at the ſame time with Cicero, and was one of his friends. He was a mathematical philoſopher, and therefore was thought to have great ſkill in judicial aſtrology. He was particularly famous by two horoſcopes which he drew, the one the horoſcope of Romulus, and the other of Rome. Plutarch ſays, "Varro, who was the moſt learned of the Romans in hiſtory, had a particular friend named Tarrantius, who, out of curioſity, applied himſelf to draw horoſcopes, by means of aſtronomical tables, and was eſteemed the moſt eminent in his time." Hiſtorians controvert ſome particular circumſtances of his calculations; but all agree in conferring on him the honorary title *Prince of aſtrologers*.

TARTAGLIA, or Tartalea (Nicholas), a noted mathematician who was born at Breſcia in Italy, probably towards the concluſion of the 15th century, as we find he was a conſiderable maſter or preceptor in mathematics in the year 1521, when the firſt of his collection of queſtions and anſwers was written, which he afterwards publiſhed in the year 1546, under the title of *Queſiti et Inventioni diverſe*, at Venice, where he then reſided as a public lecturer on mathematics, he having removed to this place about the year 1534. This work conſiſts of 9 chapters, containing anſwers to a number of queſtions on all the different branches of mathematics and philoſophy then in vogue. The laſt or 9th of theſe, contains the queſtions in Algebra, among which are thoſe celebrated letters and communications between Tartalea and Cardan, by which our author put the latter in poſſeſſion of the rules for cubic equations, which he firſt diſcovered in the year 1530.

But the firſt work of Tartalea's that was publiſhed, was his *Nova Scientia inventa*, in 4to, at Venice in 1537. This is a treatiſe on the theory and practice of gunnery, and the firſt of the kind, he being the firſt writer on the flight and path of balls and ſhells. This work was tranſlated into Engliſh, by Lucar, and printed at London in 1588, in folio, with many notes and additions by the tranſlator.

Tartalea publiſhed at Venice, in folio, 1543, the whole books of Euclid, accompanied with many curious notes and commentaries.

But the laſt and chief work of Tartalea, was his *Trattato di Numeri et Miſure*, in folio, 1556 and 1560. This is an univerſal treatiſe on arithmetic, algebra, geometry, menſuration, &c. It contains many other curious particulars of the diſputes between our author and Cardan, which ended only with the death of Tartalea, before the laſt part of this work was publiſhed, or about the year 1558.

For many other circumſtances concerning Tartalea and his writings, ſee the article Algebra, vol. 1, pa. 73.

TATIUS (Achilles), an ancient Greek writer of Alexandria; but the age he lived in is uncertain. According to Suidas, who calls him Statius, he was at firſt a Heathen, then a Chriſtian, and afterwards a biſhop. He wrote a book upon the Sphere, which ſeems to have been nothing more than a commentary upon Aratus. Part of it is extant, and was tranſlated into Latin by father Petavius, under the title of *Iſagoges in Phænomena Arati*. He wrote alſo, *Of the Loves of Cliptophon and Leucippe*, in 8 books. He is well ſpoken of by Photius.

TAURUS, *the Bull*, in Aſtronomy, one of the 12 ſigns in the zodiac, and the ſecond in order.

The Greeks fabled that this was the bull which carried Europa ſafe acroſs the ſeas to Crete; and that Jupiter, in reward for ſo ſignal a ſervice, placed the creature, whoſe form he had aſſumed on that occaſion, among the ſtars, and that this is the conſtellation formed of it. But it is probable that the Egyptians, or Babylonians, or whoever invented the conſtellations of the zodiac, placed this figure in that part of it which the ſun entered about the time of the bringing forth of calves; like as they placed the ram in the firſt part of ſpring, as the lambs appear before them, and the two kids (for that was the original figure of the ſign Gemini), afterward, to denote the time of the goats bringing forth their young.

In the conſtellation Taurus there are ſome remarkable ſtars that have names; as Aldebaran in the ſouth or right eye of the bull, the cluſter called the Pleiades in the neck, and the cluſter called Hyades in the face.

The ſtars in the conſtellation Taurus, in Ptolomy's catalogue are 44, in Tycho's catalogue 43, in Hevelius's catalogue 51, and in the Britannic catalogue 141.

TEBET, or Thevet, the 4th month of the civil year of the Hebrews, and the 10th of their eccleſiaſtical year. It anſwered to part of our December and January, and had only 29 days.

TEETH, of various ſorts of machines, as of mill wheels, &c. Theſe are often called cogs by the workmen; and by working in the pinions, rounds, or trundles, the wheels are made to turn one another.

Mr. Emerſon (in his Mechanics, prop. 25), treats of the theory of Teeth, and ſhews that they ought to

have the figure of epicycloids, for properly working in one another. Camus too (in his Cours de Mathematique, tom. 2, p. 349, &c, Edit. 1767) treats more fully on the ſame ſubject; and demonſtrates that the Teeth of the two wheels ſhould have the figures of epicycloids, but that the generating circles of theſe epicycloids ſhould have their diameters only the half of what Mr. Emerſon makes them.

Mr. Emerſon obſerves, that the Teeth ought not to act upon one another before they arrive at the line which joins their centres. And though the inner or under ſides of the Teeth may be of any form; yet it is better to make them both ſides alike, which will ſerve to make the wheels turn backwards. Alſo a part may be cut away on the back of every Tooth, to make way for thoſe of the other wheel. And the more Teeth that work together, the better; at leaſt one Tooth ſhould always begin before the other hath done working. The Teeth ought to be diſpoſed in ſuch manner as not to trouble or hinder one another, before they begin to work; and there ſhould be a convenient length, depth and thickneſs given to them, as well for ſtrength, as that they may more eaſily diſengage themſelves.

TELEGRAPH, a machine brought into uſe by the French nation, in the year 1793, contrived to communicate words or ſignals from one perſon to another at a great diſtance, in a very ſmall ſpace of time.

The Telegraph it ſeems was originally the invention of William Amontons, an ingenious philoſopher, born in Normandy in the year 1663. See his life in this Dictionary, vol. 1, pa. 105; where it is related that he pointed out a method to acquaint people at a great diſtance, and in a very little time, with whatever one pleaſed. This method was as follows: let perſons be placed in ſeveral ſtations, at ſuch diſtances from each other, that, by the help of a teleſcope, a man in one ſtation may ſee a ſignal made by the next before him: this perſon immediately repeats the ſame ſignal to the third man; and this again to a fourth, and ſo on through all the ſtations to the laſt.

This, with conſiderable improvements, it ſeems has lately been brought into uſe by the French, and called a Telegraph. It is ſaid they have availed themſelves of this contrivance to good purpoſe, in the preſent war; and from the utility of the invention, it has alſo juſt been brought into uſe in this country.

The following account of this curious inſtrument is copied from Barrere's report in the ſitting of the French Convention of Auguſt 15, 1794.—"The new-invented telegraphic language of ſignals is an artful contrivance to tranſmit thoughts, in a peculiar language, from one diſtance to another, by means of machines, which are placed at different diſtances, of from 12 to 15 miles from one another, ſo that the expreſſion reaches a very diſtant place in the ſpace of a few minutes. Laſt year an experiment of this invention was tried in the preſence of ſeveral Commiſſioners of the Convention. From the favourable report which the latter made of the efficacy of the contrivance, the Committee of Public Welfare tried every effort to eſtabliſh, by this means, a correſpondence between Paris and the frontier places, beginning with Liſle. Almoſt a whole twelvemonth has been ſpent in collecting the neceſſary inſtruments for the machines, and to teach the people employed how to uſe them. At preſent, the telegraphic language of ſignals is [illegible] in ſuch a manner, that a correſpondence may be [illegible] with Liſle upon every ſubject, and that every thing, may even proper names, may be expreſſed; an anſwer may be received, and the correſpondence thus be renewed ſeveral times a day. The machines are the invention of Citizen Chappe, and were conſtructed under his own eye; he alſo directs their eſtabliſhment at Paris. They have the advantage of reſiſting the changes in the atmoſphere, and the inclemencies of the ſeaſons. The only thing which can interrupt their effect is, if the weather is ſo very bad and turbid that the objects and ſignals cannot be diſtinguiſhed. By this invention, remoteneſs and diſtance almoſt diſappear; and all the communications of correſpondence are effected with the rapidity of the twinkling of an eye. The operations of Government can be very much facilitated by this contrivance, and the unity of the Republic can be the more conſolidated by the ſpeedy communication with all its parts. The greateſt advantage which can be derived from this correſpondence is, that, if one chooſes, its object ſhall only be known to certain individuals, or to one individual alone, or to the extremities of any diſtance; ſo that the Committee of Public Welfare may now correſpond with the Repreſentative of the People at Liſle without any other perſons getting acquainted with the object of the correſpondence. Hence it follows that, were Liſle even beſieged, we ſhould know every thing at Paris that might happen in that place, and could ſend thither the Decrees of the Convention without the enemy's being able to diſcover or to prevent it."—The deſcription and figure of the French machine, as given in ſome Engliſh prints, are as follow.

Explanation of the Machine (Telegraph) placed on the Mountain of Bellville, near Paris, for the purpoſe of communicating Intelligence.

AA is a beam or maſt of wood, placed upright on a riſing ground (fig. 3, pl. 28) which is about 15 or 16 feet high. BB is a beam or balance, moving upon the centre AA. This balance-beam may be placed vertically, or horizontally, or any how inclined, by means of ſtrong cords, which are fixed to the wheel D, on the edge of which is a double groove, to receive the two chords. This balance is about 11 or 12 feet long, and 9 inches broad, having at the ends two pieces of wood CC, which likewiſe turn upon angles by means of four other cords that paſs through the axis of the main balance, otherwiſe the balance would derange the cords; the pieces C are each about 3 feet long, and may be placed either to the right or left, ſtraight or ſquare with the balance-beam. By means of theſe three, the combination of movement is ſaid to be very extenſive, remarkably ſimple, and eaſy to perform. Below is a ſmall wooden gouge or hut, in which a perſon is employed to obſerve the movements of the machine. In the mountain neareſt to this, another perſon is to repeat theſe movements, and a third to write them down. The time taken up for each movement is 20 ſeconds; of which the motion alone is 4 ſeconds, the other 16 the machine is ſtationary. The ſtations of this machine are about 3 or 4 leagues diſtance; and there is an obſervatory near the Committee of Public Safety

Safety to obſerve the motions of the laſt, which is at Bellville. The ſigns are ſometimes made in words, and ſometimes in letters; when in words, a ſmall flag is hoiſted, and, as the alphabet may be changed at pleaſure, it is only the correſponding perſon who knows the meaning of the ſigns. In general, news are given every day, about 11 or 12 o'clock; but the people in the wooden gouge obſerve from time to time, and, as ſoon as a certain ſignal is given and anſwered, they begin, from one end to the other, to move the machine. It is painted of a dark brown colour.

Such is the account given of the French invention. Various improved contrivances have been ſince made in England, and a pamphlet has lately been publiſhed, giving an account of ſome of them, by the Rev. J. Gamble, under the title of, *Obſervations and Telegraphic Experiments*; from whence the following remarks are extracted.

The object propoſed is, to obtain an intelligible figurative language, which may be diſtinguiſhed at a diſtance, and by which the obvious delay in the diſpatch of orders or information by meſſenger may be avoided.

On firſt reflection we find the practical modes of ſuch diſtant communication muſt be confined to Sound and Viſion. Each of which is in a great degree ſubject to the ſtate of the atmoſphere: as, independent of the wind's direction, it is known that the air is ſometimes ſo far deprived of its elaſticity, or whatever other quality the conveyance of ſound depends on, that the heavieſt ordnance is ſcarce heard farther than the ſhot flies; it is alſo well known, that in thick hazy weather the largeſt objects become totally obſcured at a ſhort diſtance. No inſtrument therefore deſigned for the purpoſe can be perfect. We can only endeavour to diminiſh theſe irremediable defects as much as may be.

It ſeems the Romans had a method in their walled cities, either by a hollow formed in the maſonry, or by tubes affixed to it, ſo to confine and augment ſound as to convey information to any part they wiſhed; and in lofty houſes it is now ſometimes the cuſtom to have a pipe, by way of ſpeaking trumpet, to give orders from the upper apartments to the lower: by this mode of confining ſound its volume may be carried to a very great diſtance; but beyond a certain extent the ſound, loſing articulation, would only convey alarm, not give directions.

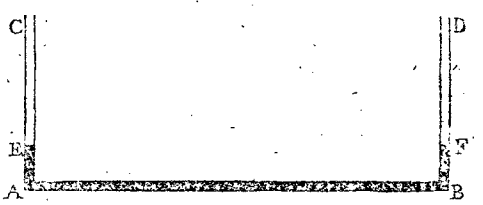
Every city among the antients had its watch-towers; and the caſtra ſtativa of the Romans, had always ſome ſpot, elevated either by nature or art, from whence ſignals were given to the troops cantoned or foraging in the neighbourhood. But I believe they had not arrived to greater refinement than that on ſeeing a certain ſignal they were immediately to repair to their appointed ſtations.

A beacon or bonfire made of the firſt inflammable materials that offered, as the moſt obvious, is perhaps the moſt antient mode of general alarm; and by being previouſly concerted, the number or point where the fires appeared might have its particular intelligence affixed. The ſame obſervations may be referred to the throwing up of rockets, whoſe number or point from whence thrown may have its affixed ſignification.

Flags or enſigns with their various devices are of earlieſt invention, eſpecially at ſea; where, from the firſt idea, which moſt probably was that of a vane to ſhew the direction of the wind, they have been long adopted as the diſtinguiſhing mark of nations, and are now ſo neatly combined by the ingenuity of a great naval commander, that by his ſyſtem every requiſite order and queſtion is received and anſwered by the moſt diſtant ſhips of a fleet.

To the adopting this or a ſimilar mode in land ſervice, the following are objections: That in the latter caſe, the variety of matter neceſſary to be conveyed, is ſo infinitely greater, that the combinations would become too complicated. And if the perſon for whom the information is intended ſhould be in the direction of the wind, the flag would then preſent a ſtraight line only, and at a little diſtance be ſcarce viſible. The Romans were ſo well aware of this inconvenience of flags, that many of their ſtandards were ſolid, and the name manipulus denotes the rudeſt of their modes, which was a truſs of hay fixed on a pole.

The principle of water always keeping its own level has been ſuggeſted, as a mode of conveying intelligence, by Mr. Daniel Brent, of Rotherhithe, and put in practice on a ſmall ſcale. As for example, ſuppoſe a pipe AB to reach from London to Dover, and to have a perpendicular tube connected to each extremity, as AC and BD. Then, if the pipe be conſtantly filled with water to a certain height, as AE, it will alſo riſe to its level in the oppoſite perpendicular tube BF; and if one inch of water be added in the tube AC, it will almoſt inſtantly produce a ſimilar elevation of the tube BD; ſo that by correſponding letters being adapted to the tubes AC and BD, at different heights, intelligence might be conveyed. But the method is liable to ſuch objections, that it is not likely it can ever be adopted to facilitate the object of very diſtant communication.



Full as many, if not greater objections, will perhaps operate againſt every mode of electricity being uſed as the vehicle of information.—And the requiſite magnitude of painted or illuminated letters offers an unſurmountable obſtacle; beſides, in them one object would be loſt, that of the language being figurative.

As to the French machine, it is evident that to every angular change of the greater beam or of the leſſer end arms, a different letter or figure may be annexed. But where the whole difference conſiſts in the variation of the angle of the greater or leſſer pieces, much error may be expected, from the inaccuracy either of the operator or the obſerver: beſides other inconveniences ariſing from the great magnitude of the machinery.

Another idea is perfectly numerical; which is to raiſe and depreſs a flag or curtain a certain number of times for each letter, according to a previouſly concerted ſyſtem: as, ſuppoſe one elevation to mean A, two to mean B, and ſo on through the alphabet. But in this caſe, the leaſt inaccuracy in giving or noting the number

number changes the letter; and beſides, the laſt letters of the alphabet would be a tedious operation.

Another method that has been propoſed, is an ingenious combination of the magnetical experiment of Comus, and the teleſcopic micrometer. But as this is only an imperfect idea of Mr. Garnet's very ingenious machine, deſcribed in the latter part of this article, no farther notice need be taken of it here.

Mr. Gamble then propoſes one on a new idea of his own. The principle of it is ſimply that of a Venetian blind, or rather what are called the lever boards of a brewhouſe, which, when horizontal, preſent ſo ſmall a ſurface to the diſtant obſerver, as to be loſt to his view, but are capable of being in an inſtant converted into a ſcreen of a magnitude adapted to the required diſtance of viſion.—Let AB and CD (fig. 4. pl. 28), two upright poſts fixed in the ground, and joined by the braces BD and EF, be conſidered as the frame work for 9 lever boards working upon centres in EB and DF, and opening in three diviſions by iron rods connected with each three of the lever boards. Let *abcd* and *efgh* be two leſſer frames fixed to the great one, having alſo three lever boards in each, and moving by iron rods, in the ſame manner as the others. If all theſe rods be brought ſo near the ground as to be in the management of the operator, he will then have five, of what may be called, keys to play on. Now as each of the handles *iklmn* commands three lever boards, by raiſing any one of them, and fixing it in its place by a catch or hook, it will give a different appearance to the machine; and by the proper variation of theſe five movements, there will be more than 25 of what may be called mutations, in each of which the machine exhibits a different appearance, and to which any letter or figure may be annexed at pleaſure.

Should it be required to give intelligence in more than one direction, the whole machine may be eaſily made to turn to different points on a ſtrong centre, after the manner of a ſingle-poſt windmill.—To uſe this machine by night, another frame muſt be connected with the back part of the Telegraph, for raiſing five lamps, of different colours, behind the openings of the lever boards; theſe lamps by night anſwer for the openings by day.

M. Gamble gives alſo particular directions for placing and uſing the machine, and for writing down the ſeveral figures or movements.

I ſhall now conclude this article with a ſhort idea of Mr. John Garnet's moſt ſimple and ingenious contrivance. This is merely a bar or plank turning upon a centre, like the ſail of a windmill, and being moved into any poſition, the diſtant obſerver turns the tube of a teleſcope into the ſame poſition, by bringing a fixed wire within it to coincide with or parallel to the bar, which is a thing extremely eaſy to do. The centre of motion of the bar has a ſmall circle about it, with letters and figures around the circumference, and an index moving round with the bar, pointing to any letter or mark that the operator wiſhes to ſet the bar to, or to communicate to the obſerver. The eye end of the teleſcope without has a like index and circle, with the correſponding letters or other marks. The conſequence is obvious; the teleſcope being turned round till its wire cover or become parallel to the bar, the index of the former neceſſarily points out the ſame letter or mark in its circle, as that of the latter, and the communication of ſentiment is immediate and perfect. The uſe of this machine is ſo eaſy, that I have ſeen it put into the hands of two common labouring men, who had never ſeen it before, and they have immediately held a quick and diſtant converſation together.

The more particular deſcription and figure of this machine, take as follows. ABDE (fig. 5, pl. 28), is the Telegraph, on whoſe centre of gravity C, about which it revolves, is a fixed pin, which goes through a hole or ſocket in the firm upright poſt G, and on the oppoſite ſide of which is fixed an index CI. Concentric to C, on the ſame poſt, is fixed a wooden or braſs circle, of 6 or 8 inches diameter, divided into 48 equal parts, 24 of which repreſent the letters of the alphabet, and between the letters, numbers. So that the index, by means of the arm AB, may be moved to any letter or number. The length of the arm ſhould be 2½ or 3 feet for every mile of diſtance. Two revolving lamps of different colours ſuſpended occaſionally at A and B, the ends of the arm, would ſerve equally at night.

Let *ss* (fig. 6, pl. 28) repreſent the ſection of the outward tube of a teleſcope perpendicular to its axis, and *xx* the like ſection of the ſliding or adjuſting tube, on which is fixed an index II. On the part of the outward tube next to the obſerver, there is fixed a circle of letters and numbers, ſimilarly divided and ſituated to the circle in figure 3; then the index II, by means of the ſliding or adjuſting tube, may be turned to any letter or number.—Now there being a croſs hair, or fine ſilver wire *fg*, fixed in the focus of the eye glaſs, in the ſame direction as the index II; ſo that when the arm AB (fig. 5) of the Telegraph is viewed at a diſtance through the teleſcope, the croſs hair may be turned, by means of the ſliding tube, to the ſame direction of the arm AB; then the index II (fig. 6) will point to the ſame letter or number on its own circle, as the index I (fig. 5) points to on the Telegraphic circle.

If, inſtead of uſing the letters and numbers to form words at length, they be uſed as ſignals, three motions of the arm will give above a hundred thouſand different ſignals.

TELESCOPE, an optical inſtrument which ſerves for diſcovering and viewing diſtant objects, either directly by glaſſes, or by reflection, by means of ſpecula, or mirrors. Accordingly,

Teleſcopes are either refracting or reflecting; the former conſiſting of different lenſes, through which the objects are ſeen by rays refracted through them to the eye; and the latter of ſpecula, from which the rays are reflected and paſſed to the eye. The lens or glaſs turned towards the object, is called the *object-glaſs*; and that next the eye, the *eye-glaſs*; and when the Teleſcope conſiſts of more than two lenſes, all but that next the object are called *eye-glaſſes*.

The invention of the Teleſcope is one of the nobleſt and moſt uſeful theſe ages have to boaſt of: by means of it, the wonders of the heavens are diſcovered to us, and aſtronomy is brought to a degree of perfection which former ages could have no idea of.

The

The diſcovery indeed was owing rather to chance than deſign; ſo that it is the good fortune of the diſcoverer, rather than his ſkill or ability, we are indebted to: on this account it concerns us the leſs to know, who it was that firſt hit upon this admirable invention. Be that as it may, it is certain it muſt have been caſual, ſince the theory it depends upon was not then known.

John Baptiſta Porta, a Neapolitan, according to Wolfius, firſt made a Teleſcope, which he infers from this paſſage in the *Magia Naturalis* of that author, printed in 1560: "If you do but know how to join "the two (viz, the concave and convex glaſſes) rightly "together, you will ſee both remote and near objects, "much larger than they otherwiſe appear, and withal "very diſtinct. In this we have been of good help "to many of our friends, who either ſaw remote "things dimly, or near ones confuſedly; and have "made them ſee every thing perfectly."

But it is certain, that Porta did not underſtand his own invention, and therefore neither troubled himſelf to bring it to a greater perfection, nor ever applied it to celeſtial obſervation. Beſides, the account given by Porta of his concave and convex leńſes, is ſo dark and indiſtinct, that Kepler, who examined it by deſire of the emperor Rudolph, declared to that prince, that it was perfectly unintelligible.

Thirty years afterwards, or in 1590, a Teleſcope 16 inches long was made, and preſented to prince Maurice of Naſſau, by a ſpectacle maker of Middleburg: but authors are divided about his name. Sirturus, in a treatiſe on the Teleſcope, printed in 1618, will have it to be John Lipperſheim: and Borelli, in a volume expreſsly on the inventor of the Teleſcope, publiſhed in 1655, ſhews that it was Zacharias Janſen, or, as Wolfius writes it, Hanſen.

Now the invention of Lipperſheim is fixed by ſome in the year 1609, and by others in 1605: Fontana, in his *Novæ Obſervationes Cæleſtium et Terreſtrium Rerum*, printed at Naples in 1646, claims the invention in the year 1608. But Borelli's account of the diſcovery of Teleſcopes is ſo circumſtantial, and ſo well authenticated, as to render it very probable that Janſen was the original inventor.

In 1620, James Metius of Alcmaer, brother of Adrian Metius who was profeſſor of mathematics at Franeker, came with Drebel to Middleburg, and there bought Teleſcopes of Janſen's children, who had made them public; and yet this Adr. Metius has given his brother the honour of the invention, in which too he is miſtakenly followed by Deſcartes.

But none of theſe artificers made Teleſcopes of above a foot and a half: Simon Marius in Germany, and Galileo in Italy, it is ſaid, firſt made long ones fit for celeſtial obſervations; though, from the recently diſcovered aſtronomical papers of the celebrated Harriot, author of the Algebra, it appears that he muſt have made uſe of Teleſcopes in viewing the ſolar maculæ, which he did quite as early as they were obſerved by Galileo. Whether Harriot made his own Teleſcopes, or whether he had them from Holland, does not appear: it ſeems however that Galileo's were made by himſelf; for Le Roſſi relates, that Galileo, being then at Venice, was told of a ſort of optic glaſs made in Holland, which brought objects nearer: upon which, ſetting himſelf to think how it ſhould be, he ground two pieces of glaſs into form as well as he could, and fitted them to the two ends of an organ-pipe; and with theſe he ſhewed at once all the wonders of the invention to the Venetians, on the top of the tower of St. Mark. The ſame author adds, that from this time Galileo devoted himſelf wholly to the improving and perfecting the Teleſcope; and that he hence almoſt deſerved all the honour uſually done him, of being reputed the inventor of the inſtrument, and of its being from him called *Galileo's tube*. Galileo himſelf, in his *Nuncius Sidereus*, publiſhed in 1610, acknowledges that he firſt heard of the inſtrument from a German; and that, being merely informed of its effects, firſt by common report, and a few days after by letter from a French gentleman, James Badovere, at Paris, he himſelf diſcovered the conſtruction by conſidering the nature of refraction. He adds in his *Saggiatore*, that he was at Venice when he heard of the effects of prince Maurice's inſtrument, but nothing of its conſtruction; that the firſt night after his return to Padua, he ſolved the problem, and made his inſtrument the next day, and ſoon after preſented it to the Doge of Venice, who, in honour of his grand invention, gave him the ducal letters, which ſettled him for life in his lectureſhip, at Padua, and doubled his ſalary, which then became treble of what any of his predeceſſors had enjoyed before. And thus Galileo may be conſidered as an inventor of the Teleſcope, though not the firſt inventor.

F. Mabillon indeed relates, in his travels through Italy, that in a monaſtery of his own order, he ſaw a manuſcript copy of the works of Commeſtor, written by one Conradus, who lived in the 13th century; in the 3d page of which was ſeen a portrait of Ptolomy, viewing the ſtars through a tube of 4 joints or draws: but that father does not ſay that the tube had glaſſes in it. Indeed it is more than probable, that ſuch tubes were then uſed for no other purpoſe but to defend and direct the ſight, or to render it more diſtinct, by ſingling out the particular object looked at, and ſhutting out all the foreign rays reflected from others, whoſe proximity might have rendered the image leſs preciſe. And this conjecture is verified by experience; for we have often obſerved that without a tube, by only looking through the hand, or even the fingers, or a pin-hole in a paper, the objects appear more clear and diſtinct than otherwiſe.

Be this as it may, it is certain that the optical principles, upon which Teleſcopes are founded, are contained in Euclid, and were well known to the ancient geometricians; and it has been for want of attention to them, that the world was ſo long without that admirable invention; as doubtleſs there are many others lying hid in the ſame principles, only waiting for reflection or accident to bring them forth.

To the foregoing abſtract of the hiſtory of the invention of the Teleſcope, it may be proper to add ſome particulars relating to the claims of our own celebrated countryman, friar Bacon, who died in 1294. Mr. W. Molyneux, in his Dioptrica Nova, pa. 256, declares his opinion, that Bacon did perfectly well underſtand all ſorts of optic glaſſes, and knew likewiſe the way

way of combining them, so as to compose some such instrument as our Telescope: and his son, Samuel Molyneux, asserts more positively, that the invention of Telescopes, in its first original, was certainly put in practice by an Englishman, friar Bacon; although its first application to astronomical purposes may probably be ascribed to Galileo. The passages to which Mr. Molyneux refers, in support of Bacon's claims, occur in his Opus Majus, pa. 348 and 357 of Jebb's edit. 1773. The first is as follows: *Si vero non sint corpora plana, per quæ visus videt, sed sphæria, tunc est magna diversitas; nam vel concavitas corporis est versus oculum vel convexitas:* whence it is inferred, that he knew what a concave and a convex glass was. The second is comprised in a whole chapter, where he says, *De visione fracta majora sunt; nam de facili patet per canones supra dictos, quod maxima possunt apparere minima, et e contra, et longe distantia videbuntur propinquissime, et e converso. Nam possumus sic figurare perspicua, et taliter ea ordinare respectu nostri visus et rerum, quod frangentur radii, et flectentur quorsumcunque voluerimus, ut sub quocunque angulo voluerimus, videbimus rem prope vel longe, &c. Sic etiam faceremus solem et lunam et stellas descendere secundum apparentiam hic inferius, &c:* that is, Greater things than these may be performed by refracted vision; for it is easy to understand by the canons above mentioned, that the greatest things may appear exceeding small, and the contrary; also that the most remote objects may appear just at hand, and the converse; for we can give such figures to transparent bodies, and dispose them in such order with respect to the eye and the objects, that the rays shall be refracted and bent towards any place we please; so that we shall see the object near at hand or at a distance, under any angle we please, &c. So that thus the sun, moon, and stars may be made to descend hither in appearance, &c. Mr. Molyneux has also cited another passage out of Bacon's Epistle ad Parisiensem, of the Secrets of Art and Nature, cap. 5, to this purpose, *Possunt etiam sic figurari perspicua, ut longissime posita appareant propinqua, et è contrario; ita quod ex incredibili distantia legeremus literas minutissimas, et numeraremus res quantumquo parvas, et stellas faceremus apparere quo vellemus:* that is, Glasses, or diaphanous bodies may be so formed, that the most remote objects may appear just at hand, and the contrary; so that we may read the smallest letters at an incredible distance, and may number things though never so small, and may make the stars appear as near as we please.

Moreover, Doctor Jebb, in the dedication of his edition of the Opus Majus, produces a passage from a manuscript, to shew that Bacon actually applied Telescopes to astronomical purposes: *Sed longe magis quam hæc,* says he, *oporteret homines haberi, qui bene, immo optime, scirent perspectivam et instrumenta ejus—quia instrumenta astronomia non vadunt nisi per visionem secundum leges istius scientiæ.*

From these passages, it is not unreasonable to conclude, that Bacon had actually combined glasses so as to have produced the effects which he mentions, though he did not complete the construction of Telescopes. Dr. Smith, however, to whose judgment particular deference is due, is of opinion that the celebrated friar wrote hypothetically, without having made any actual trial of the things he mentions: to which purpose he observes, that this author does not assert one single trial or observation upon the sun or moon, or any thing else, though he mentions them both: on the other hand, he imagines some effects of Telescopes that cannot possibly be performed by them. He adds, that persons unexperienced in looking through Telescopes expect, in viewing any object, as for instance the face of a man, at the distance of one hundred yards, through a Telescope that magnifies one hundred times, that it will appear much larger than when they are close to it: this he is satisfied was Bacon's notion of the matter; and hence he concludes that he had never looked through a Telescope.

It is remarkable that there is a passage in Thomas Digges's Stratioticos, pa. 359, where he affirms that his father, Leonard Digges, among other curious practices, had a method of discovering, by perspective glasses set at due angles, all objects pretty far distant that the sun shone upon, which lay in the country round about; and that this was by the help of a manuscript book of Roger Bacon of Oxford, who he conceived was the only man besides his father (since Archimedes) who knew it. This is the more remarkable, because the Stratioticos was first printed in 1579, more than 30 years before Metius or Galileo made their discovery of those glasses; and therefore it has hence been thought that Roger Bacon was the first inventor of Telescopes, and Leonard Digges the next reviver of them. But from what Thomas Digges says of this matter, it would seem that the instrument of Bacon, and of his father, was something of the nature of a camera obscura, or, if it were a Telescope, that it was of the reflecting kind; although the term *perspective* glass seems to favour a contrary opinion.

There is also another passage to the same effect in the preface to the Pantometria of Leonard Digges, but published by his son Thomas Digges, some time before the Stratioticos, and a second time in the year 1591. The passage runs thus: *My father by his continuall painfull practises, assisted with demonstrations mathematical, was able, and sundrie times hath by Proportional Glasses duely situate in convenient angles, not only discovered things farre off, read letters, numbered peeces of money with the very coyne and superscription thereof, cast by some of his freends of purpose upon downes in open fields, but also seven myles off declared what hath beene doone at that instant in private places: He hath also sundrie times by the sunne beames fixed* (should be *fired*) *powder, and dischargde ordinance halfe a mile and more distante,* &c.

But to whomsoever we ascribe the honour of first inventing the Telescope, the rationale of this admirable instrument, depending on the refraction of light in passing through mediums of different forms, was first explained by the celebrated Kepler, who also pointed out methods of constructing others, of superior powers, and more commodious application, than that first used: though something of the same kind, it is said, was also done by Maurolycus, whose treatise De Lumine et Umbra was published in 1575.

The Principal Effects of Telescopes, depend upon this plain maxim, viz, that objects appear larger in proportion to the angles which they subtend at the eye;

eye; and the effect is the same, whether the pencils of rays, by which objects are visible to us, come directly from the objects themselves, or from any place nearer to the eye, where they may have been united, so as to form an image of the object; because they issue again from those points in certain directions, in the same manner as they did from the corresponding points in the objects themselves. In fact therefore, all that is effected by a Telescope, is first to make such an image of a distant object, by means of a lens or mirror, and then to give the eye some assistance for viewing that image as near as possible; so that the angle, which it shall subtend at the eye, may be very large, compared with the angle which the object itself would subtend in the same situation. This is done by means of an eye-glass, which so refracts the pencils of rays, as that they may afterwards be brought to their several foci, by the natural humours of the eye. But if the eye had been so formed as to be able to see the image, with sufficient distinctness, at the same distance, without an eye-glass, it would appear to him as much magnified, as it does to another person who makes use of a glass for that purpose, though he would not in all cases have so large a field of view.

Although no image be actually formed by the foci of the pencil without the eye, yet if, by the help of an eye-glass, the pencils of rays shall enter the pupil, just as they would have done from any place without the eye, the visual angle will be the same as if an image had been actually formed in that place. Priestley's History of Light &c, pa. 69, &c.

As to the Grinding of Telescopic Glasses, the first persons who distinguished themselves in that way, were two Italians, Eustachio Divini at Rome, and Campani at Bologna, whose fame was much superior to that of Divini, or that of any other person of his time; though Divini himself pretended, that in all the trials that were made with their glasses, his of a great focal distance performed better than those of Campani, and that his rival was not willing to try them fairly, viz, with equal eye-glasses. It is however generally supposed, that Campani really excelled Divini, both in the goodness and the focal length of his object-glasses.

It was with Campani's Telescopes that Cassini discovered the nearest satellites of Saturn. They were made at the express desire of Lewis XIV, and were of 86, 100, and 136, Paris feet focal length.

Campani's laboratory was purchased, after his death, by pope Benedict XIV, who made a present of it to the academy at Bologna called the Institute; and by the account which Fougeroux has given, we learn that (except a machine which Campani constructed, to work the basons on which he ground his glasses) the goodness of his lenses depended upon the clearness of his glass, his Venetian tripoli, the paper with which he polished his glasses, and his great skill and address as a workman. It does not appear that he made many lenses of a very great focal distance. Accordingly Dr. Hook, who probably speaks with the partiality of an Englishman, says that some glasses, made by Divini and Campani, of 36 and 50 feet focal distance, did not excel Telescopes of 12 or 15 feet made in England. He adds, that Sir Paul Neilli made Telescopes of 36 feet, pretty good; and one of 50, but not of proportionable goodness.

Afterwards, Mr. Reive first, and then Mr. Cox, who were the most celebrated in England, as grinders of optic glasses, made some good Telescopes of 50 and 60 feet focal distance; and Mr. Cox made one of 100, but how good Dr. Hook could not assert. Borelli also in Italy, made object-glasses of a great focal length, one of which he presented to the Royal Society. But, with respect to the focal length of Telescopes, these and all others were far exceeded by those of Auzout, who made one object-glass of 600 feet focus; but he was never able to manage it, so as to make any use of it. And Hartsoeker, it is said, made some of a still greater focal length. Philos. Trans. Abr. vol. i, p. 193. Hook's Exper. by Derham, p. 261. Priestley as above, p. 211. See GRINDING.

Telescopes are of several kinds, distinguished by the number and form of their lenses, or glasses, and denominated from their particular uses &c: such are the *terrestrial* or *land Telescope*, the *celestial* or *astronomical Telescope*; to which may be added, the *Galilean* or *Dutch Telescope*, the *reflecting Telescope*, the *refracting Telescope*, the *aërial Telescope*, *achromatic Telescope*, &c.

Galileo's, or the *Dutch Telescope*, is one consisting of a convex object-glass, and a concave eye-glass.

This is the most ancient form of any, being the only kind made by the inventors, Galileo, &c. or known, before Huygens. The first Telescope, constructed by Galileo, magnified only 3 times; but he soon made another, which magnified 18 times: and afterwards, with great trouble and expence, he constructed one that magnified 33 times; with which he discovered the satellites of Jupiter, and the spots of the sun. The construction, properties, &c, of it, are as follow:

Construction of Galileo's, or the *Dutch* TELESCOPE. In a tube prepared for the purpose, at one end is fitted a convex object lens, either a plain convex, or convex on both sides, but a segment of a very large sphere: at the other end is fitted an eye-glass, concave on both sides, and the segment of a less sphere, so disposed as to be at the distance of the virtual focus before the image of the convex lens.

Let AB (fig. 10, pl. 23) be a distant object, from every point of which pencils of rays issue, and falling upon the convex glass DE, tend to their foci at FSG. But a concave lens HI (the focus of which is at FG) being interposed, the converging rays of each pencil are made parallel when they reach the pupil; so that by the refractive humours of the eye, they can easily be brought to a focus on the retina at PRQ. Also the pencils themselves diverging, as if they came from X, MXO is the angle under which the image will appear, which is much larger than the angle under which the object itself would have appeared. Such then is the Telescope that was at first discovered and used by philosophers: the great inconvenience of which is, that the field of view, which depends, not on the breadth of the eye-glass, as in the astronomical Telescope, but upon the breadth of the pupil of the eye, is exceedingly small: for since the pencils of the rays enter the eye very much diverging from one another, but few of them can be intercepted by the pupil; and this inconvenience increases with the magnifying power of the Telescope, so that philosophers may now well wonder

at the patience and addreſs with which Galileo and others, with ſuch an inſtrument, made the diſcoveries they did. And yet no other Teleſcope was thought of for many years after the diſcovery. Deſcartes, who wrote 30 years after, mentions no other as actually conſtructed, though Kepler had ſuggeſted ſome. Hence,

1. In an inſtrument thus framed, all people, except myopes, or ſhort-ſighted perſons, muſt ſee objects diſtinctly in an erect ſituation, and increaſed in the ratio of the diſtance of the virtual focus of the eye-glaſs, to the diſtance of the focus of the object glaſs.

2. But for myopes to ſee objects diſtinctly through ſuch an inſtrument, the eye-glaſs muſt be ſet nearer the object-glaſs, ſo that the rays of each pencil may not emerge parallel, but may fall diverging upon the eye; in which caſe the apparent magnitude will be altered a little, though ſcarce ſenſibly.

3. Since the focus of a plano-convex object lens, and the vertical focus of a plano-concave eye-lens, are at the diſtance of the diameter; and the focus of an object-glaſs convex on both ſides, and the vertical focus of an eye-glaſs concave on both ſides, are at the diſtance of a ſemidiameter; if the object-glaſs be plano-convex, and the eye glaſs plano-concave, the Teleſcope will increaſe the diameter of the object, in the ratio of the diameter of the concavity to that of the convexity: if the object-glaſs be convex on both ſides, and the eye-glaſs concave on both ſides, it will magnify in the ratio of the ſemidiameter of the concavity to that of the convexity: if the object-glaſs be plano-convex, and the eye-glaſs concave on both ſides, the ſemidiameter of the object will be increaſed in the ratio of the diameter of the convexity to the ſemidiameter of the concavity: and laſtly, if the object-glaſs be convex on both ſides, and the eye-glaſs plano-concave, the increaſe will be in the ratio of the diameter of the concavity to the ſemidiameter of the convexity.

4. Since the ratio of the ſemidiameters is the ſame as that of the diameters, Teleſcopes magnify the object in the ſame manner, whether the object-glaſs be plano-convex, and the eye-glaſs plano-concave; or whether the one be convex on both ſides, and the other concave on both.

5. Since the ſemidiameter of the concavity has a leſs ratio to the diameter of the convexity than its diameter has, a Teleſcope magnifies more if the object-glaſs be plano-convex, than if it be convex on both ſides. The caſe is the ſame if the eye-glaſs be concave on both ſides, and not plano-concave.

6. The greater the diameter of the object-glaſs, and the leſs that of the eye-glaſs, the leſs ratio has the diameter of the object, viewed with the naked eye, to its ſemidiameter when viewed with a Teleſcope, and conſequently the more is the object magnified by it.

7. Since a Teleſcope exhibits ſo much a leſs part of the object, as it increaſes its diameter more, for this reaſon, mathematicians were determined to look out for another Teleſcope, after having clearly found the imperfection of the firſt, which was diſcovered by chance. Nor were their endeavours vain, as appears from the aſtronomical Teleſcope deſcribed below.

If the ſemidiameter of the eye-glaſs have too ſmall a ratio to that of the object-glaſs, an object through the Teleſcope will not appear ſufficiently clear, becauſe the great divergency of the rays will occaſion the ſeveral pencils repreſenting the ſeveral points of the object on the retina, to conſiſt of too few rays.

It is alſo found that equal object-lenſes will not bear the ſame eye-lenſes, if they be differently tranſparent, or if there be a difference in their poliſh; a leſs tranſparent object-glaſs, or one leſs accurately ground, requiring a more ſpherical eye-glaſs than another more tranſparent, &c.

Hevelius recommends an object-glaſs convex on both ſides, whoſe diameter is 4 feet; and an eye-glaſs concave on both ſides, whoſe diameter is $4\frac{1}{2}$ tenths of a foot. An object-glaſs, equally convex on both ſides, whoſe diameter is 5 feet, he obſerves, will require an eye-glaſs of $5\frac{1}{2}$ tenths; and adds, that the ſame eye-glaſs will alſo ſerve an object-glaſs of 8 or 10 feet.

Hence, as the diſtance between the object-glaſs and eye-glaſs is the difference between the diſtance of the vertical focus of the eye-glaſs, and the diſtance of the focus of the object glaſs; the length of the teleſcope is had by ſubtracting that from this. That is, the length of the Teleſcope is the difference between the diameters of the object-glaſs and eye-glaſs, if the former be plano-convex, and the latter plano-concave; or the difference between the ſemidiameters of the object-glaſs and eye-glaſs, if the former be convex on both ſides, and the latter concave on both; or the difference between the ſemidiameter of the object-glaſs and the diameter of the eye-glaſs, if the former be convex on both ſides, and the latter plano-concave; or laſtly the difference between the diameter of the object-glaſs and the ſemidiameter of the eye-glaſs, if the former be plano-convex, and the latter concave on both ſides. Thus, for inſtance, if the diameter of an object-glaſs, convex on both ſides, be 4 feet, and that of an eye-glaſs, concave on both ſides, be $4\frac{1}{2}$ tenths of a foot; then the length of the Teleſcope will be 1 foot and $7\frac{1}{2}$ tenths.

Aſtronomical TELESCOPE; this is one that conſiſts of an object-glaſs, and an eye-glaſs, both convex. It is ſo called from being wholly uſed in aſtronomical obſervations.

It was Kepler who firſt ſuggeſted the idea of this Teleſcope; having explained the rationale, and pointed out the advantages of it in his Catoptrics, in 1611. But the firſt perſon who actually made an inſtrument of this conſtruction, was father Scheiner, who has given a deſcription of it in his Roſa Urſina, publiſhed in 1630. To this purpoſe he ſays, If you inſert two ſimilar convex lenſes in a tube, and place your eye at a convenient diſtance, you will ſee all terreſtrial objects, inverted indeed, but magnified and very diſtinct, with a conſiderable extent of view. He afterwards ſubjoined an account of a Teleſcope of a different conſtruction, with two convex eye-glaſſes, which again reverſes the images, and makes them appear in their natural poſition. Father Reita however ſoon after propoſed a better conſtruction, uſing three eye-glaſſes inſtead of two.

Conſtruction of the Aſtronomical TELESCOPE. The tube being prepared, an object-glaſs, either plano-convex,

vex, or convex on both ſides, but a ſegment of a large ſphere, is fitted in at one end; and an eye-glaſs, convex on both ſides, which is the ſegment of a ſmall ſphere, is fitted into the other end; at the common diſtance of the foci.

Thus the rays of each pencil iſſuing from every point of the object ABC, (fig. 3 pl. 30) paſſing through the object-glaſs DEF, become converging, and meet in their foci at IHG, where an image of the object will be formed. If then another convex lens KM, of a ſhorter focal length, be ſo placed, as that its focus ſhall be in IHG, the rays of each pencil, after paſſing through it, will become nearly parallel, ſo as to meet upon the retina, and form an enlarged image of the object at RST. If the proceſs of the rays be traced, it will preſently be perceived that this image muſt be inverted. For the pencil that iſſues from A, has its focus in G, and again in R, on the ſame ſide with A. But as there is always one inverſion in ſimple viſion, this want of inverſion produces juſt the reverſe of the natural appearance. The field of view in this Teleſcope will be large, becauſe all the pencils that can be received on the ſurface of the lens KM, being converging after paſſing through it, are thrown into the pupil of the eye, placed in the common interſection of the pencils at P.

Theory of the Aſtronomical TELESCOPE.—An eye placed near the focus of the eye-glaſs, of ſuch a Teleſcope, will ſee objects diſtinctly, but inverted, and magnified in the ratio of the diſtance of the focus of the eye-glaſs to the diſtance of the focus of the object-glaſs.

If the ſphere of concavity in the eye-glaſs of the Galilean Teleſcope, be equal to the ſphere of convexity in the eye-glaſs of another Teleſcope, their magnifying power will be the ſame. The concave glaſs however being placed between the object-glaſs and its focus, the Galilean Teleſcope will be ſhorter than the other, by twice the focal length of the eye-glaſs. Conſequently, if the length of the Teleſcopes be the ſame; the Galilean will have the greater magnifying power. Viſion is alſo more diſtinct in theſe Teleſcopes, owing in part perhaps to there being no intermediate image between the eye and the object. Beſides, the eye-glaſs being very thin in the centre, the rays will be leſs liable to be diſtorted by irregularities in the ſubſtance of the glaſs. Whatever be the cauſe, we can ſometimes ſee Jupiter's ſatellites very clearly in a Galilean Teleſcope, of 20 inches or 2 feet long, when one of 4 or 5 feet, of the common ſort, will hardly make them viſible.

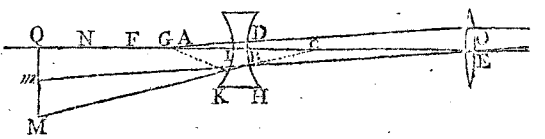
As the aſtronomical Teleſcope exhibits objects inverted, it ſerves commodiouſly enough for obſerving the ſtars, as it is not material whether *they* be ſeen erect or inverted; but for terreſtrial objects it is much leſs proper, as the inverting often prevents them from being known. But if a plane well-poliſhed metal ſpeculum, of an oval figure, and about an inch long, and inclined to the axis in an angle of 45°, be placed behind the eye-glaſs; then the eye, conveniently placed, will ſee the image, hence reflected, in the ſame magnitude as before, but in an erect ſituation; and therefore, by the addition of ſuch a ſpeculum, the aſtronomical Teleſcope is thus rendered fit to obſerve terreſtrial objects.

Since the focus of the glaſs convex on both ſides is diſtant from the glaſs itſelf a ſemidiameter, and that of a plano-convex glaſs, a diameter; if the object-glaſs be convex on both ſides, the Teleſcope will magnify the ſemidiameter of the object, in the ratio of the diameter of the eye-glaſs to the diameter of the object-glaſs; but if the object-glaſs be a plano-convex, in the ratio of the ſemidiameter of the eye-glaſs to the diameter of the object-glaſs. And therefore a Teleſcope magnifies more if the object-glaſs be a plano-convex, than if convex on both ſides. And for the ſame reaſon, a Teleſcope magnifies more when the eye-glaſs is convex on both ſides, than when it is plano-convex.

A Teleſcope magnifies the more, as the object-glaſs is a ſegment of a great ſphere, and the eye-glaſs of a leſs one. And yet the eye-glaſs muſt not be too ſmall in reſpect of the object-glaſs; for if it be, it will not refract rays enough to the eye from each point of the object; nor will it ſeparate ſufficiently thoſe that come from different points; by which means the viſion will be rendered obſcure and confuſed.—De Chales obſerves, that an object-lens of $2\frac{1}{4}$ feet will require an eye-glaſs of $1\frac{1}{2}$ tenth of a foot; and an object-glaſs of 8 or 10 feet, an eye-glaſs of 4 tenths; in which he is confirmed by Euſtachio Divini.

To ſhorten the Aſtronomical TELESCOPE; that is, to conſtruct a Teleſcope ſo, as that, though ſhorter than the common one, it ſhall magnify as much.

Having provided a drawing tube, fit in it an object-lens EO which is a ſegment of a moderate ſphere;



let the firſt eye-glaſs BD be concave on both ſides, and ſo placed in the tube, as that the focus of the object-glaſs A may be behind it, but nearer to the centre of the concavity G: then will the image be thrown in Q, ſo as that GA : GI :: AB : QI. Laſtly, fit in another object-glaſs, convex on both ſides, and a ſegment of a ſmaller ſphere, ſo as that its focus may be in Q.

This Teleſcope will magnify the diameter of the object more than if the object-glaſs were to repreſent its image at the ſame diſtance EQ; and conſequently a ſhorter Teleſcope, conſtructed this way, is equivalent to a longer in the common way. See Wolfius Elem. Math. vol. 3, p. 245.

Sir Iſaac Newton furniſhes us with another method of conſtructing the Teleſcope, in his catoptrical or reflecting Teleſcope, the conſtruction of which is given below. See *Achromatic* TELESCOPE.

Aërial TELESCOPE, a kind of aſtronomical Teleſcope, the lenſes of which are uſed without a tube. In ſtrictneſs however, the aërial Teleſcope is rather a particular manner of mounting and managing long

Teleſcopes for celeſtial obſervation in the night-time, by which the trouble of long unwieldy tubes is ſaved, than a particular kind of Teleſcope; and the contrivance was one of Huygens's. This invention was ſucceſsfully practiſed by the inventor himſelf and others, particularly with us by Dr. Pound and Dr. Bradley, with an object-glaſs of 123 feet focal diſtance, and an apparatus belonging to it, made and preſented by Huygens to the Royal Society, and deſcribed in his Aſtroſcopia Compendiaria Tubi Optici Molimine Liberata, printed at the Hague in 1684.

The principal parts of this Teleſcope may be comprehended from a view of fig. 4, pl. 30, where AB is a long pole, or a maſt, or a high tree, &c, in a groove of which ſlides a piece that carries a ſmall tube LK in which is fixed an object glaſs; which tube is connected by a fine line, with another ſmall tube OQ, which contains the eye-glaſs, &c.

La Hire contrived a little machine for managing the object-glaſs which is deſcribed Mem. de l'Acad. 1715. See Smith's Optics, book 3, chap. 10.

Hartſoeker, who made Teleſcopes of a very conſiderable focal length, contrived a method of uſing them without a tube, by fixing them to the top of a tree, a high wall, or the roof of a houſe. Miſcel. Berol. vol. 1, p. 261.

Huygens's great Teleſcope, with which Saturn's true face, and one of his ſatellites were firſt diſcovered, conſiſts of an object-glaſs of 12 feet, and an eye-glaſs of a little more than 3 inches; though he frequently uſed a Teleſcope of 23 feet long, with two eye-glaſſes joined together, each $1\frac{1}{2}$ inch diameter; ſo that the two were equal to one of 3 inches.

The ſame author obſerves, that an object-glaſs of 30 feet requires an eye-glaſs of $3\frac{3}{10}$ inches; and has given a table of proportions for conſtructing aſtronomical Teleſcopes, an abridgment of which is as follows:

Diſt. of Foc. of Obj. Glaſſ.	Diameter of Apert.	Diſt. of Foc. of Eye-glaſs.	Power or Magnitude of Diam.
Feet.	Inches and Decim.	Inches and Decim.	
1	0·55	0·61	20
2	0·77	0·85	28
3	0·95	1·05	34
4	1·09	1·20	40
5	1·23	1·35	44
6	1·34	1·47	49
7	1·45	1·60	53
8	1·55	1·71	56
9	1·64	1·80	60
10	1·73	1·90	63
15	2·12	2·33	77
20	2·45	2·70	89
25	2·74	3·01	100
30	3·00	3·30	109
40	3·46	3·81	120
50	3·87	4·26	141
60	4·24	4·66	154
70	4·58	5·04	166
80	4·90	5·39	178
90	5·20	5·72	189
100	5·49	6·03	200
120	6·00	6·60	218
140	6·48	7·12	235
160	6·93	7·62	252
180	7·35	8·09	267
200	7·75	8·53	281
220	8·12	8·93	295
240	8·48	9·33	308
260	8·83	9·71	321
280	9·16	10·08	333
300	9·49	10·44	345
400	10·95	12·05	400
500	12·25	13·47	445
600	13·42	14·76	488

Dr. Smith (Rem. p. 78) obſerves, that the magnifying powers of this table are not ſo great as Huygens himſelf intended, or as the beſt object-glaſſes now made will admit of. For the author, in his Aſtroſcopia Compendiaria, mentions an object-glaſs of 34 feet focal diſtance, which, in aſtronomical obſervations, bore an eye-glaſs of $2\frac{1}{2}$ inches focal diſtance, and conſequently magnified 163 times. According to this ſtandard, a Teleſcope of 35 feet ought to magnify 166 times, and of 1 foot 28 times; whereas the table allows but 118 times to the former, and but 20 to the latter. Now $\frac{166}{118}$ or $\frac{28}{20} = 1{\cdot}4$; by which if we multiply the numbers in the given column of magnifying powers, we ſhall gain a new column, ſhewing how much thoſe object-glaſſes ought to magnify if wrought up to the perfection of this ſtandard.

The new apertures and eye glaſſes muſt alſo be taken in the ſame proportions to one another, as the old ones have in the table; or the eye-glaſſes may be found by dividing the length of each Teleſcope by its magnifying power. And thus a new table may be eaſily made for this or any other more perfect ſtandard when offered.

The rule for computing this table depends on the following theorem, viz, that in refracting Teleſcopes of different lengths, a given object will appear equally bright and equally diſtinct, when their linear apertures and the focal diſtances of their eye-glaſſes are ſeverally in a ſubduplicate ratio of their lengths, or focal diſtances of their object-glaſſes; and then alſo the breadth of their apertures will be in the ſubduplicate ratio of their lengths.

The rule is this: Multiply the number of feet in the focal diſtance of any propoſed object-glaſs by 3000, and the ſquare-root of the product will give the breadth of its aperture in centeſms, or 100th parts of an inch; that

that it, $\sqrt{3000F}$ is the breadth of the aperture in centeſms of an inch, where F is the focal diſtance of the object-glaſs in feet. Alſo, the ſame breadth of the aperture increaſed by the 10th part of itſelf, gives the focal diſtance of the eye-glaſs in centeſms of an inch. And the magnifying powers are as the breadths of the apertures.

If, in different Teleſcopes, the ratio between the object-glaſs and eye-glaſs be the ſame, the object will be magnified the ſame in both. Hence ſome may conclude the making of large Teleſcopes a needleſs trouble. But it muſt be remembered, that an eye-glaſs may be in a leſs ratio to a greater object-glaſs than to a ſmaller: thus, for example, in Huygens's Teleſcope of 25 feet, the eye-glaſs is 3 inches: now, keeping this proportion in a Teleſcope of 50 feet, the eye-glaſs ſhould be 6 inches; but the table ſhews that $4\frac{1}{2}$ are ſufficient. Hence, from the ſame table it appears, that a Teleſcope of 50 feet magnifies in the ratio of 1 to 141; whereas that of 25 feet only magnifies in the ratio of 1 to 100.

Since the diſtance of the lens is equal to the aggregate of the diſtances of the foci of the object and eye-glaſſes; and ſince the focus of a glaſs convex on each ſide is a ſemidiameter's diſtance from the lens, and that of a plano-convex at a diameter's diſtance from the ſame; the length of a Teleſcope is equal to the aggregate of the ſemidiameters of the lenſes, if the object-glaſs be convex on both ſides; and to the ſum of the ſemidiameter of the eye-glaſs and the whole diameter of the object glaſs, if the object-glaſs be a plano-convex.

But as the diameter of the eye-glaſs is very ſmall in reſpect of that of the object-glaſs, the length of the Teleſcope is uſually eſtimated from the diſtance of the object-glaſs; i. e. from its ſemidiameter if it be convex on both ſides, or its whole diameter if plano-convex. Thus, a Teleſcope is ſaid to be 12 feet, if the ſemidiameter of the object-glaſs, convex on both ſides, be 12 feet, &c.

Since myopes ſee near objects beſt; for them, the eye-glaſs is to be removed nearer to the object-glaſs, that the rays refracted through it may be the more diverging.

To take in the larger field at one view, ſome make uſe of two eye-glaſſes, the foremoſt of which is a ſegment of a larger ſphere than that behind; to this it muſt be added, that if two lenſes be joined immediately together, ſo as the one may touch the other, the focus is removed to double the diſtance which that of one of them would be at.

Land TELESCOPE, or *Day* TELESCOPE, is one adapted for viewing objects in the day-time, on or about the earth. This contains more than two lenſes, uſually it has a convex object-glaſs, and three convex eye-glaſſes; exhibiting objects erect, yet different from that of Galileo.

In this Teleſcope, after the rays have paſſed the firſt eye glaſs HI (fig. 2, pl. 30), as in the former conſtruction, inſtead of being there received by the eye, they paſs on to another equally convex lens, ſituated at twice its focal diſtance from the other, ſo that the rays of each pencil, being parallel in that whole interval, thoſe pencils croſs one another in the common focus, and the rays conſtituting them are tranſmitted parallel to the ſecond eye-glaſs LM; after which the rays of each pencil converge to other foci at NO, where a ſecond image of the object is formed, but inverted with reſpect to the former image in EF. This image then being viewed by a third eye-glaſs QR, is painted upon the retina at XYZ, exactly as before, only in a contrary poſition.

Father Reita was the author of this conſtruction; which is effected by fitting in at one end of a tube an object-glaſs, which is either convex on both ſides, or plano-convex, and a ſegment of a large ſphere; to this add three eye-glaſſes, all convex on both ſides, and ſegments of equal ſpheres; diſpoſing them in ſuch a manner as that the diſtance between any two may be the aggregate of the diſtances of their foci. Then will an eye applied to the laſt lens, at the diſtance of its focus, ſee objects very diſtinctly, erect, and magnified in the ratio of the diſtance of the focus of one eye-glaſs, to the diſtance of the focus of the object-glaſs.

Hence, 1. An aſtronomical Teleſcope is eaſily converted into a Land Teleſcope, by uſing three eye-glaſſes for one; and the Land Teleſcope, on the contrary, into an aſtronomical one, by taking away two eye-glaſſes, the faculty of magnifying ſtill remaining the ſame.

2. Since the diſtance of the eye-glaſſes is very ſmall, the length of the Teleſcope is much the ſame as if you only uſed one.

3. The length of the Teleſcope is found by adding five times the ſemidiamer of the eye-glaſſes, to the diameter of the object-glaſs when this is a plano-convex, or to its ſemidiameter when convex on both ſides.

Huygens firſt obſerved, both in the aſtronomical and Land Teleſcope, that it contributes conſiderably to the perfection of the inſtrument, to have a ring of wood or metal, with an aperture, a little leſs than the breadth of the eye-glaſs, fixed in the place where the image is found to radiate upon the lens next the eye: by means of which, the colours, which are apt to diſturb the clearneſs and diſtinctneſs of the object, are prevented, and the whole compaſs taken in at one view, perfectly defined.

Some make Land Teleſcopes of three lenſes, which yet repreſent objects erect, and magnified as much as the former. But ſuch Teleſcopes are ſubject to very great inconveniences, both as the objects in them are tinged with falſe colours, and as they are diſtorted about the margin.

Some again uſe five lenſes, and even more; but as ſome parts of the rays are intercepted in paſſing every lens, objects are thus exhibited dim and feeble.

Teleſcopes of this kind, longer than 20 feet, will be of hardly any uſe in obſerving terreſtrial objects, on account of the continual motion of the particles of the atmoſphere, which theſe powerful Teleſcopes render viſible, and give a tremulous motion to the objects themſelves.

The great length of dioptric Teleſcopes, adapted to any important aſtronomical purpoſe, rendered them extremely inconvenient for uſe; as it was neceſſary to increaſe their length in no leſs a proportion than the duplicate

duplicate of the increaſe of their magnifying power: ſo that, in order to magnify twice as much as before, with the ſame light and diſtinctneſs, the Teleſcope required to be lengthened 4 times; and to magnify thrice as much, 9 times the length, and ſo on. This unwieldineſs of refracting Teleſcopes, poſſeſſing any conſiderable magnifying power, was one cauſe, why the attention of aſtronomers, &c, was directed to the diſcovery and conſtruction of reflecting Teleſcopes. And indeed a refracting Teleſcope, even of 1000 feet focus, ſuppoſing it poſſible to make uſe of ſuch an inſtrument, could not be made to magnify with diſtinctneſs more than 1000 times; whereas a reflecting Teleſcope, of 9 or 10 feet, will magnify 12 hundred times. The perfection of refracting Teleſcopes, it is well known, is very much limited by the aberration of the rays of light from the geometrical focus: and this ariſes from two different cauſes, viz, from the different degrees of refrangibility of light, and from the figure of the ſphere, which is not of a proper curvature for collecting the rays in a ſingle point. Till the time of Newton, no optician had imagined that the object glaſſes of Teleſcopes were ſubject to any other error beſide that which aroſe from their ſpherical figure, and therefore all their efforts were directed to the conſtruction of them, with other kinds of curvature: but that author had no ſooner demonſtrated the different refrangibility of the rays of light, than he diſcovered in this circumſtance a new and a much greater cauſe of error in Teleſcopes. Thus, ſince the pencils of each kind of light have their foci in different places, ſome nearer and ſome farther from the lens, it is evident that the whole beam cannot be brought into any one point, but that it will be drawn the neareſt to a point in the middle place between the focus of the moſt and leaſt refrangible rays; ſo that the focus will be a circular ſpace of a conſiderable diameter. Newton ſhews that this ſpace is about the 55th part of the aperture of the Teleſcope, and that the focus of the moſt refrangible rays is nearer to the object-glaſs than the focus of the leaſt refrangible ones, by about the $27\frac{1}{2}$ part of the diſtance between the object-glaſs, and the focus of the mean refrangible rays. But he ſays, that if the rays flow from a lucid point, as far from the lens on one ſide as their foci are on the other, the focus of the moſt refrangible rays will be nearer to the lens than that of the leaſt refrangible, by more than the 14th part of the whole diſtance. Hence, he concludes, that if all the rays of light were equally refrangible, the error in Teleſcopes, ariſing from the ſpherical figure of the glaſs, would be many hundred times leſs than it now is: becauſe the error ariſing from the ſpherical figure of the glaſs, is to that ariſing from the different refrangibility of the rays of light, as 1 to 5449. See ABERRATION.

Upon the whole he obſerves, that it is a wonder that Teleſcopes repreſent objects ſo diſtinctly as they do. The reaſon of which is, that the diſperſed rays are not ſcattered uniformly over all the circular ſpace above-mentioned, but are infinitely more denſe in the centre than in any other part of the circle; and that in the way from the centre to the circumference they grow continually rarer and rarer, till at the circumference they become infinitely rare: for which reaſon, theſe diſperſed rays are not copious enough to be viſible, except about the centre of the circle. He alſo mentions another argument to prove, that the different refrangibility of the rays of light is the true cauſe of the imperfection of Teleſcopes. For the diſperſions of the rays ariſing from the ſpherical figures of object-glaſſes, are as the cubes of their apertures; and therefore, to cauſe Teleſcopes of different lengths to magnify with equal diſtinctneſs, the apertures of the object-glaſſes, and the charges or magnifying powers ought to be as the cubes of the ſquare roots of their lengths, which does not anſwer to experience. But the errors of the rays, ariſing from the different refrangibility, are as the apertures of the object-glaſſes; and thence, to make Teleſcopes of different lengths to magnify with equal diſtinctneſs, their apertures and charges ought to be as the ſquare roots of their lengths; and this anſwers to experience.

Were it not for this different refrangibility of the rays, Teleſcopes might be brought to a ſufficient degree of perfection, by compoſing the object-glaſs of two glaſſes with water between them. For by this means, the refractions on the concave ſides of the glaſſes will very much correct the errors of the refractions on the convex ſides, ſo far as they ariſe from their ſpherical figure: but on account of the different refrangibility of different kinds of rays, Newton did not ſee any other means of improving Teleſcopes by refraction only, except by increaſing their length. Newton's Optics, pa. 73, 83, 89, 3d edition.

This important deſideratum in the conſtruction of dioptric Teleſcopes, has been ſince diſcovered by the ingenious Mr. Dollond; an account of which is given below.

Achromatic TELESCOPE, is a name given to the refracting Teleſcope, invented by Mr. John Dollond, and ſo contrived as to remedy the aberration ariſing from colours, or the different refrangibility of the rays of light. See ACHROMATIC.

The principles of Mr. Dollond's diſcovery and conſtruction, have been already explained under the articles ABERRATION, and ACHROMATIC. The improvement made by Mr. Dollond in his Teleſcopes, by making two object-glaſſes of crown-glaſs, and one of flint, which was tried with ſucceſs when concave eye-glaſſes were uſed, was completed by his ſon Peter Dollond; who, conceiving that the ſame method might be practiſed with ſucceſs with convex eye-glaſſes, found, after a few trials, that it might be done. Accordingly he finiſhed an object-glaſs of 5 feet focal length, with an aperture of $3\frac{4}{4}$ inches, compoſed of two convex lenſes of crown-glaſs, and one concave of white flint glaſs. But apprehending afterward that the apertures might be admitted ſtill larger, he completed one of $3\frac{1}{2}$ feet focal length, with the ſame aperture of $3\frac{4}{4}$ inches. Philoſ. Tranſ. vol. 55, p. 56.

But beſide the obligation we are under to Mr. Dollond, for correcting the aberration of the rays of light in the focus of object-glaſſes, ariſing from their different refrangibility, he made another conſiderable improvement in Teleſcopes, viz, by correcting, in a great meaſure, both this kind of aberration, and alſo that which ariſes from the ſpherical form of lenſes, by an expedient of a very different nature, viz, increaſing the

the number of eye-glaſſes. If any perſon, ſays he, would have the viſual angle of a Teleſcope to contain 20 degrees, the extreme pencils of the field muſt be bent or refracted in an angle of 10 degrees; which, if it be performed by one eye-glaſs, will cauſe an aberration from the figure, in proportion to the cube of that angle: but if two glaſſes be ſo proportioned and ſituated, as that the refraction may be equally divided between them, they will each of them produce a refraction equal to half the required angle; and therefore, the aberration being in this caſe proportional to double the cube of half the angle, will be but a 4th part of that which is in proportion to the cube of the whole angle; becauſe twice the cube of 1 is but $\frac{1}{4}$ of the cube of 2: ſo that the aberration from the figure, where two eye-glaſſes are rightly proportioned, is but a 4th part of what it muſt unavoidably be, where the whole is performed by a ſingle eye-glaſs. By the ſame way of reaſoning, when the refraction is divided among three glaſſes, the aberration will be found to be but the 9th part of what would be produced from a ſingle glaſs; becauſe 3 times the cube of 1 is but the 9th part of the cube of 3. Whence it appears, that by increaſing the number of eye-glaſſes, the indiſtinctneſs, near the borders of the field of a Teleſcope, may be very much diminiſhed, though not entirely taken away.

The method of correcting the errors ariſing from the different refrangibility of light, is of a different conſideration from the former: for, whereas the errors from the figure can only be diminiſhed in a certain proportion to the number of glaſſes, in this they may be entirely corrected, by the addition of only one glaſs; as we find in the aſtronomical Teleſcope, that two eye-glaſſes, rightly proportioned, will cauſe the edges of objects to appear free from colours quite to the borders of the field. Alſo, in the day teleſcope, where no more than two eye-glaſſes are abſolutely neceſſary for erecting the object, we find, by the addition of a third rightly ſituated, that the colours, which would otherwiſe confuſe the image, are entirely removed: but this muſt be underſtood with ſome limitation; for though the different colours, which the extreme pencils muſt neceſſarily be divided into by the edges of the eye-glaſſes, may in this manner be brought to the eye in a direction parallel to each other, ſo as, by its humours, to be converged to a point in the retina, yet if the glaſſes exceed a certain length, the colours may be ſpread too wide to be capable of being admitted through the pupil or aperture of the eye; which is the reaſon that, in long Teleſcopes, conſtructed in the common way, with three eye-glaſſes, the field is always very much contracted.

Theſe conſiderations firſt ſet Mr. Dollond upon contriving how to enlarge the field, by increaſing the number of eye-glaſſes, without any hindrance to the diſtinctneſs or brightneſs of the image: and though others had been about the ſame work before, yet obſerving that the five-glaſs Teleſcopes, ſold in the ſhops, would admit of farther improvement, he endeavoured to conſtruct one with the ſame number of glaſſes in a better manner; which ſo far anſwered his expectations, as to be allowed by the beſt judges to be a conſiderable improvement on the former. Encouraged by this ſucceſs, he reſolved to try if he could not make ſome farther enlargement of the field, by the addition of another glaſs, and by placing and proportioning the glaſſes in ſuch a manner, as to correct the aberrations as much as poſſible, without any detriment to the diſtinctneſs: and at laſt he obtained as large a field as is convenient or neceſſary, and that even in the longeſt Teleſcopes that can be made. Theſe Teleſcopes, with 6 glaſſes, having been well received both at home and abroad, the author has ſettled the date of the invention in a letter addreſſed to Mr. Short, and read at the Royal Society, March 1, 1753. Philoſ. Tranſ. vol. 48, art. 14.

Of the Achromatic Teleſcopes, invented by Mr. Dollond, there are ſeveral different ſizes, from one foot to 8 feet in length, made and ſold by his ſons P. and J. Dollond. In the 17-inch improved Achromatic Teleſcope, the object-glaſs is compoſed of three glaſſes, viz, two convex of crown-glaſs, and one concave of white flint-glaſs: the focal diſtance of this combined object-glaſs is about 17 inches, and the diameter of the aperture 2 inches. There are 4 eye-glaſſes contained in the tube, to be uſed for land objects; the magnifying power with theſe is near 50 times; and they are adjuſted to different ſights, and to different diſtances of the object, by turning a finger ſcrew at the end of the outer tube. There is another tube, containing two eye-glaſſes that magnify about 70 times, for aſtronomical purpoſes. The Teleſcope may be directed to any object by turning two ſcrews in the ſtand on which it is fixed, the one giving a vertical motion, and the other a horizontal one. The ſtand may be incloſed in the inſide of the braſs tube.

The object-glaſs of the $2\frac{1}{2}$ and $3\frac{1}{4}$ feet Teleſcopes is compoſed of two glaſſes, one convex of crown glaſs, and the other concave of white flint glaſs; and the diameters of their apertures are 2 inches and $2\frac{3}{4}$ inches. Each of them is furniſhed with two tubes; one for land objects, containing four eye-glaſſes, and another with two eye-glaſſes for aſtronomical uſes. They are adjuſted by buttons on the outſide of the wooden tube; and the vertical and horizontal motions are given by joints in the ſtands. The magnifying power of the leaſt of theſe Teleſcopes, with the eye-glaſs for land objects, is near 50 times, and with thoſe for aſtronomical purpoſes, 80 times; and that of the greateſt for land objects is near 70 times, but for aſtronomical obſervations 80 and 130 times; for this has two tubes, either of which may be uſed as occaſion requires. This Teleſcope is alſo moved by a ſcrew and rackwork, and the ſcrew is turned by means of a Hook's joint.

Theſe opticians alſo conſtruct an Achromatic pocket perſpective glaſs, or Galilean Teleſcope; ſo contrived, that all the different parts are put together and contained in one piece $4\frac{1}{2}$ inches long. This ſmall Teleſcope is furniſhed with 4 concave eye-glaſſes, the magnifying powers of which are 6, 12, 18, and 28 times. With the greateſt power of this Teleſcope, the ſatellites of Jupiter and the ring of Saturn may be eaſily ſeen. They have alſo contrived an Achromatic Teleſcope, the ſliding tubes of which are made of very thin braſs, which paſs through ſprings or tubes; the outſide tube being either of mahogany or braſs. Theſe Teleſcopes, which from their convenience for gentlemen in the army are called military Teleſcopes, have 4 convex eye-glaſſes,

glaſſes, whoſe ſurfaces and focal lengths are ſo proportioned, as to render the field of view very large. They are of 4 different lengths and ſizes, uſually called one foot, 2, 3, and 4 feet: the firſt is 14 inches when in uſe, and 5 inches when ſhut up, having the aperture of the object-glaſs $1\frac{1}{10}$ inch, and magnifying 22 times: the ſecond 28 inches for uſe, 9 inches ſhut up, the aperture $1\frac{7}{10}$ inch, and magnifying 35 times; the third 40 inches, and 10 inches ſhut, with the aperture 2 inches, and magnifying 45 times; and the fourth 52 inches, and 14 inches ſhut, with the aperture $2\frac{3}{4}$ inches, and magnifying 55 times.

Mr. Euler, who, in a memoir of the Academy of Berlin for the year 1757, p. 323, had calculated the effects of all poſſible combinations of lenſes in Teleſcopes and microſcopes, publiſhed another long memoir on the ſubject of theſe Teleſcopes, ſhewing with preciſion of what advantages they are naturally capable. See Miſcel. Taurin. vol. 3, par. 2, pag. 92.

Mr. Caleb Smith, having paid much attention to the ſubject of ſhortening and improving Teleſcopes, thought he had found it poſſible to rectify the errors which ariſe from the different degrees of refrangibility, on the principle that the ſines of refraction of rays differently refrangible, are to one another in a given proportion, when their ſines of incidence are equal; and the method he propoſed for this purpoſe, was to make the ſpecula of glaſs, inſtead of metal, the two ſurfaces having different degrees of concavity. But it does not appear that this ſcheme was ever carried into practice. See Philoſ. Tranſ. number 456, pa. 326, or Abr. vol. 8, pa. 113.

The ingenious Mr. Ramſden has lately deſcribed a new conſtruction of eye-glaſſes for ſuch Teleſcopes as may be applied to mathematical inſtruments. The conſtruction which he propoſes, is that of two plano-convex lenſes, both of them placed between the eye and the obſerved image formed by the object-glaſs of the inſtrument, and thus correcting not only the aberration ariſing from the ſpherical figure of the lenſes, but alſo that ariſing from the different refrangibility of light. For a more particular account of this conſtruction, its principle, and its effects, ſee Philoſ. Tranſ. vol. 73, art. 5.

A conſtruction, ſimilar at leaſt in its principle to that above, is aſcribed, in the Synopſis Optica Honorati Fabri, to Euſtachio Divini, who placed two equal narrow plano-convex lenſes, inſtead of one eye lens, to his Teleſcopes, which touched at their vertices; the focus of the object-glaſs coinciding with the centre of the plano-convex lens next it. And this, it is ſaid, was done at once both to make the rays that come parallel from the object fall parallel upon the eye, to exclude the colours of the rainbow from it, to augment the angle of ſight, the field of view, the brightneſs of the object, &c. This was alſo known to Huygens, who ſometimes made uſe of the ſame conſtruction, and gives the theory of it in his Dioptrics. See Hugenii Opera Varia, vol. 4, ed. 1728.

TELESCOPE, *Reflecting*, or *Catoptric*, or *Catadioptric*, is a Teleſcope which, inſtead of lenſes, conſiſts chiefly of mirrors, and exhibits remote objects by reflection inſtead of refraction.

A brief account of the hiſtory of the invention of this important and uſeful Teleſcope, is as follows. The ingenious Mr. James Gregory, of Aberdeen, has been commonly conſidered as the firſt inventor of this Teleſcope.—But it ſeems the firſt thought of a reflector had been ſuggeſted by Merſenne, about 20 years before the date of Gregory's invention: a hint to this purpoſe occurs in the 7th propoſition of his Catoptrics, which was printed in 1651: and it appears from the 3d and 20th letters of Deſcartes, in vol. 2 of his Letters, which it is ſaid were written in 1639, though they were not publiſhed till the year 1666, that Merſenne propoſed a Teleſcope with ſpecula to Deſcartes in that correſpondence; though indeed in a manner ſo very unſatisfactory, that Deſcartes, who had given particular attention to the improvement of the Teleſcope, was ſo far from approving the propoſal, that he endeavoured to convince Merſenne of its fallacy. This point has been largely diſcuſſed by Le Roi in the Encyclopedia, art. Teleſcope, and by Montucla in his Hiſt. des Mathem. tom. 2, p. 643.

Whether Gregory had ſeen Merſenne's treatiſe on optics and catoptrics, and whether he availed himſelf of the hint there ſuggeſted, or not, perhaps cannot now be determined. He was led however to the invention by ſeeking to correct two imperfections in the common Teleſcope: the firſt of theſe was its too great length, which made it troubleſome to manage; and the ſecond was the incorrectneſs of the image. It had been already demonſtrated, that a pencil of rays could not be collected in a ſingle point by a ſpherical lens; and alſo, that the image tranſmitted by ſuch a lens would be in ſome degree incurvated. Theſe inconveniences he thought might be obviated by ſubſtituting for the object-glaſs a metallic ſpeculum, of a parabolical figure, to receive the image, and to reflect it towards a ſmall ſpeculum of the ſame metal; this again was to return the image to an eye-glaſs placed behind the great ſpeculum, which was, for that purpoſe, to be perforated in its centre. This conſtruction he publiſhed in 1663, in his Optica Promota. But as Gregory, according to his own account, poſſeſſed no mechanical ſkill, and could not find a workman capable of realizing his invention, after ſome fruitleſs trials, he was obliged to give up the thoughts of bringing Teleſcopes of this kind into uſe.

Sir Iſaac Newton however interpoſed, to ſave this excellent invention from periſhing, and to bring it forward to maturity. Having applied himſelf to the improvement of the Teleſcope, and imagining that Gregory's ſpecula were neither very neceſſary, nor likely to be executed, he began with proſecuting the views of Deſcartes; who aimed at making a more perfect image of an object, by grinding lenſes, not to the figure of a ſphere, but to that formed from one of the conic ſections. But, in the year 1666, having diſcovered the different refrangibility of the rays of light, and finding that the errors of Teleſcopes, ariſing from that cauſe alone, were much more conſiderable than ſuch as were occaſioned by the ſpherical figure of lenſes, he was conſtrained to turn his thoughts to reflectors. The plague however interrupted his progreſs in this buſineſs; ſo that it was towards the end of 1668, or in the beginning of 1669, when, deſpairing of perfecting Teleſcopes by means of refracted light, and

and recurring to the conſtruction of reflectors, he ſet about making his own ſpecula, and early in the year 1672 completed two ſmall reflecting Teleſcopes. In theſe he ground the large ſpeculum into a ſpherical concave, being unable to accompliſh the parabolic form propoſed by Gregory; but though he then deſpaired of performing that work by geometrical rules, yet (as he writes in a letter that accompanied one of theſe inſtruments, which he preſented to the Royal Society) he doubted not but that the thing might in ſome meaſure be accompliſhed by mechanical devices. With a perſeverance equal to his ingenuity, he, in a great meaſure, overcame another difficulty, which was to find a metallic ſubſtance that would be of a proper hardneſs, have the feweſt pores, and receive the ſmoothest poliſh: this difficulty he deemed almoſt inſurmountable, when he conſidered that every irregularity in a reflecting ſurface would make the rays of light deviate 5 or 6 times more out of their due courſe, than the like irregularities in a refracting ſurface. After repeated trials, he at laſt found a compoſition that anſwered in ſome degree, leaving it to thoſe who ſhould come after him to find a better. Theſe difficulties have accordingly been ſince obviated by other artiſts, particularly by Dr. Mudge, the rev. Mr. Edwards, and Dr. Herſchel, &c. Newton having ſucceeded ſo far, he communicated to the Royal Society a full and ſatisfactory account of the conſtruction and performance of his Teleſcope. The Society, by their ſecretary Mr. Oldenburgh, tranſmitted an account of the diſcovery to Mr. Huygens, celebrated as a diſtinguiſhed improver of the refractor; who not only replied to the Society in terms expreſſing his high approbation of the invention, but drew up a favourable account of the new Teleſcope, which he cauſed to be publiſhed in the Journal des Sçavans of the year 1672, and by this mode of communication it was ſoon known over Europe. See Huygenii Opera Varia, tom. 4.

Notwithſtanding the excellence and utility of this contrivance, and the honourable manner in which it was announced to the world, it ſeems to have been greatly neglected for nearly half a century. Indeed when Newton had publiſhed an account of his Teleſcopes in the Philoſ. Tranſ. M. Caſſegrain, a Frenchman, in the Journal des Sçavans of 1672, claimed the honour of a ſimilar invention, and ſaid, that, before he heard of Newton's improvement, he had hit upon a better conſtruction, by uſing a ſmall convex mirror inſtead of the reflecting priſm. This Teleſcope, which was the Gregorian one diſguiſed, the large mirror being perforated, and which it is ſaid was never executed by the author, is much ſhorter than the Newtonian; and the convex mirror, by diſperſing the rays, ſerves greatly to increaſe the image made by the large concave mirror.

Newton made many objections to Caſſegrain's conſtruction, but ſeveral of them equally affect that of Gregory, which has been found to anſwer remarkably well in the hands of good artiſts.

Dr. Smith took the pains to make many calculations of the magnifying power, both of Newton's and Caſſegrain's Teleſcopes, in order to their farther improvement, which may be ſeen in his Optics, Rem. p. 97.

Mr. Short, it is alſo ſaid, made ſeveral Teleſcopes on the plan of Caſſegrain.

Dr. Hook conſtructed a Reflecting Teleſcope (mentioned by Dr. Birch in his Hiſt. of the Royal Soc. vol. 3, p. 122) in which the great mirror was perforated, ſo that the ſpectator looked directly towards the object, and it was produced before the Royal Society in 1674. On this occaſion it was ſaid that this conſtruction was firſt propoſed by Merſenne, and afterwards repeated by Gregory, but that it never had been actually executed before it was done by Hook. A deſcription of this inſtrument may be ſeen in Hook's Experiments, by Derham, p. 269.

The Society alſo made an unſucceſsful attempt, by employing an artificer to imitate the Newtonian conſtruction; however, about half a century after the invention of Newton, a Reflecting Teleſcope was produced to the world, of the Newtonian conſtruction, which the venerable author, ere yet he had finiſhed his very diſtinguiſhed courſe, had the ſatisfaction to find executed in ſuch a manner, as left no room to fear that the invention would longer continue in obſcurity. This effectual ſervice to ſcience was accompliſhed by Mr. John Hadley, who, in the year 1723, preſented to the Royal Society a Teleſcope, which he had conſtructed upon Newton's plan. The two Teleſcopes which Newton had made, were but 6 inches long, were held in the hand for viewing objects, and in power were compared to a 6-feet refractor: but the radius of the ſphere, to which the principal ſpeculum of Hadley's was ground, was 10 feet $5\frac{1}{4}$ inches, and conſequently its focal length was $62\frac{5}{8}$ inches. In the Philoſ. Tranſ. Abr. vol. 6, p. 133, may be ſeen a drawing and deſcription of this Teleſcope, and alſo of a very ingenious but complex apparatus, by which it was managed. One of theſe Teleſcopes, in which the focal length of the large mirror was not quite $5\frac{1}{4}$ feet, was compared with the celebrated Huygenian Teleſcope, which had the focal length of its object-glaſs 123 feet; and it was found that the former would bear ſuch a charge, as to make it magnify the object as many times as the latter with its due charge; and that it repreſented objects as diſtinctly, though not altogether ſo clear and bright. With this Reflecting Teleſcope might be ſeen whatever had been hitherto diſcovered by the Huygenian, particularly the tranſits of Jupiter's ſatellites, and their ſhades over the diſk of Jupiter, the black liſt in Saturn's ring, and the edge of the ſhade of Saturn caſt upon his ring. Five ſatellites of Saturn were alſo obſerved with this Teleſcope, and it afforded other obſervations on Jupiter and Saturn, which confirmed the good opinion which had been conceived of it by Pound and Bradley.

Mr. Hadley, after finiſhing two Teleſcopes of the Newtonian conſtruction, applied himſelf to make them in the Gregorian form, in which the large mirror is perforated. This ſcheme he completed in the year 1726.

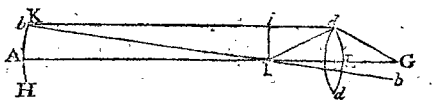
Dr. Smith prefers the Newtonian conſtruction to that of Gregory; but if long experience be admitted as a final judge in ſuch matters, the ſuperiority muſt be adjudged to the latter; as it is now, and has been for many years paſt, the only inſtrument in requeſt.

Mr. Hadley ſpared no pains, after having completed his conſtruction, to inſtruct Mr. Molyneux and Dr. Bradley; and when theſe gentlemen had made a good proficiency in the art, being deſirous that theſe Teleſcopes ſhould become more public, they liberally communicated to ſome of the chief inſtrument-makers of London, the knowledge they had acquired from him: and thus, as it is reaſonable to imagine, reflectors were completed by other and better methods than even thoſe in which they had been inſtructed. Mr. James Short in particular ſignalized himſelf as early as the year 1734, by his work in this way. He at firſt made his ſpecula of glaſs; but finding that the light reflected from the beſt glaſs ſpecula was much leſs than the light reflected from metallic ones, and that glaſs was very liable to change its form by its own weight, he applied himſelf to improve metallic ſpecula; and, by giving particular attention to the curvature of them, he was able to give them greater apertures than other workmen could do; and by a more accurate adjuſtment of the ſpecula, &c, he greatly improved the whole inſtrument. By ſome which he made, in which the larger mirror was 15 inches focal diſtance, he and ſome other perſons were able to read in the Philoſ. Tranſ. at the diſtance of 500 feet; and they ſeveral times ſaw the five ſatellites of Saturn together, which greatly ſurpriſed Mr. Maclaurin, who gave this account of it, till he found that Caſſini had ſometimes ſeen them all with a 17 feet refractor. Short's Teleſcopes were all of the Gregorian conſtruction. It is ſuppoſed that he diſcovered a method of giving the parabolic figure to his great ſpeculum; a degree of perfection which Gregory and Newton deſpaired of attaining, and which Hadley it ſeems had never attempted in either of his Teleſcopes. However, the ſecret of working that configuration, whatever it was, it ſeems died with that ingenious artiſt. Though lately in ſome degree diſcovered by Dr. Mudge and others.

On the Hiſtory of Reflecting Teleſcopes, ſee Dr. David Gregory's Elem. of Catopt. and Dioptr. Appendix by Deſaguliers: Smith's Optics, book 3, c. 2, Rem. on art. 489: and Sir John Pringle's excellent Diſcourſe on the Invention &c of the Reflecting Teleſcope.

Conſtruction of the Reflecting Teleſcope of the Newtonian form.—Let ABCD (fig. 2, pl. 32) be a large tube, open at AD, and cloſed at BC, and its length at leaſt equal to the diſtance of the focus from the metallic ſpherical concave ſpeculum GH placed at the end BC. The rays EG, FH, &c, proceeding from a remote object PR, interſect one another ſomewhere before they enter the tube, ſo that EG and *eg* are thoſe that come from the lower part of the object, and *fh* FH from its upper part: theſe rays, after falling on the ſpeculum GH, will be reflected ſo as to converge and meet in *mn*, where they will form a perfect image of the object. But as this image cannot be ſeen by the ſpectator, they are intercepted by a ſmall plane metallic ſpeculum KK, interſecting the axis at an angle of 45°, by which the rays tending to *m*, *n*, will be reflected towards a hole LL in the ſide of the tube, and the image of the object will be thus formed in *q*S; which image will be leſs diſtinct, becauſe ſome of the rays which would otherwiſe fall on the concave ſpeculum GH, are intercepted by the plane ſpeculum: it will nevertheleſs appear pretty diſtinct, becauſe the aperture AD of the tube, and the ſpeculum GH, are large. In the lateral hole LL is fixed a convex lens, whoſe focus is at S*q*; and therefore this lens will refract the rays that proceed from any point of the image, ſo as at their exit they will appear parallel, and thoſe that proceed from the extreme points S, *q*, will converge after refraction, and form an angle at O, where the eye is placed; which will ſee the image S*q*, as if it were an object, through the lens LL: conſequently the object will appear enlarged, inverted, bright, and diſtinct. In LL may be placed lenſes of different convexities, which, by being moved nearer to the image and farther from it, will repreſent the object more or leſs magnified, if the ſurface of the ſpeculum GH be of a figure truly ſpherical. If, inſtead of one lens LL, three lenſes be diſpoſed in the ſame manner with the three eye-glaſſes of the refracting Teleſcope, the object will appear erect, but leſs diſtinct than when it is obſerved with one lens. On account of the poſition of the eye in this Teleſcope, it is extremely difficult to direct the inſtrument towards any object: Huygens therefore firſt thought of adding to it a ſmall refracting Teleſcope, having its axis parallel to that of the reflector: this is called a *finder* or *director*. The Newtonian Teleſcope is alſo furniſhed with a ſuitable apparatus for the commodious uſe of it.

To determine the magnifying power of this Teleſcope, it is to be conſidered that the plane ſpeculum KK is of no uſe in this reſpect: let us then ſuppoſe that one ray proceeding from the object coincides with the axis GLIA of the lens and ſpeculum; let *bb* be



another ray proceeding from the lower extremity of the object, and paſſing through the focus I of the ſpeculum KH; this will be reflected in the direction *bid*, parallel to the axis GLA, and falling on the lens *d*L*d*, will be refracted to G, ſo that GL will be equal to LI, and *d*G = *d*I. To the naked eye the object would appear under the angle I*bi* = *b*IA; but by means of the Teleſcope it appears under the angle *d*GL = *d*IL = I*di*: and the angle I*di* is to the angle I*bi* as *b*I to I*d*; conſequently the apparent magnitude by the Teleſcope, is to that with the naked eye, as the diſtance of the focus of the ſpeculum from the ſpeculum, to the diſtance of the focus of the lens from the lens.

Conſtruction of the Gregorian Reflecting Teleſcope.—Let TYYT (fig. 3, pl. 32) be a braſs tube, in which L*ld*D is a metallic concave ſpeculum, perforated in the middle at X; and EF a leſs concave mirror, ſo fixed by the arm or ſtrong wire RT, which is moveable by means of a long ſcrew on the outſide of the tube, as to be moved nearer to, or farther from the larger ſpeculum L*ld*D; its axis being kept in the ſame line with that of the great one. Let AB repreſent a very remote object, from each part of which iſſue pencils of rays, as *cd*, CD, from A the upper extremity of the object,

object, and IL, *il*, from the lower part B; the rays IL, CD, from the extremities, croſſing one another before they enter the tube. Theſe rays, falling upon the larger mirror LD, are reflected from it into the focus KH, where they form an inverted image of the object AB, as in the Newtonian Teleſcope. From this image the rays, iſſuing as from an object, fall upon the ſmall mirror EF, the centre of which is at *e*, ſo that after reflection they would meet in their foci at QQ, and there form an erect image. But ſince an eye at that place could ſee but a ſmall part of an object, in order to bring rays from more diſtant parts of it into the pupil, they are intercepted by the plano-convex lens MN, by which means a ſmaller erect image is formed at PV, which is viewed through the meniſcus SS, by an eye at O. This meniſcus both makes the rays of each pencil parallel, and magnifies the image PV. At the place of this image all the foreign rays are intercepted by the perforated partition ZZ. For the ſame reaſon the hole near the eye O is very narrow. When nearer objects are viewed by this Teleſcope, the ſmall ſpeculum EF is removed to a greater diſtance from the larger LD, ſo that the ſecond image may be always formed in PV: and this diſtance is to be adjuſted (by means of the ſcrew on the outſide of the great tube) according to the form of the eye of the ſpectator. It is alſo neceſſary that the axis of the Teleſcope ſhould paſs through the middle of the ſpeculum EF, and its centre, the centre of the ſpeculum LL, and the middle of the hole X, the centres of the lenſes MN, SS, and the hole near O. As the hole X in the ſpeculum LL can reflect none of the rays iſſuing from the object, that part of the image which correſponds to the middle of the object, muſt appear to the obſerver more dark and confuſed than the extreme parts of it. Beſides, the ſpeculum EF will alſo intercept many rays proceeding from the object; and therefore, unleſs the aperture TT be large, the object muſt appear in ſome degree obſcure.

The magnifying power of this Teleſcope is eſtimated in the following manner. Let LD be the larger mirror (fig. 3, pl. 31), having its focus at G, and aperture in A; and FF the ſmall mirror with the focus of parallel rays in I, and the axis of both the ſpecula and lenſes MN, SS, be in the right line DIGAOK. Let *bb* be a ray of light coming from the lower extremity of a very diſtant viſible object, paſſing through the focus G, and falling upon the point *b* of the ſpeculum LD; which, after being reflected from *b* to F in a direction parallel to the axis of the mirror DAK, is reflected by the ſpeculum F ſo as to paſs through the focus I in the direction FIN to N, at the extremity of the lens MN, by which it would have been refracted to K; but by the interpoſition of another lens SS is brought to O, ſo that the eye in O ſees half the object under the angle TOS. The angle G*b*F, or AG*b*, under which the object is viewed by the naked eye, is to SOT under which it is viewed by the Teleſcope, in the ratio of G*b*F to IF*i* = *n*IN, of *n*IN to NK*n*, and of NK*n* to SOT.

But G*b*F : IF*i* :: DI : GA,
and *n*IN : *n*KN :: *n*K : *n*I,
and *n*KN : SOT :: TO : TK;

therefore G*b*F : SOT :: DI × *n*K × TO : GA × *n*I × TK. Muſſchenbroek's Introd. vol. 2, p. 819.

In Reflecting Teleſcopes of different lengths, a given object will appear equally bright and equally diſtinct, when their linear apertures, and alſo their linear breadths, are as the 4th roots of the cubes of their lengths; and conſequently when the focal diſtances of their eye-glaſſes are alſo as the 4th roots of their lengths. See the demonſtration of this propoſition in Smith's Optics, art. 361.

Hence he has deduced a rule, by which he has computed the following table for Teleſcopes of different lengths, taking, for a ſtandard, the middle eye-glaſs and aperture of Hadley's Reflecting Teleſcope, deſcribed in Philoſ. Tranſ. number 376 and 378: the focal diſtances and linear apertures being given in 1000th parts of an inch.

Table for Teleſcopes of different Lengths.

Length of the Tel. or focal diſt. of the conc.	Focal diſt. of the Eye-glaſs.	Linear amplifying or magnifying power.	Linear aperture of the concave metal.
feet	inches	- - -	inches
½	0·167	36	0·864
1	0·199	69	1·440
2	0·236	102	2·448
3	0·261	138	3·312
4	0·281	171	4·104
5	0·297	202	4·843
6	0·311	232	5·568
7	0·323	260	6·240
8	0·334	287	6·888
9	0·344	314	7·536
10	0·353	340	8·160
11	0·362	365	8·760
12	0·367	390	9·360
13	0·377	414	9·936
14	0·384	437	10·488
15	0·391	460	11·040
16	0·397	483	11·592
17	0·403	506	12·143

Mr. Hadley's Teleſcope, above mentioned, magnified 228 or 230 times; but we are informed that an object-metal of 3¼ feet focal diſtance was wrought by Mr. Haukſbee to ſo great a perfection, as to magnify 226 times, and therefore it was ſcarcely inferior to Hadley's of 5½ feet. If Haukſbee's Teleſcope be taken for a new ſtandard, it follows that a ſpeculum of one foot focal diſtance ought to magnify 93 times, whereas the above table allows it but 60. Now $\frac{93}{60} = 1{\cdot}55$, and the given column of magnifying powers multiplied by this number, gives a new column, ſhewing how much the object-metals ought to magnify if wrought up to the perfection of Haukſbee's. And thus a new table may be eaſily made for this or any other more perfect ſtandard, taking alſo the new eye-glaſſes and apertures in the ſame ratio to one another as the old ones have in this table. Smith's Optics, Rem. p. 79.

The magnifying power of any Teleſcope may be eaſily found by experiment, viz, by looking with one eye through the Teleſcope upon an object of known dimenſions, and at a given diſtance, and throwing the image upon another object ſeen with the naked eye. Dr. Smith has given a particular account of the proceſs, Rem. p. 79.

But the eaſieſt method of all, is to meaſure the diameter of the aperture of the object-glaſs, and that of the little image of it, which is formed at the place of the eye. For the proportion between theſe gives the ratio of the magnifying power, provided no part of the original pencil be intercepted by the bad conſtruction of the Teleſcope. For in all caſes the magnifying power of Teleſcopes, or microſcopes, is meaſured by the proportion of the diameter of the original pencil, to that of the pencil which enters the eye. Prieſtley's Hiſt. of Light, p. 747.

But the moſt conſiderable, and indeed truly aſtoniſhing magnifying powers, that have ever been uſed, are thoſe of Dr. Herſchel's Reflecting Teleſcopes. Some account of theſe, and of the diſcoveries made by them, has been already introduced under the article Star. For his method of aſcertaining them, ſee Philoſ. Tranſ. vol. 72, pa. 173 &c. See alſo ſeveral of the other late volumes of the Philoſ. Tranſ.

Dr. Herſchel obſerves, that though opticians have proved, that two eye-glaſſes will give a more correct image than one, he has always (from experience) perſiſted in refuſing the aſſiſtance of a ſecond glaſs, which is ſure to introduce errors greater than thoſe he would correct. "Let us reſign, ſays he, the double eye-glaſs to thoſe who view objects merely for entertainment, and who muſt have an exorbitant field of view. To a philoſopher, this is an unpardonable indulgence. I have tried both the ſingle and double eye-glaſs of equal powers, and always found that the ſingle eye-glaſs had much the ſuperiority in point of light and diſtinctneſs. With the double eye-glaſs I could not ſee the belts in Saturn, which I very plainly ſaw with the ſingle one. I would however except all thoſe caſes where a large field is abſolutely neceſſary, and where power joined to diſtinctneſs is not the ſole object of our view." Philoſ. Tranſ. vol. 72, p. 95.

Mr. Green of Deptford has lately added both to the reflecting and refracting Teleſcope an apparatus, which fits it for the purpoſes of ſurveying, levelling, meaſuring angles and diſtances, &c. See his Deſcription and Uſe of the improved Reflecting and Refracting Teleſcopes, and Scale of Surveying &c, 1778.—Mr. Ramſden too has lately adapted Teleſcopes to the like purpoſe of meaſuring diſtances from one ſtation, &c.

Meridian TELESCOPE, is one that is fixed at right angles to an axis, and turned about it in the plane of the meridian; and is otherwiſe called a *tranſit inſtrument*.—The common uſe of it is to correct the motion of a clock or watch, by daily obſerving the exact time when the ſun or a ſtar comes to the meridian. It ſerves alſo for a variety of other uſes. The tranſverſe axis is placed horizontal by a ſpirit level. For the farther deſcription and method of fixing this inſtrument by means of its levels &c, ſee Smith's Optics, p. 321. See alſo TRANSIT *Inſtrument*.

TELESCOPICAL *Stars*, are ſuch as are not viſible to the naked eye, being only diſcernible by means of a teleſcope. See STAR.

All ſtars leſs than thoſe of the 6th magnitude, are Teleſcopic to an ordinary eye.

TEMPERAMENT, in Muſic, uſually denotes a rectifying or amending the falſe or imperfect concords, by transferring to them part of the beauty of the perfect ones.

TENACITY, in Natural Philoſophy, is that quality of bodies by which they ſuſtain a conſiderable preſſure or force without breaking; and is the oppoſite quality to fragility or brittleneſs. Mem. Acad. Berlin. 1745, p. 47.

TENAILLE, in Fortification, a kind of outwork, conſiſting of two parallel ſides, with a front, having a re-entering angle. In fact, that angle, and the faces which compoſe it, are the Tenaille.

The Tenaille is of two kinds, *ſimple* and *double*.

Simple or *Single* TENAILLE, is a large outwork, conſiſting of two faces or ſides, including a re-entering angle.

Double, or *Flanked* TENAILLE, is a large outwork, conſiſting of two ſimple Tenailles, or three faliant and two re-entering angles.

The great defects of Tenailles are, that they take up too much room, and on that account are advantageous to the enemy; that the re-entering angle is not defended; the height of the parapet preventing the ſeeing down into it, ſo that the enemy can lodge there under cover; and the ſides are not ſufficiently flanked. For theſe reaſons, Tenailles are now moſtly excluded out of fortification by the beſt engineers, and never made but where time does not ſerve to form a hornwork.

TENAILLE *of the Place*, is the front of the place, comprehended between the points of two neighbouring baſtions; including the curtain, the two flanks raiſed on the curtain, and the two ſides of the baſtions which face one another. So that the Tenaille, in this ſenſe, is the ſame with what is otherwiſe called the *face of a fortreſs*.

TENAILLE *of the Ditch*, is a low work raiſed before the curtain, in the middle of the foſs or ditch; the parapet of which is only 2 or 3 feet higher than the level ground of the ravelin.

The uſe of Tenailles in general, is to defend the bottom of the ditch by a grazing fire, and likewiſe the level ground of the ravelin, which cannot be ſo conveniently defended from any other place. The firſt ſort do not defend the ditch ſo well as the others, becauſe they are too oblique a defence; but as they are not ſubject to be enfiladed, Vauban has generally preferred them in the fortifying of places. Thoſe of the ſecond ſort defend the ditch much better than the firſt, and add a low flank to thoſe of the baſtions; but as theſe flanks are liable to be enfiladed, they have not been much uſed. This defect however might be remedied, by making them ſo as to be covered by the extremities of the parapets of the oppoſite ravelins, or by ſome other work. And the ſame thing may be ſaid of the third ſort as of the ſecond.

The *Ram's-horn* is a curved Tenaille, raiſed in the foſs before the flanks, and preſenting its convexity to the

the covered way. This work ſeems preferable to either of the other Tenailles, both on account of its ſimplicity, and the defence for which it is conſtructed.

TENAILLONS, in Fortification, are works conſtructed on each ſide of the ravelin, much like the lunettes. They differ, as one of the faces of a Tenaillon is in the direction of the ravelin, whereas that of the lunette is perpendicular to it.

TENOR, in Muſic, the firſt mean or middle part, or that which is the ordinary pitch, or Tenor, of the voice, when not either raiſed to the treble, or lowered to the baſs.

TENSION, the ſtate of a thing tight, or ſtretched. Thus, animals ſuſtain and move themſelves by the Tenſion of their muſcles and nerves. A chord, or ſtring, gives an acuter or deeper ſound, as it is in a greater or leſs degree of Tenſion, that is, more or leſs ſtretched or tightened.

TERM, in Geometry, is the extreme of any magnitude, or that which bounds and limits its extent. So the Terms of a line, are points; of a ſuperficies, lines; of a ſolid, ſuperficies.

TERMS, of an equation, or of any quantity, in Algebra, are the ſeveral names or members of which it is compoſed, ſeparated from one another by the ſigns + or −. So, the quantity $ax + 2bc - 3ax^2$, conſiſts of the three Terms ax and $2bc$ and $3ax^2$.

In an equation, the Terms are the parts which contain the ſeveral powers of the ſame unknown letter or quantity: for if the ſame unknown quantity be found in ſeveral members in the ſame degree or power, they ſhall paſs but for one Term, which is called a compound one, in diſtinction from a ſimple or ſingle Term. Thus, in the equation $x^3 + \overline{a - 3b} \cdot x^2 - acx = b^3$, the four terms are x^3 and $\overline{a - 3b} \cdot x^2$ and acx and b^3; of which the ſecond Term $\overline{a - 3b} \cdot x^2$ is compound, and the other three are ſimple Terms.

TERMS, of a Product, or of a Fraction, or of a Ratio, or of a Proportion, &c, are the ſeveral quantities employed in forming or compoſing them. Thus, the Terms

of the product ab, are a and b;
of the fraction $\frac{5}{8}$, are 5 and 8;
of the ratio 6 to 7, are 6 and 7;
of the proportion $a : b :: 5 : 9$, are a, b, 5, 9.

TERMS are alſo uſed for the ſeveral times or ſeaſons of the year in which the public colleges or univerſities, or courts of law, are open, or ſit. Such are the Oxford and Cambridge Terms; alſo the Terms for the courts of King's-Bench, Common Pleas, and the Exchequer, which are the high courts of common law. But the high court of Parliament, the Chancery, and inferior courts, do not obſerve the Terms.—The reſt of the year, out of Term-time, is called *vacation*.

There are four law Terms in the year; viz,

Hilary-Term, which, at London, begins the 23d day of January, and ends the 12th of February.

Eaſter-Term, which begins the 3d Wedneſday after Eaſter-day, and ends on the Monday next after Aſcenſion-day.

Trinity-Term, which begins the Friday next after Trinity-Sunday, and ends the 4th Wedneſday after Trinity-Sunday.

Michaelmas-Term, which begins the 6th of November, and ends the 28th of November.

All theſe terms have alſo their returns, the days of which are expreſſed in the following table or ſynopſis.

Table of the Law Terms, and their Returns.

Term	Begin.	1ſt Return	2d Return	3d Return	4th Return	5th Return	End.
Hilary	January 23	January 20	January 27	February 3	February 9	- - - -	February 12
Eaſter	3 Wed. af. Eaſt.	2 Wks. af. Eaſt.	3 Wks. af. Eaſt.	4 Wks. af. Eaſt.	5 Wks. af. Eaſt.	Aſcenſ. day	Mond. af. Aſcenſ.
Trinity	Frid. af. Trin. S.	Trinity Mond.	1 Wk. af. Trin.	2 Wks. af. Trin.	3 Wks. af. Trin.	- - - -	4th Wed. af. Trin. S.
Mich.	November 6	November 3	November 12	November 18	November 25	- - - -	November 28

N. B. When the beginning or ending of any of theſe Terms happens on a Sunday, it is held on the Monday after.

Oxford TERMS. Theſe are four; which begin and end as below:

Terms	Begin.	End.
Lent Term	January 14	Sat. bef. Palm-Sund.
Eaſter Term	Wed. af. Low-Sund.	Thurſ. bef. Whitſun.
Trinity Term	Wed. af. Trin. Sund.	Sat. after the Act
Michaelmas T.	October 10	December 17

N. B. The *Act* is 1ſt Monday after the 6th of July. —When the day of the beginning or ending happens on a Sunday, the Terms begin or end the day after.

Cambridge-TERMS. Theſe are three, as below:

Terms	Begin.	End.
Lent Term	January 13	Frid. bef. Palm-Sund.
Eaſter Term	Wed. aft. Low-Sund.	Frid. aft. Commence.
Michaelmas T.	October 10	December 16

N. B. The *Commencement* is the 1ſt Tueſday in July. —There is no difference on account of the beginning or ending being Sunday.

Scottiſh

Scottiſh TERMS. In Scotland, *Candlemas Term* begins January 23d, and ends February the 12th. *Whitſuntide-Term* begins May 25th, and ends June 15th. *Lammas-Term* begins July the 20th, and ends Auguſt the 8th. *Martinmas-Term* begins November the 3d, and ends November the 29th.

Iriſh TERMS. In Ireland the Terms are the ſame as at London, except *Michaelmas-Term*, which begins October the 13th, and adjourns to November the 3d, and thence to the 6th.

TERMINATOR, in Aſtronomy, a name ſometimes given to the circle of illumination, from its property of terminating the boundaries of light and darkneſs.

TERRA, in Geography. See EARTH.

TERRA-*firma*, in Geography, is ſometimes uſed for a continent, in contradiſtinction to iſlands. Thus, Aſia, the Indies, and South America, are uſually diſtinguiſhed into Terra-firmas and iſlands.

TERRAQUEOUS, in Geography, an epithet given to our globe or earth, conſidered as conſiſting of land and water, which together conſtitute one maſs.

TERRE-PLEIN, or TERRE-PLAIN, in Fortification, the top, platform, or horizontal ſurface of the rampart, upon which the cannon are placed, and where the defenders perform their office. It is ſo called, becauſe it lies level, having only a little ſlope outwardly to counteract the recoil of the cannon. Its breadth is from 24 to 30 feet; being terminated by the parapet on the outer ſide, and inwardly by the inner talus.

TERRELLA, or little earth, is a magnet turned of a ſpherical figure, and placed ſo as that its poles, equator, &c, do exactly correſpond with thoſe of the world. It was ſo firſt called by Gilbert, as being a juſt repreſentation of the great magnetic globe we inhabit. Such a Terrella, it was ſuppoſed, if nicely poiſed, and hung in a meridian like a globe, would be turned round like the earth in 24 hours by the magnetic particles pervading it; but experience has ſhewn that this is a miſtake.

TERRESTRIAL, ſomething relating to the earth. As Terreſtrial globe, Terreſtrial line, &c.

TERTIAN; denotes an old meaſure, containing 84 gallons, ſo called becauſe it is the 3d part of a tun.

TERTIATE, in Gunnery. To Tertiate a great gun, is to examine the thickneſs of the metal at the muzzle, by which to judge of the ſtrength of the piece, and whether it be ſufficiently fortified or not.

TETRACHORD, in Muſic, called by the moderns a *fourth*, is a concord or interval of four tones.—The Tetrachord of the ancients, was a rank of four ſtrings, accounting the Tetrachord for one tone, as it is often taken in muſic.

TETRADIAPASON, or *quadruple diapaſon*, is a muſical chord, otherwiſe called a quadruple eighth, or a nine-and-twentieth.

TETRAEDRON, or TETRAHEDRON, in Geometry, is one of the five Platonic or regular bodies or ſolids, comprehended under four equilateral and equal triangles. Or it is a triangular pyramid of four equal and equilateral faces.

It is demonſtrated in geometry, that the ſide of a Tetraedron is to the diameter of its circumſcribing ſphere, as $\sqrt{2}$ to $\sqrt{3}$; conſequently they are incommenſurable.

If a denote the linear edge or ſide of a Tetraedron, b its whole ſuperficies, c its ſolidity, r the radius of its inſcribed ſphere, and R the radius of its circumſcribing ſphere; then the general relation among all theſe is expreſſed by the following equations, viz,

$$a = 2r\sqrt{6} = \tfrac{3}{2}R\sqrt{6} = \sqrt{\tfrac{1}{3}b\sqrt{3}} = \sqrt[3]{6c\sqrt{2}}.$$

$$b = 24r^2\sqrt{3} = \tfrac{8}{3}R^2\sqrt{3} = a^2\sqrt{3} = 6\sqrt[3]{c^2\sqrt{3}}.$$

$$c = 8r^3\sqrt{3} = \tfrac{8}{27}R^3\sqrt{3} = \tfrac{1}{12}a^3\sqrt{2} = \tfrac{1}{36}b\sqrt{2b\sqrt{3}}.$$

$$R = 3r = \tfrac{1}{4}a\sqrt{6} = \tfrac{1}{4}\sqrt{2b\sqrt{3}} = \tfrac{3}{2}\sqrt[3]{\tfrac{1}{3}c\sqrt{3}}.$$

$$r = \tfrac{1}{3}R = \tfrac{1}{12}a\sqrt{6} = \tfrac{1}{12}\sqrt{2b\sqrt{3}} = \tfrac{1}{2}\sqrt[3]{\tfrac{1}{3}c\sqrt{3}}.$$

See my Menſuration, pa. 248 &c, 2d ed. See alſo the articles REGULAR and BODIES.

TETRAGON, in Geometry, a quadrangle, or a figure having 4 angles. Such as a ſquare, a parallelogram, a rhombus, and a trapezium. It ſometimes alſo means peculiarly a ſquare.

TETRAGON, in Aſtrology, denotes an aſpect of two planets with regard to the earth, when they are diſtant from each other a 4th part of a circle, or 90 degrees. The Tetragon is expreſſed by the character □, and is otherwiſe called a ſquare or quartile aſpect.

TETRAGONIAS, a meteor, whoſe head is of a quadrangular figure, and its tail or train is long, thick, and uniform. It does not differ much from the meteor called *Trabs* or beam.

TETRAGONISM, a term which ſome authors uſe to expreſs the quadrature of the circle, becauſe the quadrature is the finding a ſquare equal to it.

TETRASPASTON, in Mechanics, a machine in which are four pulleys.

TETRASTYLE, in the Ancient Architecture, a building, and particularly a temple, with four columns in front.

THALES, a celebrated Greek philoſopher, and the firſt of the ſeven wiſemen of Greece, was born at Miletum, about 640 years before Chriſt. After acquiring the uſual learning of his own country, he travelled into Egypt and ſeveral parts of Aſia, to learn aſtronomy, geometry, myſtical divinity, natural knowledge or philoſophy, &c. In Egypt he met for ſome time great favour from the king, Amaſis; but he loſt it again, by the freedom of his remarks on the conduct of kings, which it is ſaid occaſioned his return to his own country, where he communicated the knowledge he had acquired to many diſciples, among the principal of whom were Anaximander, Anaximenes, and Pythagoras, and was the author of the Ionian ſect of philoſophers. He always however lived very retired, and refuſed the proffered favours of many great men. He was often viſited by Solon; and it is ſaid he took great pleaſure in the converſation of Thraſybulus, whoſe excellent wit made him forget that he was Tyrant of Miletum.

Laertius, and ſeveral other writers, agree, that he was the father of the Greek philoſophy; being the firſt that made any reſearches into natural knowledge, and mathematics. His doctrine was, that water was the principle of which all the bodies in the univerſe are compoſed; that the world was the work of God; and that God ſees the moſt ſecret thoughts in the heart of man. He ſaid, that in order to live well, we ought to abſtain from what we find fault with in others: that

bodily felicity conſiſts in health; and that of the mind in knowledge. That the moſt ancient of beings is God, becauſe he is uncreated: that nothing is more beautiful than the world, becauſe it is the work of God; nothing more extenſive than ſpace, quicker than ſpirit, ſtronger than neceſſity, wiſer than time. He uſed to obſerve, that we ought never to ſay that to any one which may be turned to our prejudice; and that we ſhould live with our friends as with perſons that may become our enemies.

In Geometry, it has been ſaid, he was a conſiderable inventor, as well as an improver; particularly in triangles. And all the writers agree, that he was the firſt, even in Egypt, who took the height of the pyramids by the ſhadow.

His knowledge and improvements in aſtronomy were very conſiderable. He divided the celeſtial ſphere into five circles or zones, the arctic and antarctic circles, the two tropical circles, and the equator. He obſerved the apparent diameter of the ſun, which he made equal to half a degree; and formed the conſtellation of the Little Bear. He obſerved the nature and courſe of eclipſes, and calculated them exactly; one in particular, memorably recorded by Herodotus, as it happened on a day of battle between the Medes and Lydians, which, Laertius ſays, he had foretold to the Ionians. And the ſame author informs us, that he divided the year into 365 days. Plutarch not only confirms his general knowledge of eclipſes, but that his doctrine was, that an eclipſe of the ſun is occaſioned by the intervention of the moon, and that an eclipſe of the moon is cauſed by the intervention of the earth.

His morals were as juſt, as his mathematics well grounded, and his judgment in civil affairs equal to either. He was very averſe to tyranny, and eſteemed monarchy little better in any ſhape.—Diogenes Laertius relates, that walking to contemplate the ſtars, he fell into a ditch; on which a good old woman, that attended him, exclaimed, "How canſt thou know what is doing in the heavens, when thou ſeeſt not what is at thy feet?"—He went to viſit Crœſus, who was marching a powerful army into Cappadocia, and enabled him to paſs the river Halys without making a bridge. Thales died ſoon after, at above 90 years of age, it is ſaid, at the Olympic games, where, oppreſſed with heat, thirſt, and a load of years, he, in public view, ſunk into the arms of his friends.

Concerning his writings, it remains doubtful whether he left any behind him; at leaſt none have come down to us. Auguſtine mentions ſome books of Natural Philoſophy; Simplicius, ſome written on Nautic Aſtrology; Laertius, two treatiſes on the Tropics and Equinoxes; and Suidas, a treatiſe on Meteors, written in verſe.

THAMMUZ, in Chronology, the 10th month of the year of the Jews, containing 29 days, and anſwering to our June.

THEMIS, in Aſtronomy, a name given by ſome to the 3d ſatellite of Jupiter.

THEODOLITE, an inſtrument much uſed in ſurveying, for taking angles, diſtances, altitudes, &c.

This inſtrument is variouſly made; different perſons having their ſeveral ways of contriving it, each attempting to make it more ſimple and portable, more accurate and expeditious, than others. It uſually conſiſts of a braſs circle, about a foot diameter, cut in form of fig. 5, pl. 31; having its limb divided into 360 degrees, and each degree ſubdivided either diagonally, or otherwiſe, into minutes. Underneath, at *cc*, are fixed two little pillars *bb* (fig. 6), which ſupport an axis, bearing a teleſcope, for viewing remote objects.

On the centre of the circle moves the index C, which is a circular plate, having a compaſs in the middle, the meridian line of which anſwers to the fiducial line *aa*; at *bb* are fixed two pillars to ſupport an axis, bearing a teleſcope like the former, whoſe line of collimation anſwers to the fiducial line *aa*. At each end of either teleſcope is, or may be, fixed a plain ſight, for the viewing of nearer objects.

The ends of the index *aa* are cut circularly, to fit the diviſions of the limb B; and when that limb is diagonally divided, the fiducial line at one end of the index ſhews the degrees and minutes upon the limb. It is alſo furniſhed with croſs ſpirit levels, for ſetting the plane of the circle truly horizontal; and a vertical arch, divided into degrees, for taking angles of elevation and depreſſion. The whole inſtrument is mounted with a ball and ſocket, upon a three-legged ſtaff.

Many Theodolites however have no teleſcopes, but only four plain ſights, two of them faſtened on the limb, and two on the ends of the index. Two different ones, mounted on their ſtand, are repreſented in fig. 2 and 3, plate 33.

The uſe of the Theodolite is abundantly ſhewn in that of the ſemicircle, which is only half a Theodolite. And the index and compaſs of the Theodolite ſerve alſo for a circumferentor, and are uſed as ſuch.

The ingenious Mr. Ramſden has lately made a moſt excellent Theodolite, for the uſe of the military ſurvey now carrying on in England.

THEODOSIUS, a celebrated mathematician, who flouriſhed in the times of Cicero and Pompey; but the time and place of his death are unknown. This Theodoſius, the Tripolite, as mentioned by Suidas, is probably the ſame with Theodoſius the philoſopher of Bythinia, who Strabo ſays excelled in the mathematical ſciences, as alſo his ſons; for the ſame perſon might have travelled from the one of thoſe places to the other, and ſpent part of his life in each of them; like as Hipparchus was called by Strabo the Bythinian; but by Ptolomy and others the Rhodian.

Theodoſius chiefly cultivated that part of geometry which relates to the doctrine of the ſphere, concerning which he publiſhed three books. The firſt of theſe contains 22 propoſitions; the ſecond 23; and the third 14; all demonſtrated in the pure geometrical manner of the Ancients. Ptolomy made great uſe of theſe propoſitions, as well as all ſucceeding writers. Theſe books were tranſlated by the Arabians, out of the original Greek, into their own language. From the Arabic, the work was again tranſlated into Latin, and printed at Venice. But the Arabic verſion being very defective, a more complete edition was publiſhed in Greek and Latin, at Paris 1558, by John Pena, Regius Profeſſor of Aſtronomy. And Vitello acquired reputation by tranſlating Theodoſius into Latin. This author's works were alſo commented on and illuſtrated by Clavius, Heleganius, and Guarinus, and laſtly by

De

De Chales, in his Curſus Mathematicus. But that edition of Theodoſius's Spherics which is now moſt in uſe, was tranſlated, and publiſhed, by our countryman the learned Dr. Barrow, in the year 1675, illuſtrated and demonſtrated in a new and conciſe method. By this author's account, Theodoſius appears not only to be a great maſter in this more difficult part of geometry, but the firſt conſiderable author of antiquity who has written on that ſubject.

Theodoſius too wrote concerning the Celeſtial Houſes; alſo of Days and Nights; copies of which, in Greek, are in the king's library at Paris. Of which there was a Latin edition, publiſhed by Peter Daſypody, in the year 1572.

THEON, of Alexandria, a celebrated Greek philoſopher and mathematician, who flouriſhed in the 4th century, about the year 380, in the time of Theodoſius the Great; but the time and manner of his death are unknown. His genius and diſpoſition for the ſtudy of philoſophy were very early improved by a cloſe application to ſtudy; ſo that he acquired ſuch a proficiency in the ſciences, as to render his name venerable in hiſtory; and to procure him the honour of being preſident of the famous Alexandrian ſchool. One of his pupils was the admirable Hypatia, his daughter, who ſucceeded him in the preſidency of the ſchool; a truſt, which, like himſelf, ſhe diſcharged with the greateſt honour and uſefulneſs. [See her life in its place in the firſt volume of this Dictionary.]

The ſtudy of nature led Theon to many juſt conceptions concerning God, and to many uſeful reflections in the ſcience of moral philoſophy; hence, it is ſaid, he wrote with great accuracy on divine providence. And he ſeems to have made it his ſtanding rule, to judge the truth of certain principles, or ſentiments, from their natural or neceſſary tendency. Thus, he ſays, that a full perſuaſion, that the Deity ſees every thing we do, is the ſtrongeſt incentive to virtue; for he inſiſts, that the moſt profligate have power to refrain their hands, and hold their tongues, when they think they are obſerved, or overheard, by ſome perſon whom they fear or reſpect. With how much more reaſon then, ſays he, ſhould the apprehenſion and belief, that God ſees all things, reſtrain men from ſin, and conſtantly excite them to their duty? He alſo repreſents this belief, concerning the Deity, as productive of the greateſt pleaſure imaginable, eſpecially to the virtuous, who might depend with greater confidence on the favour and protection of Providence. For this reaſon, he recommends nothing ſo much as meditation on the preſence of God: and he recommended it to the civil magiſtrate, as a reſtraint on ſuch as were profane and wicked, to have the following inſcription written, in large characters, at the corner of every ſtreet; GOD SEES THEE, O SINNER.

Theon wrote notes and commentaries on ſome of the ancient mathematicians. He compoſed alſo a book, entitled *Progymnaſmata*, a rhetorical work, written with great judgment and elegance; in which he criticiſed on the writings of ſome illuſtrious orators and hiſtorians; pointing out, with great propriety and judgment, their beauties and imperfections; and laying down proper rules for propriety of ſtyle. He recommends conciſeneſs of expreſſion, and perſpicuity, as the principal ornaments. This book was printed at Baſle, in the year 1541; but the beſt edition is that of Leyden, in 1626, in 8vo.

THEOPHRASTUS, a celebrated Greek philoſopher, was the ſon of Melanthus, and was born at Eretus in Bœotia. He was at firſt the diſciple of Lucippus, then of Plato, and laſtly of Ariſtotle; whom he ſucceeded in his ſchool, about the 322d year before the Chriſtian era, and taught philoſophy at Athens with great applauſe.

He ſaid of an orator without judgment, "that he was a horſe without a bridle." He uſed alſo to ſay, "There is nothing ſo valuable as time, and thoſe who laviſh it are the moſt inexcuſable of all prodigals."—He died at about 100 years of age.

Theophraſtus wrote many works, the principal of which are the following—1. An excellent moral treatiſe entitled, *Characters*, which, he ſays in the preface, he compoſed at 99 years of age. Iſaac Caſaubon has written learned commentaries on this ſmall treatiſe. It has been tranſlated from the Greek into French, by Bruyere; and it has alſo been tranſlated into Engliſh.—2. A curious treatiſe on Plants.—3. A treatiſe on foſſils or ſtones; of which Dr. Hill has given a good edition, with an Engliſh tranſlation, and learned notes, in 8vo.

THEOREM, a propoſition which terminates in theory, and which conſiders the properties of things already made or done. Or, a Theorem is a ſpeculative propoſition, deduced from ſeveral definitions compared together. Thus, if a triangle be compared with a parallelogram ſtanding on the ſame baſe, and of the ſame altitude, and partly from their immediate definitions, and partly from other of their properties already determined, it is inferred that the parallelogram is double the triangle; that propoſition is a Theorem.

Theorem ſtands contradiſtinguiſhed from problem, which denotes ſomething to be done or conſtructed, as a Theorem propoſes ſomething to be proved or demonſtrated.

There are two things to be chiefly regarded in every Theorem, viz, the propoſition, and the demonſtration. In the firſt is expreſſed what agrees to ſome certain thing, under certain conditions, and what does not. In the latter, the reaſons are laid down by which the underſtanding comes to conceive that it does or does not agree to it.

Theorems are of various kinds: as,

Univerſal THEOREM, is that which extends to any quantity without reſtriction, univerſally. As this, that the rectangle or product of the ſum and difference of any two quantities, is equal to the difference of their ſquares.

Particular THEOREM, is that which extends only to a particular quantity. As this, in an equilateral rectilinear triangle, each angle is equal to 60 degrees.

Negative THEOREM, is that which expreſſes the impoſſibility of any aſſertion. As, that the ſum of two biquadrate numbers cannot make a ſquare number.

Local THEOREM is that which relates to a ſurface. As, that triangles of the ſame baſe and altitude are equal.

Plane THEOREM, is that which relates to a ſurface that is either rectilinear or bounded by the circumference of a circle. As, that all angles in the ſame ſegment of a circle are equal.

Solid THEOREM, is that which conſiders a ſpace terminated

minated by a ſolid line; that is, by any of the three conic ſections. As this, that if a right line cut two aſymptotic parabolas, its two parts terminated by them ſhall be equal.

Reciprocal THEOREM, is one whoſe converſe is true. As, that if a triangle have two ſides equal, it has alſo two angles equal: the converſe of which is likewiſe true, viz, that if the triangle have two angles equal, it has alſo two ſides equal.

THEORY, a doctrine which terminates in the ſole ſpeculation or conſideration of its object, without any view to the practice or application of it.

To be learned in an art, &c, the Theory is ſufficient; to be a maſter of it, both the Theory and practice are requiſite.—Machines often promiſe very well in Theory, but fail in the practice.

We ſay Theory of the moon, Theory of the rainbow, of the microſcope, of the camera obſcura, &c.

THEORIES *of the Planets*, &c, are ſyſtems or hypotheſes, according to which the aſtronomers explain the reaſons of the phenomena or appearances of them.

THERMOMETER, an inſtrument for meaſuring the temperature of the air, &c, as to heat and cold.

The Thermometer and thermoſcope are uſually accounted the ſame thing. But Wolfius makes a difference; and he alſo ſhews that what we call Thermometers, are really no more than thermoſcopes.

The invention of the Thermometer is attributed to ſeveral perſons by different authors, viz, to Sanctorio, Galileo, father Paul, and to Drebbel. Thus, the invention is aſcribed to Cornelius Drebbel of Alcmar, about the beginning of the 17th century, by his countrymen Boerhaave (Chem. 1, pa. 152, 156), and Muſſchenbroeck (Introd. ad Phil. Nat. vol. 2, pa. 625).—Fulgenzio, in his Life of father Paul, gives him the honour of the firſt diſcovery.—Vincenzio Viviani (Vit. de l'Galil. pa. 67; alſo Oper. di Galil. pref. pa. 47) ſpeaks of Galileo as the inventor of Thermometers.—But Sanctorino (Com. in Galen. Art. Med. pa. 736, 842, Com. in Avicen. Can. Fen. 1, pa. 22, 78, 219) expreſsly aſſumes to himſelf this invention; and Borelli (De Mot. Animal. 2, prop. 175) and Malpighi (Oper. Poſth. pa. 30) aſcribe it to him without reſerve. Upon which Dr. Martine remarks, that theſe Florentine academicians are not to be ſuſpected of partiality in favour of one of the Patavinian ſchool.

But whoever was the firſt inventor of this inſtrument, it was at firſt very rude and imperfect; and as the various degrees of heat were indicated by the different contraction or expanſion of air, it was afterwards found to be an uncertain and ſometimes a deceiving meaſure of heat, becauſe the bulk of the air was affected, not only by the difference of heat, but alſo by the variable weight of the atmoſphere.

There are various kinds of Thermometers, the conſtruction, defects, theory, &c, of which, are as follow.

The Air THERMOMETER.—This inſtrument depends on the rarefaction of the air. It conſiſts of a glaſs tube BE (fig. 1, pl. 34) connected at one end with a large glaſs ball A, and at the other end immerſed in an open veſſel, or terminating in a ball DE, with a narrow orifice at D; which veſſel, or ball, contains any coloured liquor that will not eaſily freeze. Aquafortis tinged of a fine blue colour with ſolution of vitriol or copper, or ſpirit of wine tinged with cochineal, will anſwer this purpoſe. But the ball A muſt be firſt moderately warmed, ſo that a part of the air contained in it may be expelled through the orifice D; and then the liquor preſſed by the weight of the atmoſphere, will enter the ball DE, and riſe, for example, to the middle of the tube at C, at a mean temperature of the weather; and in this ſtate the liquor by its weight, and the air included in the ball and tube ABC, by its elaſticity, will counterbalance the weight of the atmoſphere. As the ſurrounding air becomes warmer, the air in the ball and the upper part of the tube, expanding by heat, will drive the liquor into the lower ball, and conſequently its ſurface will deſcend; on the contrary, as the ambient air becomes colder, that in the ball is condenſed, and the liquor, preſſed by the weight of the atmoſphere, will aſcend: ſo that the liquor in the tube will aſcend or deſcend more or leſs, according to the ſtate of the air contiguous to the inſtrument. To the tube is affixed a ſcale of the ſame length, divided upwards and downwards, from the middle C, into 100 equal parts, by means of which may be obſerved the aſcent and deſcent of the liquor in the tube, and conſequently the variations alſo in the temperature of the atmoſphere.

A ſimilar Thermometer may be conſtructed by putting a ſmall quantity of mercury, not exceeding the bulk of a pea, into the tube BC (fig. 4, pl. 33), bent into wreaths; that taking up the leſs height, it may be the more manageable, and leſs liable to harm; divide this tube into any number of equal parts to ſerve for a ſcale. Here the approaches of the mercury towards the ball A will ſhew the increaſe of the degree of heat. The reaſon of which is the ſame as in the former.

The defect of both theſe inſtruments conſiſts in this, that they are liable to be acted on by a double cauſe; for, not only a decreaſe of heat, but alſo an increaſe of weight of the atmoſphere, will make the liquor riſe in the one, and the mercury in the other; and, on the contrary, either an increaſe of heat, or decreaſe of the weight of the atmoſphere, will cauſe them to deſcend.

For theſe, and other reaſons, Thermometers of this kind have been long diſuſed. However, M. Amontons, in 1702, with a view of perfecting the aërial Thermometer, contrived his *Univerſal Thermometer*. Finding that the changes produced by heat and cold in the bulk of the air were ſubject to invincible irregularities, he ſubſtituted for theſe the variations produced by heat in the elaſtic force of this fluid. This Thermometer conſiſted of a long tube of glaſs (fig. 3, pl. 34) open at one end, and recurved at the other end, which terminated in a ball. A certain quantity of air was compreſſed into this ball by the weight of a column of mercury, and alſo by the weight of the atmoſphere. The effect of heat on this included air was to make it ſuſtain a greater or leſs weight; and this effect was meaſured by the variation of the column of mercury in the tube, corrected by that of the barometer, with reſpect to the changes of the weight of the external air. This inſtrument, though much more perfect than the former, is nevertheleſs ſubject to very conſiderable defects and incon-

inconveniences. Its length of 4 feet renders it unfit for a variety of experiments, and its conſtruction is difficult and complex: it is extremely inconvenient for carriage, as a very ſmall inclination of the tube would ſuffer the included air to eſcape: and the friction of the mercury in the tube, and the compreſſibility of the air, contribute to render the indications of this inſtrument extremely uncertain. Beſides, the dilatation of the air is not ſo regularly proportional to its heat, nor is its dilatation by a given heat nearly ſo uniform as he ſuppoſed.' This depends much on its moiſture; for dry air does not expand near ſo much by a given heat, as air ſtored with watery particles. For theſe, and other reaſons, enumerated by De Luc (Recherches ſur les Mod. de l'Atmo. tom. 1, pa. 278 &c), this inſtrument was imitated by very few, and never came into general uſe.

Of the Florentine THERMOMETER.—The academiſts del Cimento, about the middle of the 17th century, conſidering the inconveniencies of the air Thermometers above deſcribed, attempted another, that ſhould meaſure heat and cold by the rarefaction and condenſation of ſpirit of wine; though much leſs than thoſe of air, and conſequently the alterations in the degree of heat likely to be much leſs ſenſible.

The ſpirit of wine coloured, was included in a very fine and cylindrical glaſs tube (fig. 2, pl. 34), exhauſted of its air, having a hollow ball at one end A, and hermetically ſealed at the other end D. The ball and tube are filled with rectified ſpirit of wine to a convenient height, as to C, when the weather is of a mean temperature, which may be done by inverting the tube into a veſſel of ſtagnant coloured ſpirit, under a receiver of the air-pump, or in any other way. When the thermometer is properly filled, the end D is heated red hot by a lamp, and then hermetically ſealed, leaving the included air of about $\frac{1}{3}$ of its natural denſity, to prevent the air which is in the ſpirit from dividing it in its expanſion. To the tube is applied a ſcale, divided from the middle, into 100 equal parts, upwards and downwards.

Now ſpirit of wine rarefying and condenſing very conſiderably; as the heat of the ambient atmoſphere increaſes, the ſpirit will dilate, and ſo aſcend in the tube; and as the heat decreaſes, the ſpirit will deſcend; and the degree or quantity of the motion will be ſhewn by the attached ſcale.

Theſe Thermometers could not be ſubject to any inconvenience by an evaporation of the liquor, or a variable gravity of the incumbent atmoſphere. Inſtruments of this kind were firſt introduced into England by Mr. Boyle, and they ſoon came into general uſe among philoſophers in other countries. They are however ſubject to conſiderable inconveniences, from the weight of the liquor itſelf, and from the elaſticity of the air above it in the tube, both which prevent the freedom of its aſcent; beſides, the rarefactions are not exactly proportional to the ſurrounding heat. Moreover ſpirit of wine is incapable of bearing very great heat or very great cold: it boils ſooner than any other liquor; and therefore the degrees of heat of boiling fluids cannot be determined by this Thermometer. And though it retains its fluidity in pretty ſevere cold, yet it ſeems not to condenſe very regularly in them: and at Torneao, near the polar circle, the winter cold was ſo ſevere, as Maupertuis informs us, that the ſpirits were frozen in all their Thermometers. So that the degrees of heat and cold, which ſpirit of wine is capable of indicating, is much too limited to be of very great or general uſe.

Another great defect of theſe, and other Thermometers, is, that their degrees cannot be compared with each other. It is true they mark the variations of heat and cold; but each marks for itſelf, and after its own manner; becauſe they do not proceed from any point of temperature that is common to all of them.

From theſe and various other imperfections in theſe Thermometers, it happens, that the compariſons of them become ſo precarious and defective: and yet the moſt curious and intereſting uſe of them, is what ought to ariſe from ſuch compariſon. It is by this we ſhould know the heat or cold of another ſeaſon, of another year, another climate, &c; and what is the greateſt degree of heat or cold that men and other animals can ſubſiſt in.

Reaumur contrived a new Thermometer, in which the inconveniences of the former are propoſed to be remedied. He took a large ball and tube, the content or dimenſions of which are known in every part; he graduated the tube, ſo that the ſpace from one diviſion to another might contain a 1000th part of the liquor, which liquor would contain 1000 parts when it ſtood at the freezing point: then putting the ball of his Thermometer and part of the tube into boiling water, he obſerved whether it roſe 80 diviſions: if it exceeded theſe, he changed his liquor, and by adding water lowered it, till upon trial it ſhould juſt riſe 80 diviſions; or if the liquor, being too low, fell ſhort of 80 diviſions, he raiſed it by adding rectified ſpirit to it. The liquor thus prepared ſuited his purpoſe, and ſerved for making a Thermometer of any ſize, whoſe ſcale would agree with his ſtandard. Such liquor, or ſpirits, being about the ſtrength of common brandy, may eaſily be had any where, or made of a proper degree of denſity by raiſing or lowering it.

The abbé Nollet made many excellent Thermometers upon Reaumur's principle. Dr. Martine however expreſſes his apprehenſions that Thermometers of this kind cannot admit of ſuch accuracy as might be wiſhed. The balls or bulbs, being large, as 3 or 4 inches in diameter, are neither heated nor cooled ſoon enough to ſhew the variations of heat. Small bulbs and ſmall tubes, he ſays, are much more convenient, and may be conſtructed with ſufficient accuracy. Though it muſt be allowed that Reaumur, by his excellent ſcale, and by depriving the ſpirit of its air, and expelling the air by means of heat from the ball and tube of his Thermometer, has brought it to as much perfection as may be; yet it is liable to ſome of the inconveniences of ſpirit Thermometers, and is much inferior to mercurial ones. Theſe two kinds do not agree together in indicating the ſame degrees of intenſe cold; for when the mercury has ſtood at 22° below 0, the ſpirit indicated only 18°, and when the mercury ſtood at 28° or 37° below 0, the ſpirit reſted at 25° or 29°. See the deſcription of Reaumur's Thermometer at large in Mem. de l'Acad. des Scienc. an. 1730, pa. 645, Hiſt. pa. 15. Ib. an. 1731, pa. 354, Hiſt. pa. 7.

Mercurial

Mercurial THERMOMETER.——It is a moſt important circumſtance in the conſtruction of Thermometers, to procure a fluid that meaſures equal variations of heat by correſponding equal variations in its own bulk: and the fluid which poſſeſſes this eſſential requiſite in the moſt perfect degree, is mercury: the variations in its bulk approaching nearer to a proportion with the correſponding variations of its heat, than any other fluid. Beſides, it is the moſt eaſy to purge of its air; and is alſo the moſt proper for meaſuring very conſiderable variations of heat and cold, as it will bear more cold before freezing, and more heat before boiling, than any other fluid. Mercury is alſo more ſenſible than any other fluid, air excepted, or conforms more ſpeedily to the ſeveral variations of heat. Moreover, as mercury is an homogeneous fluid, it will in every Thermometer exhibit the ſame dilatation or condenſation by the ſame variations of heat.

Dr. Halley, though apprized only of ſome of the remarkable properties of mercury above recited, ſeems to have been the firſt who ſuggeſted the application of this fluid to the conſtruction of Thermometers. Philoſ. Tranſ. Abr. vol. 2, pa. 34.

Boerhaave (Chem. 1, pa. 720) ſays, theſe mercurial Thermometers were firſt contrived by Olaus Roemer; but the claims of Fahrenheit of Amſterdam, who gave an account of his invention to the Royal Society in 1724, (Philoſ. Tranſ. num. 381, or Abr. vol. 7, pa. 49) have been generally allowed. And though Prius and others, in England, Holland, France, and other countries, have made this inſtrument as well as Fahrenheit, moſt of the mercurial Thermometers are graduated according to his ſcale, and are called *Fahrenheit's Thermometers.*

The cone or cylinder, which theſe Thermometers are often made with, inſtead of the ball, is made of glaſs of a moderate thickneſs, left, when the exhauſted tube is hermetically ſealed, its internal capacity ſhould be diminiſhed by the weight of the ambient atmoſphere. When the mercury is thoroughly purged of its air and moiſture by boiling, the Thermometer is filled with a ſufficient quantity of it; and before the tube is hermetically ſealed, the air is wholly expelled from it by heating the mercury, ſo that it may be rarefied and aſcend to the top of the tube. To the ſide of the tube is annexed a ſcale (fig. 3, pl. 34), which Fahrenheit divided into 600 parts, beginning with that of the ſevere cold which he had obſerved in Iceland in 1709, or that produced by ſurrounding the bulb of the Thermometer with a mixture of ſnow or beaten ice and ſal ammoniac or ſea ſalt. This he apprehended to be the greateſt degree of cold, and accordingly he marked this, as the beginning of his ſcale, with 0; the point at which mercury begins to boil, he conceived to ſhew the greateſt degree of heat, and this he made the limit of his ſcale. The diſtance between theſe two points he divided into 600 equal parts or degrees; and by trials he found at the freezing point, when water juſt begins to freeze, or ſnow or ice juſt begins to thaw, that the mercury ſtood at 32 of theſe diviſions, therefore called the degree of the freezing point; and when the tube was immerſed in boiling water, the mercury roſe to 212, which therefore is the boiling point, and is juſt 180 degrees above the former or freezing point.

But the preſent method of making the ſcale of theſe Thermometers, which is the ſort in moſt common uſe, is firſt to immerge the bulb of the Thermometer in ice or ſnow juſt beginning to thaw, and mark the place where the mercury ſtands with a 32; then immerge it in boiling water, and again mark the place where the mercury ſtands in the tube, which mark with the num. 212, exceeding the former by 180; dividing therefore the intermediate ſpace into 180 equal parts, will give the ſcale of the Thermometer, and which may afterwards be continued upwards and downwards at pleaſure.

Other Thermometers of a ſimilar conſtruction have been accommodated to common uſe, having but a portion of the above ſcale. They have been made of a ſmall ſize and portable form, and adapted with appendages to particular purpoſes; and the tube with its annexed ſcale has often been encloſed in another thicker glaſs tube, alſo hermetically ſealed, to preſerve the Thermometer from injury. And all theſe are called *Fahrenheit's Thermometers.*

In 1733, M. De l'Iſle of Peterſburgh conſtructed a mercurial Thermometer (ſee fig. 3, pl. 34), on the principles of Reaumur's ſpirit Thermometer. In his Thermometer, the whole bulk of quickſilver, when immerged in boiling water, is conceived to be divided into 100,000 parts; and from this one fixed point the various degrees of heat, either above or below it, are marked in theſe parts on the tube or ſcale, by the various expanſion or contraction of the quickſilver in all imaginable varieties of heat.—Dr. Martine apprehends it would have been better if De l'Iſle had made the integer 100,000 parts, or fixed point, at freezing water, and from thence computed the dilatations or condenſations of the quickſilver in thoſe parts; as all the common obſervations of the weather, &c, would have been expreſſed by numbers increaſing as the heat increaſed, inſtead of decreaſing, or counting the contrary way. However, in practice it will not be very eaſy to determine exactly all the diviſions from the alteration of the bulk of the contained fluid. And beſides, as glaſs itſelf is dilated by heat, though in a leſs proportion than quickſilver, it is only the exceſs of the dilatation of the contained fluid above that of the glaſs that is obſerved; and therefore if different kinds of glaſs be differently affected by a given degree of heat, this will make a ſeeming difference in the dilatations of the quickſilver in the Thermometers conſtructed in the Newtonian method, either by Reaumur's rules or De l'Iſle's. Accordingly it has been found, that the quickſilver in De l'Iſle's Thermometers, has ſtood at different degrees of the ſcale when immerged in thawing ſnow: having ſtood in ſome at 154°, while in others it has been at 156 or even 158°.

Metallic THERMOMETER.—This is a name given to a machine compoſed of two metals, which, whilſt it indicates the variations of heat, ſerves to correct the errors hence reſulting in the going of pendulum clocks and watches. Inſtruments of this kind have been contrived by Graham, Le Roy, Ellicot, Harriſon, and other eminent artificers. See the Philoſ. Tranſ. vol. 44, pa. 689, and vol. 45, pa. 129, and vol. 51, pa. 823, where the particular deſcriptions &c may be ſeen.

M. De Luc has likewiſe deſcribed two Thermometers

of metal, which he uſes for correcting the effects of heat upon a barometer, and an hygrometer of his conſtruction connected with them. See Philoſ. Tranſ. vol. 68, p. 437.

Oil THERMOMETERS.—To this claſs belongs Newton's Thermometer, conſtructed in 1701, with linſeed oil, inſtead of ſpirit of wine. This fluid has the advantage of being ſufficiently homogeneous, and capable of a conſiderable rarefaction, not leſs than 15 times greater than that of ſpirit of wine. It has not been obſerved to freeze even in very great colds; and it ſuſtains a great heat, about 4 times that of water, before it boils. With theſe advantages it was made uſe of by Sir I. Newton, who diſcovered by it the comparative degree of heat for boiling water, melting wax, boiling ſpirit of wine, and melting tin; beyond which it does not appear that this Thermometer was applied. The method he uſed for adjuſting the ſcale of this oil Thermometer, was as follows: ſuppoſing the bulb, when immerged in thawing ſnow, to contain 10,000 parts, he found the oil expanded by the heat of the human body ſo as to take up a 39th more ſpace, or 10256 ſuch parts; and by the heat of water boiling ſtrongly 10725; and by the heat of melting tin 11516. So that, reckoning the freezing point as a common limit between heat and cold, he began his ſcale there, marking it 0, and the heat of the human body he made 12°; and conſequently, the degrees of heat being proportional to the degrees of rarefaction, or 256 : 725 :: 12 : 34, this number 34 will expreſs the heat of boiling water; and, by the ſame rule, 72 that of melting tin. Philoſ. Tranſ. number 270, or Abridg. vol. 4, par. 2, p. 3.

There is an inſuperable inconvenience attending all Thermometers made with oil, or any other viſcid fluid, viz, that ſuch liquor adheres too much to the ſides of the tube, and ſo inevitably diſturbs the regularity and uniformity of the Thermometer.

Of the fixed points of THERMOMETERS.—Various methods have been propoſed by different authors, for finding a fixed point or degree of heat, from which to reckon the other degrees, and adjuſt the ſcale; ſo that different obſervations and inſtruments might be compared together. Mr. Boyle was very ſenſible of the inconveniences ariſing from the want of a univerſal ſcale and mode of graduation; and he propoſed either the freezing of the eſſential oil of aniſeeds, or of diſtilled water, as a term to begin the numbers at, and from thence to graduate them according to the proportional dilatations or contractions of the included ſpirits.

Dr. Halley (Philoſ. Tranſ. Abr. vol. 2, p. 36) ſeems to have been fully apprized of the bad effects of the indefinite method of conſtructing Thermometers, and wiſhed to have them adjuſted to ſome determined points. What he ſeems to prefer, for this purpoſe, is the degree of temperature found in ſubterranean places, where the heat in ſummer or cold in winter appears to have no influence. But this degree of temperature, Dr. Martine ſhews, is a term for the univerſal conſtruction of Thermometers, both inconvenient and precarious, as it cannot be eaſily aſcertained, and as the difference of ſoils and depths may occaſion a conſiderable variation. Another term of heat, which he thought might be of uſe in a general graduation of Thermometers, is that of boiling ſpirit of wine that has been highly rectified.

The firſt trace that occurs of the method of actually applying fixed points or terms to the Thermometer, and of graduating it, ſo that the unequal diviſions of it might correſpond to equal degrees of heat, is the project of Renaldini, profeſſor at Padua, in 1694: it is thus deſcribed in the Acta Erud. Lipſ. "Take a ſlender tube, about 4 palms long, with a ball faſtened to the ſame; pour into it ſpirit of wine, enough juſt to fill the ball, when ſurrounded with ice, and not a drop over: in this ſtate ſeal the orifice of the tube hermetically, and provide 12 veſſels, each capable of containing a pound of water, and ſomewhat more; and into the firſt pour 11 ounces of cold water, into the ſecond 10 ounces, into the third 9, &c; this done, immerge the Thermometer in the firſt veſſel, and pour into it one ounce of hot water, obſerving how high the ſpirit riſes in the tube, and noting the point with unity; then remove the Thermometer into the ſecond veſſel, into which are to be poured 2 ounces of hot water, and note the place the ſpirit riſes to with 2: by thus proceeding till the whole pound of water is ſpent, the inſtrument will be found divided into 12 parts, denoting ſo many terms or degrees of heat; ſo that at 2 the heat is double to that at 1, at 3 triple, &c."

But this method, though plauſible, Wolfius ſhews, is deceitful, and built on falſe ſuppoſitions; for it takes for granted, that we have one degree of heat, by adding one ounce of hot water to 11 of cold; two degrees by adding 2 ounces to 10, &c: it ſuppoſes alſo, that a ſingle degree of heat acts on the ſpirit of wine, in the ball, with a ſingle force; a double with a double force, &c; laſtly it ſuppoſes, that if the effect be produced in the Thermometer by the heat of the ambient air, which is here produced by the hot water, the air has the ſame degree of heat with the water.

Soon after this project of Renaldini, viz, in 1701, Newton conſtructed his oil Thermometer, and placed the baſe or loweſt fixed point of his ſcale at the temperature of thawing ſnow, and 12 at that of the human body, &c, as above explained.—De Luc obſerves, that the 2d term of this ſcale ſhould have been at a greater diſtance from the firſt, and that the heat of boiling water would have anſwered the purpoſe better than that of the human body.

In 1702, Amontons contrived his univerſal Thermometer, the ſcale of which was graduated in the following manner. He choſe for the firſt term, the weight that counterbalanced the air included in his Thermometer, when it was heated by boiling water: and in this ſtate he ſo adjuſted the quantity of mercury contained in it, till the ſum of its height in the tube, and of its height in the barometer at the moment of obſervation, was equal to 73 inches. Fixing this number at the point to which the mercury in the tube roſe by plunging it in boiling water, it is evident that if the barometer at this time was at 28 inches, the height of the column of mercury in the Thermometer, above the level of that in the ball, was 45 inches; but if the height of the barometer was leſs by a certain quantity, the column of the Thermometer ought to be greater by the ſame quantity, and reciprocally. He formed his ſcale on the ſuppoſition, that the weight of the atmoſphere was always equal to that of a column of mercury of 28 inches, and he divided it into inches

from

from the point 73 downward, marking the diviſions with 72, 71, 70, &c, and ſubdividing the inches into lines. But as the weight of the atmoſphere is variable, the barometer muſt be obſerved at the ſame time with the Thermometer, that the number indicated by this laſt inſtrument may be properly corrected, by adding or ſubtracting the quantity which the mercury is below or above 28 inches in the barometer. In this ſcale then, the freezing point is at 51½ inches, correſponding to 32 degrees of Fahrenheit, and the heat of boiling water at 73 inches, anſwering to 212 of Fahrenheit's; and thus they may be eaſily compared together.

The fixed points of Fahrenheit's Thermometer, as has been already obſerved, are the congelation produced by ſal ammoniac and the heat of boiling water. The interval between theſe points is divided into 212 equal parts; the former of theſe points being marked 0, and the other 212.

Reaumur in his Thermometer, the conſtruction of which he publiſhed in 1730, begins his ſcale at an artificial congelation of water in warm weather, which, as he uſes large bulbs for his glaſſes, gives the freezing point much higher than it ſhould be, and at boiling water he marks 80 degrees, which point Dr. Martine thinks is more vague and uncertain than his freezing point. In order to determine the correſpondence of his ſcale with that of Fahrenheit, it is to be conſidered that his boiling water heat, is really only the boiling heat of weakened ſpirit of wine, coinciding nearly, as Dr. Martine apprehends, with Fahrenheit's 180 degrees. And as his 10¼ degrees is the conſtant heat of the cave of the obſervatory at Paris, or Fahrenheit's 53°, he thence finds his freezing point, inſtead of anſwering juſt to 32°, to be ſomewhat above 34°.

De l'Iſle's Thermometer, an account of which he preſented to the Peterſburgh Academy in 1733, has only one fixed point, which is the heat of boiling water, and, contrary to the common order, the ſeveral degrees are marked from this point downward, according to the condenſations of the contained quickſilver, and conſequently by numbers increaſing as the heat decreaſes. The freezing point of De l'Iſle's ſcale, Dr. Martine makes near to his 150°, correſponding to Fahrenheit's 32, by means of which they may be compared; but Ducreſt ſays, that this point ought to be marked at leaſt at 154°.

Ducreſt, in his ſpirit Thermometer, conſtructed in 1740, made uſe of two fixed points; the firſt, or 0, indicated the temperature of the earth, and was marked on his ſcale in the cave of the Paris Obſervatory; and the other was the heat of boiling water, which that ſpirit in his Thermometer was made to endure, by leaving the upper part of the tube full of air. He divided the interval between theſe points into 100 equal parts; calling the diviſions upward, degrees of heat, and thoſe below 0, degrees of cold.—It is ſaid that he has ſince regulated his Thermometer by the degree of cold indicated by melting ice, which he found to be 10⅔.

The Florentine Thermometers were of two ſorts. In one ſort the freezing point, determined by the degree at which the ſpirit ſtood in the ordinary cold of ice or ſnow (probably in a thawing ſtate) and coinciding with 32° of Fahrenheit, fell at 20°; and in the other ſort at 13½. And the natural heat of the viſcera of cows and deer, &c, raiſed the ſpirit in the latter, or leſs ſort, to about 40°, coinciding with their ſummer heat, and nearly with 102° in Fahrenheit's; and in their other or long Thermometer, the ſpirit, when expoſed to the great midſummer heat in their country, roſe to the point at which they marked 80°.

In the Thermometer of the Paris Obſervatory, made of ſpirit of wine by De la Hire, the ſpirit always ſtands at 48° in the cave of the obſervatory, correſponding to 53 degrees in Fahrenheit's; and his 28° correſponded with 51 inches 6 lines in Amontons' Thermometer, and conſequently with the freezing point, or 32° of Fahrenheit's.

In Poleni's Thermometer, made after the manner of Amontons', but with leſs mercury, 47 inches correſponded, according to Dr. Martine, with 51 in that of Amontons, and 53 with 59½.

In the ſtandard Thermometer of the Royal Society of London, according to which Thermometers were for a long time conſtructed in England, Dr. Martine found that 34½ degrees anſwered to 64° in Fahrenheit, and 0 to 89.

In the Thermometers graduated for adjuſting the degrees of heat proper for exotic plants, &c, in ſtoves and greenhouſes, the middle temperature of the air is marked at 0, and the degrees of heat and cold are numbered both above and below. Many of theſe are made on no regular and fixed principles. But in that formerly much uſed, called Fowler's regulator, the ſpirit fell, in melting ſnow, to about 34° under 0; and Dr. Martine found that his 16° above 0, nearly coincided with 64° of Fahrenheit.

Dr. Hales (Statical Eſſays, vol. 1, p. 58), in his Thermometer, made with ſpirit of wine, and uſed in experiments on vegetation, began his ſcale with the loweſt degree of freezing, or 32° of Fahrenheit, and carried it up to 100°, which he marked where the ſpirit ſtood when the ball was heated in hot water, upon which ſome wax floating firſt began to coagulate, and this point Dr. Martine found to correſpond with 142° of Fahrenheit. But by experience it is found that Hales's 100 falls conſiderably above our 142.

In the Edinburgh Thermometer, made with ſpirit of wine, and uſed in the meteorological obſervations publiſhed in the Medical Eſſays, the ſcale is divided into inches and tenths. In melting ſnow the ſpirit ſtood at 8 2/10, and the heat of the human ſkin raiſed it to 22 2/10. Dr. Martine found that the heat of the perſon who graduated it, was 97 of Fahrenheit.

As it is often of uſe to compare different Thermometers, in order to judge of the reſult of former obſervations, I have annexed from Dr. Martine's Eſſays, the table by which he compared 15 different thermometers. See Plate 34, fig. 3.

There is a Thermometer which has often been uſed in London, called the Thermometer of Lyons, becauſe M. Criſtin

M. Criſtin brought it there into uſe, which is made of mercury: the freezing point is marked 0, and the interval from that point to the heat of boiling water is divided into 100 equal degrees.

From the abſtract of the hiſtory of the conſtruction of Thermometers it appears, that freezing and boiling water have furniſhed the diſtinguiſhing points that have been marked upon almoſt all Thermometers. The inferior fixed point is that of freezing, which ſome have determined by the freezing of water, and others by the melting of ice; plunging the ball of the Thermometer into the water and ice, while melting, which is the beſt way. The ſuperior fixed point of almoſt all Thermometers, is the heat of boiling water. But this point cannot be conſidered as fixed and certain, unleſs the heat be produced by the ſame degree of boiling, and under the ſame weight of the atmoſphere; for it is found that the higher the barometer, or the heavier the atmoſphere, the greater is the heat when the water boils. It is now agreed therefore that the operation of plunging the ball of the Thermometer in the boiling water, or ſuſpending it in the ſteam of the ſame in an incloſed veſſel, be performed when the water boils violently, and when the barometer ſtands at 30 Engliſh inches, in a temperature of 55° of the atmoſphere, marking the height of the Thermometer then for the degree of 212 of Fahrenheit; the point of melting ice being 32 of the ſame; thus having 180 degrees between thoſe two fixed points, ſo determined. This was Mr. Bird's method, who it is apprehended firſt attended to the ſtate of the barometer, in the making of Thermometers. But theſe inſtruments may be made equally true under any preſſure of the atmoſphere, by making a proper allowance for the difference in the height of the barometer from 30 inches. M. De Luc, in his Recherches ſur les Mod. de l'Atmoſphere, from a ſeries of experiments, has given an equation for the allowance on account of this difference, in Paris meaſure, which has been verified by Sir George Schuckburgh, Philoſ. Tranſ. 1775 and 1778; alſo Dr. Horſley, Dr. Maſkelyne, and Sir George Shuckburgh have adapted the equation and rules, to Engliſh meaſures, and have reduced the allowances into tables for the uſe of the artiſt. Dr. Horſley's rule, deduced from De Luc's, is this:

$$\frac{99}{8990000}\log.\ z - 92{\cdot}804 = h,$$

where h denotes the height of a Thermometer plunged in boiling water, above the point of melting ice, in degrees of Bird's Fahrenheit, and z the height of the barometer in 10ths of an inch. From this rule he has computed the following table, for finding the heights, to which a good Bird's Fahrenheit will riſe, when plunged in boiling water, in all ſtates of the barometer, from 27 to 31 Engliſh inches; which will ſerve, among other uſes, to direct inſtrument makers in making a true allowance for the effect of the variation of the barometer, if they ſhould be obliged to finiſh a Thermometer at a time when the barometer is above or below 30 inches; though it is beſt to fix the boiling point when the barometer is at that height.

The numbers in the firſt column of this table expreſs heights of the quickſilver in the barometer in Engliſh inches and decimal parts; the 2d column ſhews the equation to be applied, according to the ſign prefixed, to 212° of Bird's Fahrenheit, to find the true boiling point for every ſuch ſtate of the barometer. The boiling point for all intermediate ſtates of the barometer may be had with ſufficient accuracy by taking proportional parts, by means of the 3d column of differences of the equations. See Philoſ. Tranſ. vol. 64, art. 39; alſo Dr. Maſkelyne's paper, vol. 64, art. 20.

Sir Geo. Shuckburgh (Philoſ. Tranſ. vol. 69, pa. 362) has alſo given ſeveral tables and rules relating to the boiling point, both from his own obſervations and De Luc's, form whence is extracted the following table, for the uſe of artiſts in conſtructing the Thermometer.

Height of the Barometer.	Corr. of the Boil. Point.	Differences.	Correct. accord. to De Luc.	Differences.

The Royal Society too, fully ſenſible of the importance of adjuſting the fixed points of Thermometers, appointed a committee of ſeven gentlemen to conſider of the beſt method for this purpoſe; and their report may be ſeen in the Philoſ. Tranſ. vol. 67, art. 37.

They obſerve, that although the boiling point be placed ſo much higher on ſome of the Thermometers now made, than on others, yet this does not produce any conſiderable error in the obſervations of the weather, at leaſt in this climate; for an error of 1½ degree in the poſition of the boiling point, will make an error only of half a degree in the poſition of 92°, and of not more than

than a quarter of a degree in the point of 62°. It is only in nice experiments, or in trying the heat of hot liquors, that this error in the boiling point can be of much ſignification.

In adjuſting the freezing, as well as the boiling point, the quickſilver in the tube ought to be kept of the ſame heat as that in the ball. When the freezing point is placed at a conſiderable diſtance from the ball, the pounded ice ſhould be piled up very near to it; if it be not ſo piled, then the obſerved point, to be very accurate, ſhould be corrected, according to the following table.

Heat of the Air.	Correction.
42°	·00087
52	·00174
62	·00261
72	·00348
82	·00435

The correction in this table is expreſſed in 10000th parts of the diſtance between the freezing point and the ſurface of the ice: ex. gr. if the freezing point ſtand 6 inches above the ſurface of the ice, and the heat of the room be 62, then the point of 32 ſhould be placed 6 × ·00261, or ·01566 of an inch lower down than the obſerved point.

The committee farther obſerve, that in trying the heat of liquors, care ſhould be taken that the quickſilver in the tube of the Thermometer be heated to the ſame degree as that in the ball; or if this cannot be done conveniently, the obſerved heat ſhould be corrected on that account; for the manner of doing which, and a table calculated for that purpoſe, ſee Philoſ. Tranſ. vol. 67, art. 37.

It was for ſome time thought, eſpecially from the experiments at Peterſburgh, that quickſilver ſuffered a cold of ſeveral hundred degrees below 0 before it congealed and became fixed and malleable; but later experiments have ſhewn that this perſuaſion was merely owing to a deception in the experiments, and later ones have made it appear that its point of congelation is no lower than — 40°, or rather — 39°, of Fahrenheit's ſcale. But that it will bear however to be cooled a few degrees below that point, to which it leaps up again on beginning to congeal; and that its rapid deſcent in a Thermometer, through many hundred degrees, when it has once paſſed the above-mentioned limit, proceeds merely from its great contraction in the act of freezing. See Philoſ. Tranſ. vol. 73, art. *20, 20, 21.

Miſcellaneous Obſervations.

It is abſolutely neceſſary that thoſe who would derive any advantage from theſe inſtruments, ſhould agree in uſing the ſame liquor, and in determining, according to the ſame method, the two fundamental points. If they agree in theſe fixed points, it is of no great importance whether they divide the interval between them into a greater or a leſs number of equal parts. The ſcale of Fahrenheit, in which the fundamental interval between 212°, the point of boiling water, and 32° that of melting ice, is divided into 180 parts, ſhould be retained in the northern countries, where Fahrenheit's Thermometer is uſed: and the ſcale in which the fundamental interval is divided into 80 parts, will ſerve for thoſe countries where Reaumur's Thermometer is adopted. But no inconvenience is to be apprehended from varying the ſcale for particular uſes, provided care be taken to ſignify into what number of parts the fundamental interval is divided, and the point where 0 is placed.

With regard to the choice of tubes, it is beſt to have them exactly cylindrical through their whole length. The capillary tubes are preferable to others, becauſe they require ſmaller bulbs, and they are alſo more ſenſible, and leſs brittle. The moſt convenient ſize for common experiments has the internal diameter about the 40th or 50th of an inch, about 9 inches long, and made of thin glaſs, that the riſe and fall of the mercury may be better ſeen.

For the whole proceſs of filling, marking, and graduating, ſee De Luc's Recherches &c, tom. 1, p. 393, &c.

Experiments with THERMOMETERS.

The following is a table of ſome obſervations made with Fahrenheit's Thermometer, the barometer ſtanding at 29 inches, or little higher.

At 600° Mercury boils.
546 Oil of vitriol boils.
242 Spirit of nitre boils.
240 Lixivium of tartar boils.
213 Cow's milk boils.
212 Water boils.
206 Human urine boils.
190 Brandy boils.
175 Alcohol boils.
156 Serum of blood and white of eggs harden.
146 Kills animals in a few minutes.
108 to 99, Hens hatch eggs.
107 to 103 Heat of ſkin in ducks, geeſe, hens, pigeons, partridges, and ſwallows.
106 Heat of ſkin in a common ague and fever.
103 to 100 Heat of ſkin in dogs, cats, ſheep, oxen, ſwine, and moſt other quadrupeds.
99 to 92, Heat of the human ſkin in health.
97 Heat of a ſwarm of bees.
96 A perch died in 3 minutes in water ſo warm.
80 Heat of air in the ſhade, in very hot weather.
74 Butter begins to melt.
64 Heat of air in the ſhade, in warm weather.
55 Mean temperature of air in England.
43 Oil of olives begins to ſtiffen and grow opake.
32 Water juſt freezing, or ſnow and ice juſt melting.
30 Milk freezes.
28 Urine and common vinegar freezes.
25 Blood out of the body freezes.
20 Burgundy, Claret, and Madeira freeze.
5 Greateſt cold in Pennſylvania in 1731-2; lat. 40°.
4 Greateſt cold at Utrecht in 1728-9.
0 A mixture of ſnow and ſalt, which can freeze oil of tartar per deliquium, but not brandy.
— 39 Mercury freezes.

Martine's Eſſays, p. 284, &c.

On

On the general ſubject of Thermometers alſo ſee Martine's Eſſays, Medical and Philoſophical. Deſaguliers's Exp. Phil. vol. 2, p. 289. Muſſchenbroeck's Int. ad Phil. Nat. vol. 2, p. 625, ed. 1762. De Luc's Recherches ſur les Modif. &c, tom. 1, part 2, ch. 2. Nollet's Leçons de Phyſique, tom. 4, p. 375.

THERMOMETERS *for particular uſes.*—In 1757, lord Cavendiſh preſented to the Royal Society an account of a curious conſtruction of Thermometers, of two different forms; one contrived to ſhew the greateſt degree of heat, and the other the greateſt cold, that may happen at any time in a perſon's abſence. Philoſ. Tranſ. vol. 50, p. 300.

Since the publication of Mr. Canton's diſcovery of the compreſſibility of ſpirits of wine and other fluids, there are two corrections neceſſary to be made in the reſult given by lord Cavendiſh's Thermometer. For in eſtimating, for inſtance, the temperature of the ſea at any depth, the Thermometer will appear to have been colder than it really was: and beſides, the expanſion of ſpirits of wine by any given number of degrees of Fahrenheit's Thermometer, is greater in the higher degrees than in the lower. For the method of making theſe two corrections by Mr. Cavendiſh, ſee Phipps's Voyage to the North Pole, p. 145.

Inſtruments of this kind, for determining the degree of heat or cold in the abſence of the obſerver, have been invented and deſcribed by others. Van Swinden (Diſſ. ſur la Comparaiſon du Therm. p. 253 &c) deſcribes one, which he ſays was the firſt of the kind, made on a plan communicated by Bernoulli to Leibnitz. Mr. Kraft, he alſo tells us, made one nearly like it. Mr. Six has lately, viz, in 1782, propoſed another conſtruction of a Thermometer of the ſame kind, deſcribed in the Philoſ. Tranſ. vol. 72, p. 72 &c.

M. De Luc has deſcribed the beſt method of conſtructing a Thermometer, fit for determining the temperature of the air, in the meaſuring of heights by the barometer. He has alſo ſhewn how to divide the ſcale of a Thermometer, ſo as to adapt it for aſtronomical purpoſes in the obſervation of refractions. See Recherches &c, tom. 2, p. 35 and 265.

Mr. Cavallo, in 1781, propoſed the conſtruction of a *Thermometrical Barometer*, which, by means of boiling water, might indicate the various gravity of the atmoſphere, or the height of the barometer. This Thermometer, he ſays, with its apparatus, might be packed up into a ſmall portable box, and ſerve for determining the heights of mountains &c, with greater facility, than with the common portable barometer. The inſtrument, in its preſent ſtate, conſiſts of a cylindrical tin veſſel, about 2 inches in diameter, and 5 inches high, in which veſſel the water is contained, which may be made to boil by the flame of a large wax-candle. The Thermometer is faſtened to the tin veſſel in ſuch a manner, as that its bulb may be about an inch above the bottom. The ſcale of this Thermometer, which is of braſs, exhibits on one ſide of the glaſs tube a few degrees of Fahrenheit's ſcale, viz, from 200° to 216°. On the other ſide of the tube are marked the various barometrical heights, at which the boiling water ſhews thoſe particular degrees of heat which are ſet down in Sir Geo. Shuckburgh's table. With this inſtrument the barometrical height is ſhewn within one 10th of an inch. The degrees of this Thermometer are rather longer than one 9th of an inch, and therefore may be divided into many parts, eſpecially by a Nonius. But a conſiderable imperfection ariſes from the ſmallneſs of the tin veſſel, which does not admit a ſufficient quantity of water; but when the quantity of water ſhall be ſufficiently large, as for inſtance 10 or 12 ounces, and is kept boiling in a proper veſſel, its degree of heat under the ſame preſſure of the atmoſphere is very ſettled; whereas when a Thermometer is kept in a ſmall quantity of boiling water, the mercury in its ſtem does not ſtand very ſteady, ſometimes riſing or falling ſo much as half a degree. Mr. Cavallo propoſes a farther improvement of this inſtrument, in the Philoſ. Tranſ. vol. 71, p. 524.

The ingenious Mr. Wedgwood, ſo well known for his various improvements in the different ſorts of pottery ware, has contrived to make a Thermometer for meaſuring the higher degrees of heat, by means of a diſtinguiſhing property of argillaceous bodies, viz, the diminution of their bulk by fire. This diminution commences in a low red heat, and proceeds regularly, as the heat increaſes, till the clay becomes vitrified. The total contraction of ſome good clays which he has examined in the ſtrongeſt of his own fires, is conſiderably more than one-fourth part in every dimenſion. By meaſuring the contraction of ſuch ſubſtances then, Mr. Wedgwood contrived to meaſure the moſt intenſe heats of ovens, furnaces, &c. For the curious particulars of which, ſee Philoſ. Tranſ. vol. 72, p. 305 &c.

THERMOSCOPE, an inſtrument ſhewing the changes happening in the air with reſpect to heat and cold.

The word Thermoſcope is often uſed indifferently with that of thermometer. There is ſome difference however in the literal import of the two; the firſt ſignifying an inſtrument that ſhews or exhibits the changes of heat &c to the eye; and the latter an inſtrument that meaſures thoſe changes; ſo that a thermometer ſhould be a more accurate Thermoſcope.

THIR, in Chronology, the name of the 5th month of the Ethiopians, which correſponds, according to Ludolf, to the month of January.

THIRD, in Muſic, a concord reſulting from a mixture of two ſounds containing an interval of 2 degrees: being called a third, becauſe containing 3 terms, or ſounds, between the extremes.

There is a greater and a leſs Third. The former takes its form from the ſeſquiquarta ratio, 4 to 5. The logarithm or meaſure of the octave $\frac{2}{1}$ being 1·00000, the meaſure of the greater Third $\frac{5}{4}$ will be 0·32193.—The *greater Third* is by practitioners often taken for the third part of an octave; which is an error, ſince three greater Thirds fall ſhort of the octave by a dieſis; for $\frac{5}{4} \times \frac{5}{4} \times \frac{5}{4} \times \frac{128}{125} = \frac{2}{1}$.

The *leſſer Third* takes its form from the ſeſquiquinta ratio 5 to 6; the meaſure or logarithm of this leſſer Third $\frac{6}{5}$, being 0·26303, that of the octave $\frac{2}{1}$ being 1·00000.

Both theſe Thirds are of great uſe in melody; making as it were the foundation and life of harmony.

THIRD-*Point*, or *Tierce-point*, in Architecture, the point of ſection in the vertex of an equilateral triangle.—Arches or vaults of the Third Point, are thoſe conſiſting

ſifting of two arches of a circle, meeting in an angle at top.

THREE-*legged-ſtaff*, an inſtrument conſiſting of three wooden legs, made with joints, ſo as to ſhut all together, and to take off in the middle for the better carriage. It has uſually a ball and ſocket on the top; and its uſe is to ſupport and adjuſt inſtruments for aſtronomy, ſurveying, &c.

THUNDER, a noiſe in the lower region of the air, excited by a ſudden exploſion of electrical clouds; which are therefore called Thunder-clouds.

The phenomenon of Thunder is variouſly accounted for. Seneca, Rohault, and ſome other authors, both ancient and modern, account for Thunder, by ſuppoſing two clouds impending over one another, the upper and rarer of which, becoming condenſed by a freſh acceſſion of air raiſed by warmth from the lower parts of the atmoſphere, or driven upon it by the wind, immediately falls forcibly down upon the lower and denſer cloud; by which fall, the air interpoſed between the two being compreſſed, that next the extremities of the two clouds is ſqueezed out, and leaves room for the extremity of the upper cloud to cloſe tight upon the under; thus a great quantity of the air is encloſed, which at length eſcaping through ſome winding irregular vent or paſſage, occaſions the noiſe called Thunder.

But this lame device could only reach at moſt to the caſe of Thunder heard without lightning; and therefore recourſe has been had to other modes of ſolution. Thus, it has been ſaid that Thunder is not occaſioned by the falling of clouds, but by the kindling of ſulphurous exhalations, in the ſame manner as the noiſe of the aurum fulminans. "There are ſulphurous exhalations, ſays Sir I. Newton, always aſcending into the air when the earth is dry; there they ferment with the nitrous acids, and, ſometimes taking fire, generate Thunder, lightning, &c."

The effects of Thunder are ſo like thoſe of fired gunpowder, that Dr. Wallis thinks we need not ſcruple to aſcribe them to the ſame cauſe; and the principal ingredients in gunpowder, we know, are nitre and ſulphur; charcoal only ſerving to keep the parts ſeparate, for their better kindling. Hence, if we conceive in the air a convenient mixture of nitrous and ſulphurous particles; and thoſe, by any cauſe, to be ſet on fire, ſuch exploſion may well follow, and with ſuch noiſe and light as attend the firing of gunpowder; and being once kindled, it will run from place to place, different ways, as the exhalations happen to lead it; much as is found in a train of gunpowder.

But a third, and moſt probable opinion is, that Thunder is the report or noiſe produced by an electrical exploſion in the clouds. Ever ſince the year 1752, in which the identity of the matter of lightning and of the electrical fluid has been aſcertained, philoſophers have generally agreed in conſidering Thunder as a conculſion produced in the air by an exploſion of electricity. For the illuſtration and proof of this theory, ſee ELECTRICITY, and LIGHTNING.

It may here be obſerved, that Mr. Henry Eeles, in a letter written in 1751, and read before the Royal Society in 1752, conſiders the electrical fire as the cauſe of Thunder, and accounts for it on this hypotheſis; and he tells us, that he did not know of any other perſon's having made the ſame conjecture. Philoſ. Tranſ. vol. 47, p. 524 &c.

That rattling in the noiſe of Thunder, which makes it ſeem as if it paſſed through arches, or were variouſly broken, is probably owing to the ſound being excited among clouds hanging over one another, and the agitated air paſſing irregularly between them.

The exploſion, if high in the air, and remote from us, will do no miſchief; but when near, it may deſtroy trees, animals, &c.

This proximity, or ſmall diſtance, may be eſtimated nearly by the interval of time between ſeeing the flaſh of lightning, and hearing the report of the Thunder, eſtimating the diſtance, after the rate of 1142 feet per ſecond of time, or $3\frac{2}{3}$ ſeconds to the mile. Dr. Wallis obſerves, that commonly the difference between the two is about 7 ſeconds, which, at the rate above mentioned, gives the diſtance almoſt 2 miles. But ſometimes it comes in a ſecond or two, which argues the exploſion very near us, and even among us. And in ſuch caſes, the doctor aſſures us, he has ſometimes foretold the miſchiefs that happened.

The noiſe of Thunder, and the flame of lightning, are eaſily made by art. If a mixture of oil or ſpirit of vitriol be made with water, and ſome filings of ſteel added to it, there will immediately ariſe a thick ſmoke, or vapour, out of the mouth of the veſſel; and if a lighted candle be applied to this, it will take fire, and the flame will immediately deſcend into the veſſel, which will be burſt to pieces with a noiſe like that of a cannon.

This is ſo far analogous to Thunder and lightning, that a great exploſion and fire are occaſioned by it; but in this they differ, that this matter when once fired is deſtroyed, and can give no more exploſions; whereas, in the heavens, one clap of Thunder uſually follows another, and there is a continued ſucceſſion of them for a long time. Mr. Homberg explained this by the lightneſs of the air above us, in compariſon of that near, which therefore would not ſuffer all the matter ſo kindled to be diſſipated at once, but keeps it for ſeveral returns.

THUNDERBOLT. When lightning acts with extraordinary violence, and breaks or ſhatters any thing, it is called a *Thunderbolt*, which the vulgar, to fit it for ſuch effects, ſuppoſe to be a hard body, and even a ſtone.—But that we need not have recourſe to a hard ſolid body to account for the effects commonly attributed to the Thunderbolt, will be evident to any one, who conſiders thoſe of the pulvis fulminans, and of gunpowder; but, more eſpecially the aſtoniſhing powers of electricity, when only collected and employed by human art, and much more when directed and exerciſed in the courſe of nature.

When we conſider the known effects of electrical exploſions, and thoſe produced by lightning, we ſhall be at no loſs to account for the extraordinary operations vulgarly aſcribed to Thunderbolts. As ſtones and bricks ſtruck by lightning are often found in a vitrified ſtate, we may reaſonably ſuppoſe, with Beccaria, that ſome ſtones in the earth, having been ſtruck in this manner, gave occaſion to the vulgar opinion of the Thunderbolt.

THUNDER-*clouds*, in Phyſiology, are thoſe clouds which

which are in a ſtate fit for producing lightning and thunder.

From Beccaria's exact and circumſtantial account of the external appearances of Thunder-clouds, the following particulars are extracted.

The firſt appearance of a Thunder ſtorm, which uſually happens when there is little or no wind, is one denſe cloud, or more, increaſing very faſt in ſize, and riſing into the higher regions of the air. The lower ſurface is black and nearly level; but the upper finely arched, and well defined. Many of theſe clouds often ſeem piled upon one another, all arched in the ſame manner; but they are continually uniting, ſwelling, and extending their arches.

At the time of the riſing of this cloud, the atmoſphere is commonly full of a great many ſeparate clouds, that are motionleſs, and of odd whimſical ſhapes. All theſe, upon the appearance of the Thunder-cloud, draw towards it, and become more uniform in their ſhapes as they approach; till, coming very near the Thunder-cloud, their limbs mutually ſtretch toward one another, and they immediately coaleſce into one uniform maſs. Theſe he calls adſcititious clouds, from their coming in, to enlarge the ſize of the Thunder-cloud. But ſometimes the Thunder-cloud will ſwell, and increaſe very faſt, without the conjunction of any adſcititious clouds; the vapours in the atmoſphere forming themſelves into clouds wherever it paſſes. Some of the adſcititious clouds appear like white fringes, at the ſkirts of the Thunder-cloud, or under the body of it, but they keep continually growing darker and darker, as they approach to unite with it.

When the Thunder-cloud is grown to a great ſize, its lower ſurface is often ragged, particular parts being detached towards the earth, but ſtill connected with the reſt. Sometimes the lower ſurface ſwells into various large protuberances bending uniformly downward; and ſometimes one whole ſide of the cloud will have an inclination to the earth, and the extremity of it nearly touch the ground. When the eye is under the Thunder-cloud, after it is grown larger, and well formed, it is ſeen to ſink lower, and to darken prodigiouſly; at the ſame time that a number of ſmall adſcititious clouds (the origin of which can never be perceived) are ſeen in a rapid motion, driving about in very uncertain directions under it. While theſe clouds are agitated with the moſt rapid motions, the rain commonly falls in the greateſt plenty, and if the agitation be exceedingly great, it commonly hails.

While the Thunder-cloud is ſwelling, and extending its branches over a large tract of country, the lightning is ſeen to dart from one part of it to another, and often to illuminate its whole maſs. When the cloud has acquired a ſufficient extent, the lightning ſtrikes between the cloud and the earth, in two oppoſite places, the path of the lightning lying through the whole body of the cloud and its branches. The longer this lightning continues, the leſs denſe does the cloud become, and the leſs dark its appearance; till at length it breaks in different places, and ſhews a clear ſky.

Theſe Thunder-clouds were ſometimes in a poſitive as well as a negative ſtate of electricity. The electricity continued longer of the ſame kind, in proportion as the Thunder-cloud was ſimple, and uniform in its direction; but when the lightning changed its place, there commonly happened a change in the electricity of the apparatus, over which the clouds paſſed. It would change ſuddenly after a very violent flaſh of lightning, but the change would be gradual when the lightning was moderate, and the progreſs of the Thunder-cloud ſlow. Beccar. Lettere dell'Elettriciſmo pa. 107; or Prieſtley's Hiſt. Elec. vol. 1, p. 397. See alſo LIGHTNING.

THUNDER-*Houſe*, in Electricity, is an inſtrument invented by Dr. James Lind, for illuſtrating the manner in which buildings receive damage from lightning, and to evince the utility of metallic conductors in preſerving them from it.

A (fig. 1, pl. 35), is a board about ½ of an inch thick, and ſhaped like the gable end of a houſe. This board is fixed perpendicularly upon the bottom board B, upon which the perpendicular glaſs pillar CD is alſo fixed in a hole about 8 inches diſtant from the baſis of the board A. A ſquare hole ILMK, about a quarter of an inch deep, and nearly one inch wide, is made in the board A, and is filled with a ſquare piece of wood, nearly of the ſame dimenſions. It is nearly of the ſame dimenſions, becauſe it muſt go ſo eaſily into the hole, that it may drop off, by the leaſt ſhaking of the inſtrument. A wire LK is faſtened diagonally to this ſquare piece of wood. Another wire IH of the ſame thickneſs, having a braſs ball H, ſcrewed on its pointed extremity, is faſtened upon the board A: ſo alſo is the wire MN, which is ſhaped in a ring at O. From the upper extremity of the glaſs pillar CD, a crooked wire proceeds, having a ſpring ſocket F, through which a double knobbed wire ſlips perpendicularly, the lower knob G of which falls juſt above the knob H. The glaſs pillar DC muſt not be made very faſt into the bottom board; but it muſt be fixed ſo that it may be pretty eaſily moved round its own axis, by which means the braſs ball G may be brought nearer to or farther from the ball H, without touching the part EFG. Now when the ſquare piece of wood LMIK (which may repreſent the ſhutter of a window or the like) is fixed into the hole ſo that the wire LK ſtands in the dotted repreſentation IM, then the metallic communication from H to O is complete, and the inſtrument repreſents a houſe furniſhed with a proper metallic conductor; but if the ſquare piece of wood LMIK be fixed ſo that the wire LK ſtands in the direction LK, as repreſented in the figure, then the metallic conductor HO, from the top of the houſe to its bottom, is interrupted at IM, in which caſe the houſe is not properly ſecured.

Fix the piece of wood LMIK, ſo that its wire may be as repreſented in the figure, in which caſe the metallic conductor HO is diſcontinued. Let the ball G be fixed at about half an inch perpendicular diſtance from the ball H; then, by turning the glaſs pillar DC, remove the former ball from the latter; by a wire or chain connect the wire EF with the wire Q of the jar P; and let another wire or chain, faſtened to the hook O, touch the outſide coating of the jar. Connect the wire Q with the prime conductor, and charge the jar; then, by turning the glaſs pillar DC, let the ball G come gradually near the ball H, and when they are arrived ſufficiently near one another, you will obſerve, that the jar explodes and the piece of wood LMIK is puſhed

puſhed out of the hole to a conſiderable diſtance from the Thunder-houſe.

Now the ball G, in this experiment, repreſents an electrified cloud, which, when it is arrived ſufficiently near the top of the houſe A, the electricity ſtrikes it; and as this houſe is not ſecured with a proper conductor, the exploſion breaks part of it, i. e. knocks off the piece of wood IM.

Repeat the experiment with only this variation, viz, that this piece of wood IM be ſituated ſo that the wire LK may ſtand in the ſituation IM; in which caſe the conductor HO is not diſcontinued; and you will obſerve that the exploſion will have no effect upon the piece of wood LM; this remaining in the hole unmoved; which ſhews the uſefulneſs of the metallic conductor.

Farther, unſcrew the braſs ball H from the wire HI, ſo that this may remain pointed, and with this difference only in the apparatus repeat both the above experiments, and you will find that the piece of wood IM is in neither caſe moved from its place, nor will any exploſion be heard; which not only demonſtrates the preference of conductors with pointed terminations to thoſe with blunted ones, but alſo ſhews that a houſe, furniſhed with ſharp terminations, although not furniſhed with a regular conductor, is almoſt ſufficiently guarded againſt the effects of lightning.

Mr. Henley, having connected a jar containing 509 ſquare inches of coated ſurface with his prime conductor, obſerved that if it was ſo charged as to raiſe the index of his electrometer to 60°, by bringing the ball on the wire of the Thunder-houſe, to the diſtance of half an inch from that connected with the prime conductor, the jar would be diſcharged, and the piece in the Thunder-houſe thrown out to a conſiderable diſtance. Uſing a pointed wire for a conductor to the Thunder-houſe, inſtead of the knob, the charge being the ſame as before, the jar was diſcharged ſilently, though ſuddenly; and the piece was not thrown out of the Thunder-houſe. In another experiment, having made a double circuit to the Thunder-houſe, the firſt by the knob, the ſecond by a ſharp-pointed wire, at an inch and a quarter diſtance from each other, but of exactly the ſame height (as in fig. 2) the charge being the ſame; although the knob was brought firſt under that connected with the prime conductor, which was raiſed half an inch above it, and followed by the point, yet no exploſion could fall upon the knob; the point drew off the whole charge ſilently, and the piece in the Thunder-houſe remained unmoved.

Phil. Tranſ. vol. 64, p. 136. See POINTS in Electricity.

THURSDAY, the 5th day of the Chriſtian's week, but the 6th of the Jews. The name is from Thor, one of the Saxon Gods.

THUS, in Sea-Language, a word uſed by the pilot in directing the helmſman or ſteerſman to keep the ſhip in her preſent ſituation when ſailing with a ſcant wind, ſo that ſhe may not approach too near the direction of the wind, which would ſhiver her ſails, nor fall to leeward, and run farther out of her courſe.

TIDES, two periodical motions of the waters of the ſea; called alſo the *flux* and *reflux*, or the *ebb* and *flow*.

The Tides are found to follow periodically the courſe of the ſun and moon, both as to time and quantity. And hence it has been ſuſpected, in all ages, that the Tides were ſomehow produced by the influence of theſe luminaries. Thus, ſeveral of the ancients, and among others, Pliny, Ptolomy, and Macrobius, were acquainted with the influence of the ſun and moon upon the Tides; and Pliny ſays expreſsly, that the cauſe of the ebb and flow is in the ſun, which attracts the waters of the ocean; and adds, that the waters riſe in proportion to the proximity of the moon to the earth. It is indeed now well known, from the diſcoveries of Sir Iſaac Newton, that the Tides are cauſed by the gravitation of the earth towards the ſun and moon. Indeed the ſagacious Kepler, long ago, conjectured this to be the cauſe of the Tides: "If, ſays he, the earth ceaſed to attract its waters towards itſelf, all the water in the ocean would riſe and flow into the moon: the ſphere of the moon's attraction extends to our earth, and draws up the water." Thus thought Kepler, in his Introd. ad Theor. Mart. This ſurmiſe, for it was then no more, is now abundantly verified in the theory laid down by Newton, and by Halley, from his principles.

As to the Phenomena of the TIDES: 1. The ſea is obſerved to flow, for about 6 hours, from ſouth towards north; the ſea gradually ſwelling; ſo that, entering the mouths of rivers, it drives back the river-waters towards their heads, or ſprings. After a continual flux of 6 hours, the ſea ſeems to reſt for about a quarter of an hour; after which it begins to ebb, or retire back again, from north to ſouth, for 6 hours more; in which time, the water ſinking, the rivers reſume their natural courſe. Then, after a ſeeming pauſe of a quarter of an hour, the ſea again begins to flow, as before: and ſo on alternately.

2. Hence, the ſea ebbs and flows twice a day, but falling every day gradually later and later, by about 48 minutes, the period of a flux and reflux being on an average about 12 hours 24 minutes, and the double of each 24 hours 48 minutes; which is the period of a lunar day, or the time between the moon's paſſing a meridian, and coming to it again. So that the ſea flows as often as the moon paſſes the meridian, both the arch above the horizon, and that below it; and ebbs as often as ſhe paſſes the horizon, both on the eaſtern and weſtern ſide.

Other phenomena of the Tides are as below; and the reaſons of them will be noticed in the Theory of the Tides that follows.

3. The elevation towards the moon a little exceeds the oppoſite one. And the quantity of the aſcent of the water is diminiſhed from the equator towards the poles.

4. From the ſun, every natural day, the ſea is twice elevated, and twice depreſſed, the ſame as for the moon. But the ſolar Times are much leſs than the lunar ones, on account of the immenſe diſtance of the ſun; yet they are both ſubject to the ſame laws.

5. The Tides which depend upon the actions of the ſun and moon, are not diſtinguiſhed, but compounded, and ſo forming as to ſenſe one united Tide, increaſing and decreaſing, and thus making neap and ſpring Tides: for, by the action of the ſun, the

lunar Tide is only changed; which change varies every day, by reaſon of the inequality between the natural and lunar day.

6. In the ſyzygies the elevations from the action of both luminaries concur, and the ſea is more elevated. But the ſea aſcends leſs in the quadratures; for where the water is elevated by the action of the moon, it is depreſſed by the action of the ſun; and vice verſa. Therefore, while the moon paſſes from the ſyzygy to the quadrature, the daily elevations are continually diminiſhed: on the contrary, they are increaſed while the moon moves from the quadrature to the ſyzygy. At a new moon alſo, *cæteris paribus*, the elevations are greater; and thoſe that follow one another the ſame day, are more different than at full moon.

7. The greateſt elevations and depreſſions are not obſerved till the 2d or 3d day after the new or full moon. And if we conſider the luminaries receding from the plane of the equator, we ſhall perceive that the agitation is diminiſhed, and becomes leſs, according as the declination of the luminaries becomes greater.

8. In the ſyzygies, and near the equinoxes, the Tides are obſerved to be the greateſt, both luminaries being in or near the equator.

9. The actions of the ſun and moon are greater, the nearer thoſe bodies are to the earth; and the leſs, as they are farther off. Alſo the greateſt Tides happen near the equinoxes, or rather when the ſun is a little to the ſouth of the equator, that is, a little before the vernal, and after the autumnal equinox. But yet this does not happen regularly every year, becauſe ſome variation may ariſe from the ſituation of the moon's orbit, and the diſtance of the ſyzygy from the equinox.

10. All theſe phenomena obtain, as deſcribed, in the open ſea, where the ocean is extended enough to be ſubject to theſe motions. But the particular ſituations of places, as to ſhores, capes, ſtraits, &c, diſturb theſe general rules. Yet it is plain, from the moſt common and univerſal obſervations, that the Tides follow the laws above laid down.

11. The mean force of the moon to move the ſea, is to that of the ſun, nearly as $4\frac{1}{2}$ to 1. And therefore, if the action of the ſun alone produce a Tide of 2 feet, which it has been ſtated to do, that of the moon will be 9 feet; from which it follows, that the ſpring Tides will be 11 feet, and the neap Tides 7 feet high. But as to ſuch elevations as far exceed theſe, they happen from the motion of the waters againſt ſome obſtacles, and from the ſea violently entering into ſtraits or gulphs where the force is not broken till the water riſes higher.

Theory of the TIDES.

1. If the earth were entirely fluid, and quieſcent, it is evident that its particles, by their mutual gravity towards each other, would form the whole maſs into the figure of an exact ſphere. Then ſuppoſe ſome power to act on all the particles of this ſphere with an equal force, and in parallel directions; by ſuch a power the whole maſs will be moved together, but its figure will ſuffer no alteration by it, being ſtill the ſame perfect ſphere, whoſe centre will have the ſame motion as each particle.

Upon this ſuppoſition, if the motion of the earth round the common centre of gravity of the earth and moon were deſtroyed, and the earth left to the influence of its gravitation towards the moon, as the acting power above mentioned; then the earth would fall or move ſtraight towards the moon, but ſtill retaining its true ſpherical figure.

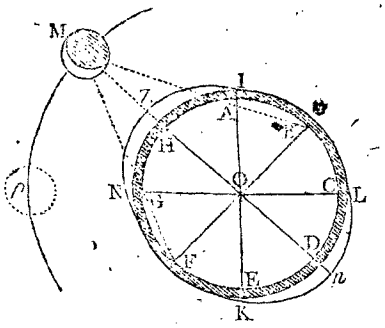
But the fact is, that the effects of the moon's action, as well as the action itſelf, on different parts of the earth, are not equal: thoſe parts, by the general law of gravity, being moſt attracted that are neareſt the moon, and thoſe being leaſt attracted that are fartheſt from her, while the parts that are at a middle diſtance are attracted by a mean degree of force: beſides, all the parts are not acted on in parallel lines, but in lines directed towards the centre of the moon: on both which accounts the ſpherical figure of the fluid earth muſt ſuffer ſome change from the action of the moon. So that, in falling, as above, the nearer parts, being moſt attracted, would fall quickeſt; the farther parts, being leaſt attracted, would fall ſloweſt; and the fluid maſs would be lengthened out, and take a kind of ſpheroidical form.

Hence it appears, and what muſt be carefully obſerved, that it is not the action of the moon itſelf, but the inequalities in that action, that cauſe any variation from the ſpherical figure; and that, if this action were the ſame in all the particles as in the central parts, and operating in the ſame direction, no ſuch change would enſue.

Let us now admit the parts of the earth to gravitate toward its centre: then, as this gravitation far exceeds the action of the moon, and much more exceeds the differences of her actions on different parts of the earth, the effect that reſults from the inequalities of theſe actions of the moon, will be only a ſmall diminution of the gravity of thoſe parts of the earth which it endeavoured in the former ſuppoſition to ſeparate from its centre; that is, thoſe parts of the earth which are neareſt to the moon, and thoſe that are fartheſt from her, will have their gravity toward the earth ſomewhat abated; to ſay nothing of the lateral parts. So that ſuppoſing the earth fluid, the columns from the centre to the neareſt, and to the fartheſt parts, muſt riſe, till by their greater height they be able to balance the other columns, whoſe gravity is leſs altered by the inequalities of the moon's action. And thus the figure of the earth muſt ſtill be an oblong ſpheroid.

Let us now conſider the earth, inſtead of falling toward the moon by its gravity, as projected in any direction, ſo as to move round the centre of gravity of the earth and moon: it is evident that in this caſe, the ſeveral parts of the fluid earth will ſtill preſerve their relative poſitions; and the figure of the earth will remain the ſame as if it fell freely toward the moon; that is, the earth will ſtill aſſume a ſpheroidal form, having its longeſt diameter directed toward the moon.

From



From the above reaſoning it appears, that the parts of the earth directly under the moon, as at H, and alſo the oppoſite parts at D, will have the flood or highwater at the ſame time; while the parts, at B and F, at 90° diſtance, or where the moon appears in the horizon, will have the ebbs or loweſt waters at that time.

Hence, as the earth turns round its axis from the moon to the moon again in 24 hours 48 minutes, this oval of water muſt ſhift with it; and thus there will be two Tides of flood and two of ebb in that time.

But it is further evident that, by the motion of the earth on her axis, the moſt elevated part of the water is carried beyond the moon in the direction of the rotation. So that the water continues to riſe after it has paſſed directly under the moon, though the immediate action of the moon there begins to decreaſe, and comes not to its greateſt elevation till it has got about half a quadrant farther. It continues alſo to deſcend after it has paſſed at 90° diſtance from the point below the moon, to a like diſtance of about half a quadrant. The greateſt elevation therefore is not in the line drawn through the centres of the earth and moon, nor the loweſt points where the moon appears in the horizon, but all theſe about half a quadrant removed eaſtward from theſe points, in the direction of the motion of rotation. Thus in open ſeas, where the water flows freely, the moon M is generally paſt the north and ſouth meridian, as at *p*, when the high water is at Z and at *n*: the reaſon of which is plain, becauſe the moon acts with the ſame force after ſhe has paſſed the meridian, and thus adds to the libratory or waving motion, which the water acquired when ſhe was in the meridian; and therefore the time of high water is not preciſely at the time of her coming to the meridian, but ſome time after, &c.

Beſides, the Tides anſwer not always to the ſame diſtance of the moon, from the meridian, at the ſame places; but are variouſly affected by the action of the ſun, which brings them on ſooner when the moon is in her firſt and third quarters, and keeps them back later when ſhe is in her 2d and 4th; becauſe, in the former caſe the Tide raiſed by the ſun alone would be earlier than the Tide raiſed by the moon, and in the latter caſe later.

2. We have hitherto adverted only to the action of the moon in producing Tides; but it is manifeſt that, for the ſame reaſons, the inequality of the ſun's action on different parts of the earth, would produce a like effect, and a like variation from the exact ſpherical figure of a fluid earth. So that in reality there are two Tides every natural day from the action of the ſun, as there are in the lunar day from that of the moon, ſubject to the ſame laws; and the lunar Tide, as we have obſerved, is ſomewhat changed by the action of the ſun, and the change varies every day on account of the inequality between the natural and the lunar day. Indeed the effect of the ſun in producing Tides, becauſe of his immenſe diſtance, muſt be conſiderably leſs than that of the moon, though the gravity toward the ſun be much greater: for it is not the action of the ſun or moon itſelf, but the inequalities in that action, that have any effect: the ſun's diſtance is ſo great, that the diameter of the earth is but as a point in compariſon with it, and therefore the difference between the ſun's actions on the neareſt and fartheſt parts, becomes vaſtly leſs than it would be if the ſun were as near as the moon. However the immenſe bulk of the ſun makes the effect ſtill ſenſible, even at ſo great a diſtance; and therefore, though the action of the moon has the greateſt ſhare in producing the Tides, the action of the ſun adds ſenſibly to it when they conſpire together, as in the full and change of the moon, when they are nearly in the ſame line with the centre of the earth, and therefore unite their forces: conſequently, in the ſyzygies, or at new and full moon, the Tides are the greateſt, being what are called the *Spring-Tides*. But the action of the ſun diminiſhes the effect of the moon's action in the quarters, becauſe the one raiſes the water in that caſe where the other depreſſes it; therefore the Tides are the leaſt in the quadratures, and are called *Neap-Tides*.

Newton has calculated the effects of the ſun and moon reſpectively upon the Tides, from their attractive powers. The former he finds to be to the force of gravity, as 1 to 12868200, and to the centrifugal force at the equator as 1 to 44527. The elevation of the waters by this force is conſidered by Newton as an effect ſimilar to the elevation of the equatorial parts above the polar parts of the earth, ariſing from the centrifugal force at the equator; and as it is 44527 times leſs, he finds it to be $24\frac{1}{2}$ inches, or 2 feet and $\frac{1}{2}$ an inch.

To find the force of the moon upon the water, Newton compares the ſpring-tides at the mouth of the river Avon, below Briſtol, with the neap-tides there, and finds the proportion as 9 to 5; whence, after ſeveral neceſſary corrections, he concludes that the force of the moon to that of the ſun, in raiſing the waters of the ocean, is as 4·4815 to 1; ſo that the force of the moon is able of itſelf to produce an elevation of 9 feet $1\frac{3}{4}$ inch, and the ſun and moon together may produce an elevation of about 11 feet 2 inches, when at their mean diſtances from the earth, or an elevation of about $12\frac{3}{4}$ feet, when the moon is neareſt the earth. The height to which the water is found to riſe, upon coaſts of the open and deep ocean, is agreeable enough to this computation.

Dr. Horſley eſtimates the force of the moon to that of the ſun, as 5·0469 to 1, in his edit. of Newton's Princip. See the Princip. lib. 3, ſect. 3, pr. 36 and 37; alſo Maclaurin's Diſſert. de Cauſa Phyſica Fluxus et Refluxus Maris apud Phil. Nat. Princ. Math. Comment.

ment. le Seur & Jacquier, tom. 3, p. 272. And other calculators make the proportion ſtill more different.

3. It muſt be obſerved, that the ſpring-tides do not happen preciſely at new and full moon, nor the neap-tides at the quarters, but a day or two after; becauſe, as in other caſes, ſo in this, the effect is not greateſt or leaſt when the immediate influence of the cauſe is greateſt or leaſt. As, for example, the greateſt heat is not on the day of the ſolſtice, when the immediate action of the ſun is greateſt, but ſome time after; ſo likewiſe, if the actions of the ſun and moon ſhould ſuddenly ceaſe, yet the Tides would continue to have their courſe for ſome time; and like alſo as the waves of the ſea continue after a ſtorm.

4. The different diſtances of the moon from the earth produce a ſenſible variation in the Tides. When the moon approaches toward the earth, her action on every part increaſes, and the differences of that action, on which the Tides depend, alſo increaſe; and as the moon approaches, her action on the neareſt parts increaſes more quickly than that on the remote parts, ſo that the Tides increaſe in a higher proportion as the moon's diſtances decreaſe. In fact, it is ſhewn by Newton, that the Tides increaſe in proportion as the cubes of the diſtances decreaſe; ſo that the moon at half her diſtance would produce a Tide 8 times greater.

The moon deſcribes an oval about the earth, and at her neareſt diſtance produces a Tide ſenſibly greater than at her greateſt diſtance from the earth: and hence it is that two great ſpring-tides never ſucceed each other immediately; for if the moon be at her leaſt diſtance from the earth at the change, ſhe muſt be at her greateſt diſtance at the full, having made half a revolution in the intervening time, and therefore the ſpring-tide then will be much leſs than that at the laſt change was; and for the ſame reaſon, if a great ſpring-tide happen at the time of full moon, the Tide at the enſuing change will be leſs.

5. The ſpring-tides are higheſt, and the neap-tides loweſt, about the time of the equinoxes, or the latter end of March and September; and, on the contrary, the ſpring-tides are the loweſt, and the neap-tides the higheſt, at the ſolſtices, or about the latter end of June and December: ſo that the difference between the ſpring and neap Tides, is much more conſiderable about the equinoctial than the ſolſtitial ſeaſons of the year. To illuſtrate and evince the truth of this obſervation, let us conſider the effect of the luminaries upon the Tides, when in and out of the plane of the equator. Now it is manifeſt, that if either the ſun or moon were in the pole, they could not have any effect on the Tides; for their action would raiſe all the water at the equator, or at any parallel, quite around, to a uniform height; and therefore any place of the earth, in deſcribing its parallel to the equator, would not meet, in its courſe, with any part of the water more elevated than another; ſo that there could be no Tide in any place, that is, no alteration in the height of the waters.

On the other hand, the effect of the ſun or moon is greateſt when in the equinoctial; for then the axis of the ſpheroidal figure, ariſing from their action, moves in the greateſt circle, and the water is put into the greateſt agitation; and hence it is that the ſpring-tides produced when the ſun and moon are both in the equinoctial, are the greateſt of any, and the neaptides the leaſt of any about that time. And when the luminary is any where between the equinoctial and the pole, the Tides are the ſmaller.

6. The higheſt ſpring tides are after the autumnal and before the vernal equinox: the reaſon of which is, becauſe the ſun is nearer the earth in winter than in ſummer.

7. Since the greateſt of the two Tides happening in every diurnal revolution of the moon, is that in which the moon is neareſt the zenith, or nadyr: for this reaſon, while the ſun is in the northern ſigns, the greater of the two diurnal Tides in our climates, is that ariſing from the moon above the horizon; when the ſun is in the ſouthern ſigns, the greateſt is that ariſing from the moon below the horizon. Thus it is found by obſervation that the evening Tides in the ſummer exceed the morning Tides, and in winter the morning Tides exceed the evening Tides. The difference is found at Briſtol to amount to 15 inches, and at Plymouth to 12. It would be ſtill greater, but that a fluid always retains an impreſſed motion for ſome time; ſo that the preceding Tides affect always thoſe that follow them. Upon the whole, while the moon has a north declination, the greateſt Tides in the northern hemiſphere are when ſhe is above the horizon, and the reverſe while her declination is ſouth.

8. Such would the Tides regularly be, if the earth were all over covered with the ſea very deep, ſo that the water might freely follow the influence of the ſun and moon; but, by reaſon of the ſhoalneſs of ſome places, and the narrowneſs of the ſtraits in others, through which the Tides are propagated, there ariſes a great diverſity in the effect according to the various circumſtances of the places. Thus, a very ſlow and imperceptible motion of the whole body of water, where it is very deep, as 2 miles for inſtance, will ſuffice to raiſe its ſurface 10 or 12 feet in a Tide's time: whereas, if the ſame quantity of water were to be conveyed through a channel of 40 fathoms deep, it would require a very rapid ſtream to effect it in ſo large inlets as are the Engliſh channel, and the German ocean; whence the Tide is found to ſet ſtrongeſt in thoſe places where the ſea grows narroweſt, the ſame quantity of water being in that caſe to paſs through a ſmaller paſſage. This is particularly obſervable in the ſtraits between Portland and Cape la Hogue in Normandy, where the Tide runs like a ſluice: and would be yet more ſo between Dover and Calais, if the Tide coming round the iſland did not check it.

This force, when once impreſſed, continues to carry the water above the ordinary height in the ocean, eſpecially where the water meets a direct obſtacle, as it does in St. Maloes; and where it enters into a long channel which, running far into the land, grows very ſtrait at its extremity, as it does into the Severn ſea at Chepſtow and Briſtol.

This ſhoalneſs of the ſea, and the intercurrent continents, are the reaſons that in the open ocean the Tides riſe but to very ſmall heights in proportion to what they do in wide-mouthed rivers, opening in the direc-

tion

tion of the ſtream of the Tide; and that high water is not ſoon after the moon's appulſe to the meridian, but ſome hours after it, as it is obſerved upon all the weſtern coaſt of Europe and Africa, from Ireland to the Cape of Good Hope; in all which a ſouth-weſt moon makes high water; and the ſame it is ſaid is the caſe on the weſtern ſide of America. So that Tides happen to different places at all diſtances of the moon from the meridian, and conſequently at all hours of the day.

To allow the Tides their full motion, the ocean in which they are produced, ought to be extended from eaſt to weſt 90 degrees at leaſt; becauſe that is the diſtance between the places where the water is moſt raiſed and depreſſed by the moon. Hence it appears that it is only in the great oceans that ſuch Tides can be produced, and why in the larger Pacific ocean they exceed thoſe in the Atlantic ocean. Hence alſo it is obvious, why the Tides are not ſo great in the torrid zone, between Africa and America, where the ocean is narrower, as in the temperate zones on either ſide; and hence we may alſo underſtand why the Tides are ſo ſmall in iſlands that are very far diſtant from the ſhores. It is farther manifeſt that, in the Atlantic ocean, the water cannot riſe on one ſhore but by deſcending on the other; ſo that at the intermediate iſlands it muſt continue at a mean height between its elevations on thoſe two ſhores. But when Tides paſs over ſhoals, and through ſtraits into bays of the ſea, their motion becomes more various, and their height depends on many circumſtances.

To be more particular. The Tide that is produced on the weſtern coaſts of Europe, in the Atlantic, correſponds to the ſituation of the moon already deſcribed. Thus it is high water on the weſtern coaſts of Ireland, Portugal and Spain, about the 3d hour after the moon has paſſed the meridian: from thence it flows into the adjacent channels, as it finds the eaſieſt paſſage. One current from it, for inſtance, runs up by the ſouth of England, and another comes in by the north of Scotland; they take a conſiderable time to move all this way, making always high water ſooner in the places to which they firſt come; and it begins to fall at theſe places while the currents are ſtill going on to others that are farther diſtant in their courſe. As they return, they are not able to raiſe the Tide, becauſe the water runs faſter off than it returns, till, by a new Tide propagated from the open ocean, the return of the current is ſtopped, and the water begins to riſe again. The Tide propagated by the moon in the German ocean, when ſhe is 3 hours paſt the meridian, takes 12 hours to come from thence to London bridge; ſo that when it is high water there, a new Tide is already come to its height in the ocean; and in ſome intermediate place it muſt be low water at the ſame time. Conſequently when the moon has north declination, and we ſhould expect the Tide at London to be the greateſt when the moon is above the horizon, we find it is leaſt; and the contrary when ſhe has ſouth declination.

At ſeveral places it is high water 3 hours before the moon comes to the meridian; but that Tide, which the moon puſhes as it were before her, is only the Tide oppoſite to that which was raiſed by her when ſhe was 9 hours paſt the oppoſite meridian.

It would be endleſs to recount all the particular ſolutions, which are eaſy conſequences from this doctrine: as, why the lakes and ſeas, ſuch as the Caſpian ſea and the Mediterranean ſea, the Black ſea and the Baltic, have little or no ſenſible Tides: for lakes are uſually ſo ſmall, that when the moon is vertical ſhe attracts every part of them alike, ſo that no part of the water can be raiſed higher than another: and having no communication with the ocean, it can neither increaſe nor diminiſh their water, to make it riſe and fall; and ſeas that communicate by ſuch narrow inlets, and are of ſo immenſe an extent, cannot ſpeedily receive and empty water enough to raiſe or ſink their ſurface any thing ſenſibly.

In general; when the time of high water at any place is mentioned, it is to be underſtood on the days of new and full moons.—Among pilots, it is cuſtomary to reckon the time of flood, or high water, by the point of the compaſs the moon bears on, at that time, allowing $\frac{3}{4}$ of an hour for each point. Thus, on the full and change days, in places where it is flood at noon, the Tide is ſaid to flow north and ſouth, or at 12 o'clock: in other places, on the ſame days, where the moon bears 1, 2, 3, 4, or more points to the eaſt or weſt of the meridian, when it is high water, the Tide is ſaid to flow on ſuch point; thus, if the moon bears SE, at flood, it is ſaid to flow SE and NW, or 3 hours before the meridian, that is, at 9 o'clock; if it bears SW, it flows SW and NE, or at 3 hours after the meridian; and in like manner for the other points of the moon's bearing.

The times of high water in any place fall about the ſame hours after a period of about 15 days, or between one ſpring Tide and another; but during that period, the times of high water fall each day later by about 48 minutes.

On the ſubject of this article, ſee Newton Princ. Math. lib. 3, prop. 24, and De Syſtem. Mundi ſect. 38, &c. Apud Opera edit. Horſley, tom. 3, pa. 52 &c. p. 203 &c. Maclaurin's Account of Newton's Diſcoveries, book 4, ch. 7. Ferguſon's Aſtron. ch. 17. Robertſon's Navig. book 6, ſect. 7, 8, 9. Lalande's Aſtron. vol. 4.

TIDE *Dial*, an inſtrument contrived by Mr. Ferguſon, for exhibiting and determining the ſtate of the Tides. For the conſtruction and uſe of which ſee his Aſtron. p. 297.

TIDE *Tables*, are tables commonly exhibiting the times of high water at ſundry places, as they fall on the days of the full and change of the moon, and ſometimes the height of them alſo. Theſe are common in moſt books on Navigation, particularly Robertſon's, and the 2d ed. of Tables requiſite to be uſed with the Nautical Almanac. See one at HIGH-*water*.

TIERCE, or TERCE, a liquid meaſure, as of wine, oil, &c, containing 42 gallons, or the 3d part of a pipe; whence its name.

TIME, a ſucceſſion of phenomena in the univerſe; or a mode of duration, marked by certain periods and meaſures; chiefly indeed by the motion and

and revolution of the luminaries, and particularly of the ſun.

The idea of Time in general, Locke obſerves, we acquire by conſidering any part of infinite duration, as ſet out by periodical meaſures: the idea of any particular Time, or length of duration, as a day, an hour, &c, we acquire firſt by obſerving certain appearances at regular and ſeemingly equidiſtant periods. Now, by being able to repeat theſe lengths or meaſures of Time as often as we will, we can imagine duration, where nothing really endures or exiſts; and thus we imagine tomorrow, or next year, &c.

Some of the later ſchool-philoſophers define Time to be the duration of a thing whoſe exiſtence is neither without beginning nor end: by this, Time is diſtinguiſhed from eternity.

Ariſtotle and the Peripatetics define it, *numerus motus ſecundum prius & poſterius*, or a multitude of tranſient parts of motion, ſucceeding each other, in a continual flux, in the relation of priority and poſteriority. Hence it ſhould follow that Time is motion itſelf, or at leaſt the duration of motion, conſidered as having ſeveral parts, ſome of which are continually ſucceeding to others. But on this principle, Time or temporal duration would not agree to bodies at reſt, which yet nobody will deny to exiſt in Time, or to endure for a Time.

To avoid this inconvenience, the Epicureans and Corpuſcularians made Time to be a ſort of flux different from motion, conſiſting of infinite parts, continually and immediately ſucceeding each other, and this from eternity to eternity. But others directly explode this notion, as eſtabliſhing an eternal being, independent of God. For how ſhould there be a flux before any thing exiſted to flow? and what ſhould that flux be, a ſubſtance, or an accident? According to the philoſophic poet,

"Time of itſelf is nothing, but from thought
Receives its riſe; by labouring fancy wrought
From things conſider'd, whilſt we think on ſome
As preſent, ſome as paſt, or yet to come.
No thought can think on Time, that's ſtill confeſt,
But thinks on things in motion or at reſt."

And ſo on. Vide Lucretius, book i.

Time may be diſtinguiſhed, like place, into *abſolute* and *relative*.

Abſolute Time, is Time conſidered in itſelf, and without any relation to bodies, or their motions.

Relative or *Apparent* Time, is the ſenſible meaſure of any duration by means of motion.

Some authors diſtinguiſh Time into *aſtronomical* and *civil*.

Aſtronomical Time, is that which is taken purely from the motion of the heavenly bodies, without any other regard.

Civil Time, is the former Time accommodated to civil uſes, and formed or diſtinguiſhed into years, months, days, &c.

Time makes the ſubject of chronology.

Time, in muſic, is an affection of ſound, by which it is ſaid to be long or ſhort, with regard to its continuance in the ſame tone or degree of tune.

Muſical Time is diſtinguiſhed into *common* or *duple* Time, and *triple* Time.

Double, *duple*, or *common Time*, is when the notes are in a duple duration of each other, viz, a ſemibreve equal to 2 minims, a minim to 2 crotchets, a crotchet to 2 quavers, &c.

Common or double Time is of two kinds. The firſt when every bar or meaſure is equal to a ſemibreve, or its value in any combination of notes of a leſs quantity. The ſecond is where every bar is equal to a minim, or its value in leſs notes. The movements of this kind of meaſure are various, but there are three common diſtinctions; the firſt *ſlow*, denoted at the beginning of the line by the mark C; the 2d *briſk*, marked thus ; and the 3d *very briſk*, thus marked .

Triple Time is when the durations of the notes are triple of each other, that is, when the ſemibreve is equal to 3 minims, the minim to 3 crotchets, &c. and it is marked T.

Time-*keepers*, in a general ſenſe, denote inſtruments adapted for meaſuring time. See Chronometer.

In a more peculiar and definite ſenſe, Time-keeper is a term firſt applied by Mr. John Harriſon to his watches, conſtructed and uſed for determining the longitude at ſea, and for which he received, at different times, the parliamentary reward of 20 thouſand pounds. And ſeveral other artiſts have ſince received alſo conſiderable ſums for their improvements of Time-keepers; as Arnold, Mudge, &c. See Longitude.

This appellation is now become common among artiſts, to diſtinguiſh ſuch watches as are made with extraordinary care and accuracy for nautical or aſtronomical obſervations.

The principles of Mr. Harriſon's Time-keeper, as they were communicated by himſelf, to the commiſſioners appointed to receive and publiſh the ſame in the year 1765, are as below:

"In this Time-keeper there is the greateſt care taken to avoid friction, as much as can be, by the wheel moving on ſmall pivots, and in ruby-holes, and high numbers in the wheels and pinions.

"The part which meaſures time goes but the eighth part of a minute without winding up; ſo that part is very ſimple, as this winding-up is performed at the wheel next to the balance-wheel; by which means there is always an equal force acting at that wheel, and all the reſt of the work has no more to do in the meaſuring of time than the perſon that winds up once a day.

"There is a ſpring in the inſide of the fuſee, which I will call a ſecondary main ſpring. This ſpring is always kept ſtretched to a certain tenſion by the main ſpring; and during the time of winding-up the Time-keeper, at which time the main-ſpring is not ſuffered to act, this ſecondary-ſpring ſupplies its place.

"In common watches in general, the wheels have about one-third the dominion over the balance, that the balance-ſpring has; that is, if the power which the balance-ſpring has over the balance be called three, that

that from the wheel is one: but in this my Time-keeper, the wheels have only about one-eightieth part of the power over the balance that the balance ſpring has; and it muſt be allowed, the leſs the wheels have to do with the balance, the better. The wheels in a common watch having this great dominion over the balance, they can, when the watch is wound up, and the balance at reſt, ſet the watch a-going; but when my Time-keeper's balance is at reſt, and the ſpring is wound up, the force of the wheels can no more ſet it a-going, than the wheels of a common regulator can, when the weight is wound-up, ſet the pendulum a-vibrating; nor will the force from the wheels move the balance when at reſt, to a greater angle in proportion to the vibration that it is to fetch, than the force of the wheels of a common regulator can move the pendulum from the perpendicular, when it is at reſt.

"My Time-keeper's balance is more than three times the weight of a large ſized common watch balance, and three times its diameter; and a common watch balance goes through about ſix inches of ſpace in a ſecond, but mine goes through about twenty-four inches in that time: ſo that had my Time-keeper only theſe advantages over a common watch, a good performance might be expected from it. But my Time-keeper is not affected by the different degrees of heat and cold, nor agitation of the ſhip; and the force from the wheels is applied to the balance in ſuch a manner, together with the ſhape of the balance-ſpring, and (if I may be allowed the term) an artificial cycloid, which acts at this ſpring; ſo that from theſe contrivances, let the balance vibrate more or leſs, all its vibrations are performed in the ſame time; and therefore if it go at all, it muſt go true. So that it is plain from this, that ſuch a Time-keeper goes entirely from principle, and not from chance."

We muſt refer thoſe who may deſire to ſee a minute account of the conſtruction of Mr. Harriſon's Time-keeper, to the publication by order of the commiſſioners of longitude.

We ſhall here ſubjoin a ſhort view of the improvements in Mr. Harriſon's watch, from the account preſented to the board of longitude by Mr. Ludlam, one of the gentlemen to whom, by order of the commiſſioners, Mr. Harriſon diſcovered and explained the principle upon which his Time-keeper is conſtructed. The defects in common watches which Mr. Harriſon propoſes to remedy, are chiefly theſe: 1. That the main ſpring acts not conſtantly with the ſame force upon the wheels, and through them upon the balance: 2. That the balance, either urged with an unequal force, or meeting with a different reſiſtance from the air, or the oil, or the friction, vibrates through a greater or leſs arch: 3. That theſe unequal vibrations are not performed in equal times: and, 4. That the force of the balance-ſpring is altered by a change of heat.

To remedy the firſt defect, Mr. Harriſon has contrived that his watch ſhall be moved by a very tender ſpring, which never unrolls itſelf more than one-eighth part of a turn, and acts upon the balance through one wheel only. But ſuch a ſpring cannot keep the watch in motion a long time. He has, therefore, joined another, whoſe office is to wind up the firſt ſpring eight times in every minute, and which is itſelf wound up but once a day. To remedy the ſecond defect, he uſes a much ſtronger balance ſpring than in a common watch. For if the force of this ſpring upon the balance remains the ſame, whilſt the force of the other varies, the errors ariſing from that variation will be the leſs, as the fixed force is the greater. But a ſtronger ſpring will require either a heavier or a larger balance. A heavier balance would have a greater friction. Mr. Harriſon, therefore, increaſes the diameter of it. In a common watch it is under an inch, but in Mr. Harriſon's two inches and two tenths. However, the methods already deſcribed only leſſening the errors, and not removing them, Mr. Harriſon uſes two ways to make the times of the vibrations equal, though the arches may be unequal: one is to place a pin, ſo that the balance-ſpring preſſing againſt it, has its force increaſed, but increaſed leſs when the variations are larger: the other to give the pallets ſuch a ſhape, that the wheels preſs them with leſs advantage, when the vibrations are larger. To remedy the laſt defect, Mr. Harriſon uſes a bar compounded of two thin plates of braſs and ſteel, about two inches in length, riveted in ſeveral places together, faſtened at one end and having two pins at the other, between which the balance ſpring paſſes. If this bar be ſtraight in temperate weather (braſs changing its length by heat more than ſteel) the braſs ſide becomes convex when it is heated, and the ſteel ſide when it is cold: and thus the pins lay hold of a different part of the ſpring in different degrees of heat, and lengthen or ſhorten it as the regulator does in a common watch.

The principles, on which Mr. Arnold's Time-keeper is conſtructed, are theſe: The balance is unconnected with the wheel work, except at the time it receives the impulſe to make it continue its motion, which is only whilſt it vibrates 10° out of 380° which is the whole vibration; and during this ſmall interval it has little or no friction, but what is on the pivots, which work in ruby holes on diamonds. It has but one pallet, which is a plane ſurface formed out of a ruby, and has no oil on it. Watches of this conſtruction, ſays Mr. Lyons, go whilſt they are wound up; they keep the ſame rate of going in every poſition, and are not affected by the different forces of the ſpring; and the compenſation for heat and cold is abſolutely adjuſtable. Phipps's Voyage to the North Pole, p. 230. See LONGITUDE.

TISRI, or TIZRI, in chronology, the firſt Hebrew month of the civil year, and the 7th of the eccleſiaſtical or ſacred year. It anſwered to part of our September and October.

TOD *of wool*, is mentioned in the ſtatute 12 Carol. II. c. 32, as a weight containing 2 ſtone, or 28 pounds.

TOISE, a French meaſure, containing 6 of their feet, ſimilar to our fathom.

TONDIN, or TANDINO, in Architecture. See TORE.

TONE, or TUNE, in Muſic, a property of ſound, by which it comes under the relation of grave and acute; or the degree of elevation any ſound has, from the degree of ſwiftneſs of the vibrations of the parts of the ſonorous body.

For the cauſe, meaſure, degree, difference, &c, of Tones, ſee TUNE.

The word Tone is taken in four different ſenſes among the ancients. 1, For any ſound, 2, For a certain interval; as when it is ſaid the difference between the diapente and diateſſaron is a Tone. 3, For a certain locus or compaſs of the voice; in which ſenſe they uſed the Dorian, Phrygian, Lydian Tones. 4. For tenſion; as when they ſpeak of an acute, a grave, or a middle Tone. Wallis's Append. Ptolom. Harm. p. 172.

TONE is more particularly uſed, in muſic, for a certain degree or interval of tune, by which a ſound may be either raiſed or lowered from one extreme of a concord to the other, ſo as ſtill to produce true melody.

In tempered ſcales of muſic, the Tones are made equal, but in a true and accurate practice of ſinging they are not ſo. Pepuſch, in Philoſ. Tranſ. No. 481, p. 274.

Beſide the concords, or harmonical intervals, muſicians admit three leſs kinds of intervals, which are the meaſures and component parts of the greater, and are called *degrees*.

Of theſe degrees, two are called Tones, and the third a ſemitone. Their ratios in numbers are 8 to 9, called a *greater Tone*; 9 to 10, called a *leſſer Tone*; and 15 to 16, a *ſemitone*.

The Tones ariſe out of the ſimple concords, and are equal to their differences. Thus the greater Tone, 8 : 9, is the difference of a 5th and a 4th; the leſs Tone 9 : 10, the difference of a leſs 3d and a 4th, or of a 5th and a greater 6th; and the ſemitone 15 : 16, the difference of a greater 3d and a 4th.

Of theſe Tones and ſemitones every concord is compounded, and conſequently every one is reſolvable into a certain number of them. Thus the leſs 3d conſiſts of one greater Tone and one ſemitone: the greater 3d, of one greater Tone and one leſs Tone: the 4th, of one greater Tone, one leſs Tone, and one ſemitone: and the 5th, of two greater Tones, one leſs Tone, and one ſemitone.

TONSTALL (CUTHBERT), a learned Engliſh divine and mathematician, was born in the year 1476. He entered a ſtudent at the univerſity of Oxford about the year 1491; but afterwards, being driven from thence by the plague, he went to Cambridge, and ſhortly after to the univerſity of Padua in Italy, which was then in a flouriſhing ſtate of literature, where his genius and learning acquired him great reſpect from every one, particularly for his knowledge in mathematics, philoſophy, and juriſprudence.

Upon his return home, he met with great favours from the government, obtaining ſeveral church preferments, and the office of ſecretary to the cabinet of the king, Henry the 8th. This prince, having alſo employed him on ſeveral foreign embaſſies, was ſo well ſatisfied with his conduct, that he firſt gave him the biſhopric of London in 1522, and afterwards that of Durham in 1530.

Tonſtall approved at firſt of the diſſolution of the marriage of his benefactor with Catherine of Spain, and even wrote a book in favour of that diſſolution; but he afterwards condemned that work, and experienced a great reverſe of fortune. He was ejected from the ſee of Durham for his religion in the time of Edward the 6th, to which however he was reſtored again by queen Mary in the beginning of her reign, but was again expelled in 1559 when queen Elizabeth was ſettled in her throne, and he died in a priſon a few months after, in the 84th year of his age.

Tonſtall was doubtleſs one of the moſt learned men of his time. "He was, ſays Wood, a very good Grecian and Ebritian, an eloquent rhetorician, a ſkilful mathematician, a noted civilian and canoniſt, and a profound divine. But that which maketh for his greateſt commendation, is, that Eraſmus was his friend, and he a faſt friend to Eraſmus, in an epiſtle to whom from Sir Thomas More, I find this character of Tonſtall, that, "As there was no man more adorned with knowledge and good literature, no man more ſevere and of greater integrity for his life and manners; ſo there was no man a more ſweet and pleaſant companion, with whom a man would rather chooſe to converſe."

His writings that were publiſhed, were chiefly the following:

1. *In Laudem Matrimonii*, Lond. 1518, 4to.—But that for which he is chiefly entitled to a place in this work, was his book upon arithmetic, viz,

2. *De Arte Supputandi*, Lond. 1522, 4to, dedicated to Sir Thomas More. This was afterwards ſeveral times printed abroad.

3. A Sermon on Palm Sunday before king Henry the 8th, &c. Lond. 1539 and 1633, 4to.

4. *De Veritate Corporis & Sanguinis Domini in Euchariſtia*. Lutet. 1554, 4to.

5. *Compendium in decem Libros Ethicorum Ariſtotelis*. Par. 1554, in 8vo.

6. *Contra impios Blaſphematores Dei prædeſtinationis opera*. Antw. 1555, 4to.

7. Godly and devout Prayers in Engliſh and Latin. 1558, in 8vo.

TOPOGRAPHY, is a deſcription or draught of ſome particular place, or ſmall tract of land; as that of a city or town, manor or tenement, field, garden, houſe, caſtle, or the like; ſuch as ſurveyors ſet out in their plots, or make draughts of, for the information and ſatisfaction of the proprietors.

Topography differs from Chorography, as a particular from a more general.

TORNADO, a ſudden and violent guſt of wind ariſing ſuddenly from the ſhore, and afterwards veering round all points of the compaſs like a hurricane; very frequent on the coaſt of Guinea.

TORRENT, in Hydrography, a temporary ſtream of water, falling ſuddenly from mountains, &c, where there have been great rains, or an extraordinary thaw of ſnow; ſometimes making great ravages in the plains.

TORRICELLI (EVANGELISTE), an illuſtrious mathematician and philoſopher of Italy, was born at Faenza in 1608, and trained up in Greek and Latin literature by an uncle, who was a monk. Natural inclination led him to cultivate mathematical knowledge, which he purſued ſome time without a maſter; but at about 20 years of age, he went to Rome, where he

continued

continued the purſuit of it under father Benedict Caſtelli. Caſtelli had been a ſcholar of the great Galileo, and had been appointed by the pope profeſſor of mathematics at Rome. Torricelli made ſuch progreſs under this maſter, that having read Galileo's *Dialogues*, he compoſed a *Treatiſe concerning motion* upon his principles. Caſtelli, ſurpriſed at the performance, carried it and read it to Galileo, who heard it with great pleaſure, and conceived a high eſteem and friendſhip for the author. Upon this, Caſtelli propoſed to Galileo, that Torricelli ſhould come and live with him; recommending him as the moſt proper perſon he could have, ſince he was the moſt capable of comprehending thoſe ſublime ſpeculations, which his own great age, infirmities, and want of ſight, prevented him from giving to the world. Galileo accepted the propoſal, and Torricelli the employment, as things of all others the moſt advantageous to both. Galileo was at Florence, at which place Torricelli arrived in 1641, and began to take down what Galileo dictated, to regulate his papers, and to act in every reſpect according to his directions. But he did not long enjoy the advantages of this ſituation, as Galileo died at the end of only three months.

Torricelli was then about returning to Rome; but the Grand Duke engaged him to continue at Florence, making him his own mathematician for the preſent, and promiſing him the profeſſor's chair as ſoon as it ſhould be vacant.

Here he applied himſelf intenſely to the ſtudy of mathematics, phyſics, and aſtronomy, making many improvements and ſome diſcoveries. Among others, he greatly improved the art of making microſcopes and teleſcopes; and it is generally acknowledged that he firſt found out the method of aſcertaining the weight of the atmoſphere by a proportionate column of quickſilver, the barometer being called from him the *Torricellian tube*, and *Torricellian experiment*. In ſhort, great things were expected from him, and great things would probably have been farther performed by him, if he had lived: but he died, after a few days illneſs, in 1647, when he was but juſt entered the 40th year of his age.

Torricelli publiſhed at Florence in 1644, a volume of ingenious pieces, intitled, *Opera Geometrica*, in 4to. There was alſo publiſhed at the ſame place, in 1715, *Lezzioni Accademiche*, conſiſting of 96 pages in 4to. Theſe are diſcourſes that had been pronounced by him upon different occaſions. The firſt of them was to the academy of La Cruſca, by way of thanks for admitting him into their body. The reſt are upon ſubjects of mathematics and phyſics. Prefixed to the whole is a long life of Torricelli by Thomas Buonaventuri, a Florentine gentleman.

TORRICELLIAN, a term very frequent among phyſical writers, uſed in the phraſes, *Torricellian tube*, or *Torricellian experiment*, on account of the inventor Torricelli, a diſciple of the great Galileo.

TORRICELLIAN *Tube*, is the barometer tube, being a glaſs tube, open at one end, and hermetically ſealed at the other, about 3 feet long, and $\frac{2}{10}$ of an inch in diameter.

TORRICELLIAN *Experiment*, or the filling the barometer tube, is performed by filling the Torricellian tube with mercury, then ſtopping the open orifice with the finger, inverting the tube, and plunging that orifice into a veſſel of ſtagnant mercury. This done, the finger is removed, and the tube ſuſtained perpendicular to the ſurface of the mercury in the veſſel.

The conſequence is, that part of the mercury falls out of the tube into the veſſel, and there remains only enough in the tube to fill about 30 inches of its capacity, above the ſurface of the ſtagnant mercury in the veſſel; theſe being ſuſtained in the tube by the preſſure of the atmoſphere on the ſurface of the ſtagnant mercury; and according as the atmoſphere is more or leſs heavy, or as the winds, blowing upward or downward, heave up or depreſs the air, and ſo increaſe or diminiſh its weight and ſpring, more or leſs mercury is ſuſtained, from 28 to 31 inches.

The Torricellian Experiment conſtitutes what we now call the *Barometer*.

TORRICELLIAN *Vacuum*, is the vacuum produced by filling a tube with mercury, and when inverted allowing it to deſcend to ſuch a height as is counterbalanced by the preſſure of the atmoſphere, as in the Torricellian Experiment and Barometer, the vacuum being that part of the tube above the ſurface of the mercury.

TORRID *Zone*, is that round the middle of the earth, extending to $23\frac{1}{2}$ degrees on both ſides of the equator.

TORUS, or TORE, in Architecture, is a large round moulding in the baſes of the columns.

TOUCAN, or *American Gooſe*, is one of the modern conſtellations of the ſouthern hemiſphere, conſiſting of 9 ſmall ſtars.

TRACTION, or *Drawing*, is the act of a moving power, by which the moveable is brought nearer to the mover, called alſo attraction.

TRACTRIX, in Geometry, a curve line called alſo Catenaria; which ſee.

TRAJECTORY, a term often uſed generally for the path of any body moving either in a void, or in a medium that reſiſts its motion; or even for any curve paſſing through a given number of points. Thus Newton, Princip. lib. 1, prob. 22, propoſes to deſcribe a Trajectory that ſhall paſs through five given points.

TRAJECTORY *of a Comet*, is its path or orbit, or the line it deſcribes in its motion. This path, Hevelius, in his Cometographia, will have to be very nearly a right line; but Dr. Halley concludes it to be, as it really is, a very excentric ellipſis; though its place may often be well computed on the ſuppoſition of its being a parabola.—Newton, in prop. 41 of his 3d book, ſhews how to determine the Trajectory of a comet from three obſervations; and in his laſt prop. how to correct a Trajectory graphically deſcribed.

TRAMMELS, in Mechanics, an inſtrument uſed by artificers for drawing ovals upon boards, &c. One part of it conſiſts of a croſs with two grooves at right angles; the other is a beam carrying two pins which ſlide in thoſe grooves, and alſo the deſcribing pencil. All the engines for turning ovals are conſtructed on the ſame principles with the Trammels: the only difference is, that in the Trammels the board is at reſt, and the pencil

cil moves upon it: in the turning engine, the tool, which ſupplies the place of the pencil, is at reſt, and the board moves againſt it. See a demonſtration of the chief properties of theſe inſtruments by Mr. Ludlam, in the Philoſ. Tranſ. vol. 70, pa. 378 &c.

TRANSACTIONS, *Philoſophical*, are a collection of the principal papers and matters read before certain philoſophical ſocieties, as the Royal Society of London, and the Royal Society of Edinburgh. Theſe Tranſactions contain the ſeveral diſcoveries and hiſtories of nature and art, either made by the members of thoſe ſocieties, or communicated by them from their correſpondents, with the various experiments, obſervations, &c, made by them, or tranſmitted to them, &c.

The Philoſ. Tranſ. of the Royal Society of London were ſet on foot in 1665, by Mr. Oldenburg, the then ſecretary of that Society, and were continued by him till the year 1677. They were then diſcontinued upon his death, till January 1678, when Dr. Grew reſumed the publication of them, and continued it for the months of December 1678, and January and February 1679, after which they were intermitted till January 1683. During this laſt interval their want was in ſome meaſure ſupplied by Dr. Hook's Philoſophical Collections. They were alſo interrupted for 3 years, from December 1687 to January 1691, beſide other ſmaller interruptions amounting to near a year and a half more, before October 1695, ſince which time the Tranſactions have been carried on regularly to the preſent day, with various degrees of credit and merit.

Till the year 1752 theſe Tranſactions were publiſhed in numbers quarterly, and the printing of them was always the ſingle act of the reſpective ſecretaries till that time; but then the ſociety thought fit that a committee ſhould be appointed to conſider the papers read before them, and to ſelect out of them ſuch as they ſhould judge moſt proper for publication in the future Tranſactions. For this purpoſe the members of the council for the time being, conſtitute a ſtanding committee: they meet on the firſt Thurſday of every month, and no leſs than ſeven of the members of the committee (of which number the preſident, or in his abſence a vice preſident, is always to be one) are allowed to be a *quorum*, capable of acting in relation to ſuch papers; and the queſtion with regard to the publication of any paper, is always decided by the majority of votes taken by ballot.

They are publiſhed annually in two parts, at the expence of the ſociety; and each fellow, or member, is entitled to receive one copy *gratis* of every part publiſhed after his admiſſion into the ſociety. For many years paſt, the collection, in two parts, has made one volume in each year; and in the year 1793 the number of the volumes was 83, being 10 leſs than the number of the year in the century. They were formerly much reſpected for the great number of excellent papers and diſcoveries contained in them; but within the laſt dozen years there has been a great falling off, and the volumes are now conſidered as of very inferior merit, as well as quantity.

There is alſo a very uſeful Abridgment, of thoſe volumes of the Tranſactions that were publiſhed before the year 1752, when the ſociety began to publiſh the Tranſactions on their own account. Thoſe to the end of the year 1700 were abridged, in 3 volumes, by Mr. John Lowthorp: thoſe from the year 1700 to 1720 were abridged, in 2 volumes, by Mr. Henry Jones: and thoſe from 1719 to 1733 were abridged, in 2 volumes, by Mr. John Eames and Mr. John Martyn; Mr. Martyn alſo continued the abridgment of thoſe from 1732 to 1744 in 2 volumes, and of thoſe from 1744 to 1750 in 2 volumes; making in all 11 volumes, of very curious and uſeful matters in all the arts and ſciences.

The Royal Society of Edinburgh, inſtituted in 1783, have alſo publiſhed 3 volumes of their Philoſophical Tranſactions; which are deſervedly held in the higheſt reſpect for the importance of their contents.

TRANSCENDENTAL *Quantities*, among Geometricians, are indeterminate ones; or ſuch as cannot be expreſſed or fixed to any conſtant equation: ſuch is a tranſcendental curve, or the like.

M. Leibnitz has a diſſertation in the Acta Erud. Lipſ. in which he endeavours to ſhew the origin of ſuch quantities; viz. why ſome problems are neither plain, ſolid, nor ſurſolid, nor of any certain degree, but do *tranſcend* all algebraic equations.

He alſo ſhews how it may be demonſtrated without calculus, that an algebraic quadratrix for the circle or hyperbola is impoſſible: for if ſuch a quadratrix could be found, it would follow, that by means of it any angle, ratio, or logarithm, might be divided in a given proportion of one right line to another, and this by one univerſal conſtruction: and conſequently the problem of the ſection of an angle, or the invention of any number of mean proportionals, would be of a certain finite degree. Whereas the different degrees of algebraic equations, and therefore the problem underſtood in general of any number of parts of an angle, or mean proportionals, is of an indefinite degree, and *tranſcends* all algebraical equations.

Others define Tranſcendental equations, to be ſuch fluxional equations as do not admit of fluents in common finite algebraical equations, but as expreſſed by means of ſome curve, or by logarithms, or by infinite ſeries; thus the expreſſion $y = \frac{\dot{x}}{\sqrt{aa - xx}}$ is a Tranſcendental equation, becauſe the fluents cannot both be expreſſed in finite terms. And the equation which expreſſes the relation between an arc of a circle and its ſine is a Tranſcendental equation; for Newton has demonſtrated that this relation cannot be expreſſed by any finite algebraic equation, and therefore it can only be by an infinite or a Tranſcendental equation.

It is alſo uſual to rank exponential equations among Tranſcendental ones; becauſe ſuch equations, although expreſſed in finite terms, have variable exponents, which cannot be expunged but by putting the equation into fluxions, or logarithms, &c. Thus, the exponential equation

equation $y = a^x$, gives $x \times \log. a = \log. y$, or $\dot{x} \times \log. a = \frac{\dot{y}}{y}$.

TRANSCENDENTAL *Curve*, in the Higher Geometry, is ſuch a one as cannot be defined by an algebraic equation; or of which, when it is expreſſed by an equation, one of the terms is a variable quantity, or a curve line. And when ſuch curve line is a geometrical one, or one of the firſt degree or kind, then the Tranſcendental curve is ſaid to be of the ſecond degree or kind, &c.

Theſe curves are the ſame with what Des Cartes, and others after him, call mechanical curves, and which they would have excluded out of geometry; contrary however to the opinion of Newton and Leibnitz; for as much as, in the conſtruction of geometrical problems, one curve is not to be preferred to another as it is defined by a more ſimple equation, but as it is more eaſily deſcribed than that other: beſides, ſome of theſe Tranſcendental, or mechanical curves, are found of greater uſe than almoſt all the algebraical ones.

M. Leibnitz, in the Acta Erudit. Lipſ. has given a kind of Tranſcendental equations, by which theſe Tranſcendental curves are actually defined, and which are of an indefinite degree, or are not always the ſame in every point of the curve. Now whereas algebraiſts uſe to aſſume ſome general letters or numbers for the quantities ſought, in theſe Tranſcendental problems Leibnitz aſſumes general or indefinite equations for the lines ſought; thus, for example, putting x and y for the abſciſs and ordinate, the equation he uſes for a line required, is $a + bx + cy + exy + fxx + gyy$ &c $= 0$: by the help of which indefinite equation, he ſeeks for the tangent; and comparing that which reſults with the given property of tangents, he finds the value of the aſſumed letters a, b, c, &c, and thus defines the equation of the line ſought.

If the compariſon abovementioned do not ſucceed, he pronounces the line ſought not to be an algebraical, but a Tranſcendental one.

This ſuppoſed, he proceeds to find the ſpecies of Tranſcendency: for ſome Tranſcendentals depend on the general diviſion or ſection of a ratio, or upon logarithms, others upon circular arcs, &c.

Here then, beſide the ſymbols x and y, he aſſumes a third, as v, to denote the Tranſcendental quantity; and of theſe three he forms a general equation of the line ſought, from which he finds the tangent according to the differential method, which ſucceeds even in Tranſcendental quantities. This found, he compares it with the given properties of the tangents, and ſo diſcovers not only the values of a, b, c, &c, but alſo the particular nature of the Tranſcendental quantity.

Tranſcendental problems are very well managed by the method of fluxions. Thus, for the relation of a circular arc and right line, let a denote the arc, and x the verſed ſine, to the radius 1, then is $a =$ fluent of $\frac{\dot{x}}{\sqrt{2x - xx}}$; and if the ordinate of a cycloid be y, then is

$$x = \sqrt{2x - xx} + \text{fluent of } \frac{\dot{x}}{\sqrt{2x - xx}}.$$

Thus is the analytical calculus extended to thoſe lines which have hitherto been excluded, for no other cauſe but that they were thought incapable of it.

TRANSFORMATION, in Geometry, is the changing or reducing of a figure, or of a body, into another of the ſame area, or the ſame ſolidity, but of a different form. As, to Tranſform or reduce a triangle to a ſquare, or a pyramid to a parallelopipedon.

TRANSFORMATION *of Equations*, in Algebra, is the changing equations into others of a different form, but of equal value. This operation is often neceſſary, to prepare equations for a more eaſy ſolution, ſome of the principal caſes of which are as follow.—1. The ſigns of the roots of an equation are changed, viz, the poſitive roots into negative, and the negative roots into poſitive ones, by only changing the ſigns of the 2d, 4th, and all the other even terms of the equation. Thus, the roots of the equation

$x^4 - x^3 - 19x^2 + 49x - 30 = 0$, are $+1, +2, +3, -5$;

whereas the roots of the ſame equation having only the ſigns of the 2d and 4th terms changed, viz, of

$x^4 + x^3 - 19x^2 - 49x - 30 = 0$, are $-1, -2, -3, +5$.

2. To Tranſform an equation into another that ſhall have its roots greater or leſs than the roots of the propoſed equation by ſome given difference, proceed as follows. Let the propoſed equation be the cubic $x^3 - ax^2 + bx - c = 0$; and let it be required to Tranſform it into another, whoſe roots ſhall be leſs than the roots of this equation by ſome given difference d; if the root y of the new equation muſt be the leſs, take it $y = x - d$, and hence $x = y + d$; then inſtead of x and its powers ſubſtitute $y + d$ and its powers, and there will ariſe this new equation

$$\text{(A)} \quad \left.\begin{array}{rrrr} y^3 & + 3dy^2 & + 3d^2y & + d^3 \\ & - ay^2 & - 2ady & - ad^2 \\ & & + by & + bd \\ & & & - c \end{array}\right\} = 0,$$

whoſe roots are leſs than the roots of the former equation by the difference d. If the roots of the new equation had been required to be greater than thoſe of the old one, we muſt then have ſubſtituted $y = x + d$, or $x = y - d$, &c.

3. To take away the 2d or any other particular term out of an equation; or to Tranſform an equation, ſo as the new equation may want its 2d, or 3d, or 4th, &c term of the given equation $x^3 - ax^2 + bx - c = 0$, which is tranſformed into the equation (A) in the laſt article. Now to make any term of this equation (A) vaniſh, is only to make the coefficient of that term $= 0$, which will form an equation that will give the value of the aſſumed quantity d, ſo as to produce the deſired effect, viz, to make that term vaniſh. So, to take away the 2d term, make $3d - a = 0$, which makes the aſſumed quantity $d = \frac{1}{3}a$. To take away the 3d term, we muſt put the ſum of the coefficients of that term $= 0$, that is $3d^2 - 2ad + b = 0$, or $3d^2 - 2ad = -b$; then by reſolving this quadratic equation, there is found the aſſumed quantity $d = \frac{1}{3}a \pm \frac{1}{3}\sqrt{a^2 - 3b}$, by the ſubſtitution of which for d, the 3d term will be taken away out of the equation.

In like manner, to take away the 4th term, we muſt make the ſum of its coefficients $d^3 - ad^2 + bd - c = 0$;

and

and so on for any other term whatever. And in the same manner we must also proceed when the proposed equation is not a cubic, but of any height whatever, as

$$x^n - ax^{n-1} + bx^{n-2} - cx^{n-3} \&c = 0:$$

this is first, by substituting $y + d$ for x, to be Transformed to this new equation

$$\left.\begin{aligned} y^n + ndy^{n-1} + \tfrac{1}{2}n.\overline{n-1}.d^2y^{n-2} \&c \\ - ay^{n-1} - a.\overline{n-1}.dy^{n-2} \&c \\ + by^{n-2} \&c \end{aligned}\right\} = 0;$$

then; to take away the 2d term, we must make $nd - a = 0$, or $d = \frac{a}{n}$; to take away the 3d term, we must make $\frac{1}{2}n.\overline{n-1}.d^2 - a.\overline{n-1}d + b = 0$, or $d^2 - \frac{2a}{n}d = -\frac{2b}{n(n-1)}$; and so on.

From whence it appears that, to take away the 2d term of an equation, we must resolve a simple equation; for the 3d term, a quadratic equation; for the 4th term, a cubic equation, and so on.

4. To multiply or divide the roots of an equation by any quantity; or to Transform a given equation to another, that shall have its roots equal to any multiple or submultiple of those of the proposed equation. This is done by substituting, for x and its powers, $\frac{y}{m}$ or py, and their powers, viz, $\frac{y}{m}$ for x, to multiply the roots by m; and py for x, to divide the roots by p.

Thus, to multiply the roots by m, substituting $\frac{y}{m}$ for x in the proposed equation

$x^n - ax^{n-1} + bx^{n-2} \&c = 0$, and it becomes

$$\frac{y^n}{m^n} - \frac{ay^{n-1}}{m^{n-1}} + \frac{by^{n-2}}{m^{n-2}} \&c = 0;$$

or multiply all by m^n, then is

$$y^n - amy^{n-1} + bm^2y^{n-2} - cm^3y^{n-3} \&c = 0,$$

an equation that hath its roots equal to m times the roots of the proposed equation.

In like manner, substituting py for x, in the proposed equation, &c, it becomes

$$y^n - \frac{ay^{n-1}}{p} + \frac{by^{n-2}}{p^2} - \frac{cy^{n-3}}{p^3} \&c = 0,$$

an equation that hath its roots equal to those of the proposed equation divided by p.

From whence it appears, that to multiply the roots of an equation by any quantity m, we must multiply its terms, beginning at the 2d term, respectively by the terms of the geometrical series, m, m^2, m^3, m^4, &c. And to divide the roots of an equation by any quantity p, that we must divide its terms, beginning at the 2d, by the corresponding terms of this series p, p^2, p^3, p^4, &c.

5. And sometimes, by these Transformations, equations are cleared of fractions, or even of surds. Thus the equation

$x^3 - ax^2\sqrt{p} + bx - c\sqrt{p} = 0$, by putting $y = x\sqrt{p}$, or multiplying the terms, from the 2d, by the geometricals $\sqrt{p}$, p, $p\sqrt{p}$, is Transformed to

$$y^3 - apy^2 + bpy - cp^2 = 0.$$

6. An equation, as $x^3 - ax^2 + bx - c = 0$, may be Transformed into another, whose roots shall be the reciprocals of the roots of the given equation, by substituting $\frac{1}{y}$ for x; by which it becomes

$\frac{1}{y^3} - \frac{a}{y^2} + \frac{b}{y} - c = 0$, or, multiplying all by y^3, the same becomes $cy^3 - by^2 + ay - 1 = 0$.

On this subject, see Newton's Alg. on the Transmutation of Equations; Maclaurin's Algeb. pt. 2, chap. 3 and 4. Saunderson's Algebra, vol. 2, pa. 687, &c.

TRANSIT, in Astronomy, denotes the passage of any planet, just before or over another planet or star; or the passing of a star or planet over the meridian, or before an astronomical instrument.

Venus and Mercury, in their Transits over the sun, appear like dark specks.

Doctor Halley computed the times of a number of these visible Transits, for the last and present century, and published in the Philos. Trans. numb. 193. See also Abridg. vol. 1, pa. 427 &c. A Synopsis of these Transits is as follows, those of Mercury happening in the months of April and October, and those of Venus in May and November, both old-style; and if 11 days be added to the dates below, the sums will give the times for the new-style. First for Mercury, and then for Venus.

A Series of the Moments when Mercury is seen in Conjunction with the Sun, and within his Disc, with the Distances of the same Planet from the Sun's Centre.

In April, Old-Style.

" Thoſe Tranſits which have the mark *, are but partly viſible at London; but thoſe which are marked **, are totally viſible.

" Now it is to be obſerved, that at the aſcending node of Mercury in the month of October, the diameter of the ſun takes up 32′ 34″, and therefore the greateſt duration of a central Tranſit is 5h 29m. But in the month of April the diameter of the ſun is 31′ 54″, whence by reaſon of the ſlower motion of the planet, there ariſes the greateſt duration 8h 1m. Now if Mercury approaches obliquely, theſe durations become ſhorter on account of the diſtance from the centre of the ſun. And that the calculation may be more perfect, I have added the following Tables, in which are exhibited the half durations of theſe eclipſes, to every minute of the diſtance ſeen from the centre of the ſun. Theſe added to or ſubtracted from the moment of conjunction found by the foregoing Table, give the beginning and end of the whole phenomenon."

Of the Viſible Conjunction of Venus with the Sun.

" Though Venus is the moſt beautiful of all the ſtars, yet (ſays Dr. Halley) like the reſt of her ſex, ſhe does not care to appear in ſight without her borrowed ornaments, and her aſſumed ſplendor. For the confined laws of motion envy this ſpectacle to the mortals of a whole age, like the ſecular games of the Ancients; though it be far the moſt noble among all thoſe that aſtronomy can pretend to ſhew. Now it ſhall be declared hereafter, that by this one obſervation alone, the diſtance of the ſun from the earth may be determined with the greateſt certainty which hitherto has been included within wide limits, becauſe of the parallax which is otherwiſe inſenſible. But as to the periods, they cannot be deſcribed ſo accurately as thoſe of Mercury, ſince Venus has been obſerved within the ſun's diſk but once ſince the beginning of the world, and that by our Horrox." Dr. Halley then exhibits the principles of calculating theſe Tranſits, from whence he infers that,

" After 18 years Venus returns to the ſun, taking away 2d 10h 52½m, from the moment of the foregoing Tranſit; and the planet proceeds in a path which is 24′ 41″ more to the ſouth than the former.

" After 235 years adding 2d 10h 9m, Venus may again enter the ſun, but in a more northern path by 11′ 33″. But if the foregoing year is biſſextile, 3d 10h 9m muſt be added.

" After 243 years Venus may alſo paſs the ſun, only taking away 0h 43m from the time of the former; but

but proceeds more ſoutherly by 13′ 8″. Now if the foregoing year be biſſextile, add 23h 17m.

"And in all theſe appulſes of Venus to the ſun, in the month of November, the angle of her path with the ecliptic is 9° 5′, and her horary motion within the ſun is 4′ 7″. And ſince the ſemidiameter of the ſun is 16′ 21″, the greateſt duration of the Tranſit of the centre of Venus comes out 7h 56m.

"Then let the ſun and Venus be in conjunction at the deſcending node in the month of May; and by the ſame numbers the ſame intervals may be computed. After 8 years let there be taken away 2d 6h 55′. And Venus will make her Tranſit in a more northern path by 19′ 58″.

"After 235 years add 2d 8h 18m, or if the foregoing year be biſſextile 3d 8h 18m, and you will have Venus more to the South by 9′ 21″.

"Laſtly, after 243 years add 0d 1h 23m, or if the foregoing year be biſſextile 1d 1h 23m, and Venus will be found in conjunction with the ſun, but in a more northerly path by 10′ 37″.

"In every Tranſit within the ſun at this node, the angle of Venus's path with the ecliptic is 8° 28′, and her horary motion is 4′ 0″; and the ſemidiameter of the ſun ſubtending 15′ 51″, the greateſt duration of the central Tranſit comes out alſo 7h 56m, exactly the ſame as at the other node.

"As to the epochs, from that only ingreſs which Horrox obſerved, the ſun being then juſt ready to ſet, it is concluded, that Venus was in conjunction with the ſun at London in the year 1639, Nov. 24d 6h 37m, and that ſhe declined towards the ſouth 8′ 30″. But in the month of May no mortal has ſeen her as yet within the ſun. But from my numbers, which I judge to be not very different from the heavens, it appears that Venus for the next time will enter the ſun in 1761, May 25d 17h 55m, that being the middle of the eclipſe, and then will be diſtant from his centre 4′ 15″, towards the ſouth. Hence and from the foregoing revolutions all the phenomena of this kind will be eaſily exhibited for a whole millennium, as I have computed them in the following Table.

In November.

"As for the durations of theſe eclipſes of Venus, they may be computed after the ſame manner as thoſe of Mercury in reſpect of the centre. But ſince Venus's diameter is pretty large, and ſince the parallaxes alſo may bring a very notable difference as to time, a particular calculation muſt neceſſarily be made for every place.

"Now the diameter of Venus is ſo great, that while ſhe adheres to the ſun's limb almoſt 20 minutes of time will be elapſed, that is, when ſhe applies directly to the ſun. But when ſhe is incident obliquely, ſhe continues longer in the limb. Now that diameter, according to Horrox's obſervation, takes up 1′ 18″, when ſhe is in conjunction with the ſun at the aſcending node, and 1′ 12″ at the other node.

"Now the chief uſe of theſe conjunctions is accurately to determine the ſun's diſtance from the earth, or his parallax, which aſtronomers have in vain attempted to find by various other methods; for the minuteneſs of the angles required eaſily eludes the neceſt inſtruments. But in obſerving the ingreſs of Venus into the ſun, and her egreſs from the ſame, the ſpace of time between the moments of the internal contacts, obſerved to a ſecond of time, that is, to $\frac{1}{15}$ of a ſecond or 4‴ of an arch, may be obtained by the aſſiſtance of a moderate teleſcope and a pendulum clock, that is conſiſtent with itſelf exactly for 6 or 8 hours. Now from two ſuch obſervations rightly made in proper places, the diſtance of the ſun within a 500th part may be certainly concluded, &c." See PARALLAX.

TRANSIT *Inſtrument*, in Aſtronomy, is a teleſcope fixed at right angles to a horizontal axis; this axis being ſo ſupported that the line of collimation may move in the plane of the meridian.

The axis, to the middle of which the teleſcope is fixed, ſhould gradually taper toward its ends, and terminate in cylinders well turned and ſmoothed; and a proper weight or balance is put on the tube, ſo that it may ſtand at any elevation when the axis reſts on the ſupporters. Two upright poſts of wood or ſtone, firmly fixed at a proper diſtance, are to ſuſtain the ſupporters to this inſtrument; theſe ſupporters are two thick braſs plates,

plates, having well ſmoothed angular notches in their upper ends to receive the cylindrical arms of the axis; each of the notched plates is contrived to be moveable by a ſcrew, which ſlides them upon the ſurfaces of two other plates immoveably fixed to the two upright poſts; one plate moving in a vertical direction, and the other horizontally, they adjuſt the teleſcope to the planes of the horizon and meridian; to the plane of the horizon, by a ſpirit level hung in a poſition parallel to the axis, and to the plane of the meridian in the following manner. Obſerve the times by the clock when a circumpolar ſtar, ſeen through this inſtrument, Tranſits both above and below the pole; then if the times of deſcribing the eaſtern and weſtern parts of its circuit be equal, the teleſcope is then in the plane of the meridian; otherwiſe the notched plates muſt be gently moved till the time of the ſtar's revolution is biſected by both the upper and lower Tranſits, taking care at the ſame time that the axis keeps its horizontal poſition.

When the teleſcope is thus adjuſted, a mark muſt be ſet up, or made, at a conſiderable diſtance (the greater the better) in the horizontal direction of the interſection of the croſs wires, and in a place where it can be illuminated in the night-time by a lanthorn near it, which mark, being on a fixed object, will ſerve at all times afterwards to examine the poſition of the teleſcope, by firſt adjuſting the tranverſe axis by the level.

To adjuſt a clock by the ſun's Tranſit over the meridian, note the times by the clock, when the preceding and following edges of the ſun's limb touch the croſs wires: the difference between the middle time and 12 hours, ſhews how much the mean, or clock time, is faſter and ſlower than the apparent or ſolar time, for that day; to which the equation of time being applied, it will ſhew the time of mean noon for that day, by which the clock may be adjuſted.

TRANSMISSION, in Optics, &c, denotes the property of a tranſparent or tranſlucent body, by which it admits the rays of light to paſs through its ſubſtance; in which ſenſe, the word ſtands oppoſed to reflection.

For the cauſe of Tranſmiſſion, or the reaſon why ſome bodies Tranſmit the rays, and others reflect them, ſee TRANSPARENCY and OPACITY.

The rays of light, Newton obſerves, are ſubject to fits of eaſy Tranſmiſſion and reflection. See LIGHT, and REFLECTION.

TRANSMUTATION, or TRANSFORMATION, in Geometry, denotes the reduction or change of one figure or body into another of the ſame area or ſolidity; as a triangle into a ſquare, a pyramid into a cube, &c.

TRANSMUTATION, in the Higher Geometry, has been uſed for the converting of a figure into another of the ſame kind and order, whoſe reſpective parts riſe to the ſame dimenſions in an equation, and admit the ſame tangents, &c.

If a rectilineal figure be to be Tranſmuted into another, it is ſufficient that the interſections of the lines which compoſe it be transferred, and lines drawn through the ſame in the new figure. But if the figure to be Tranſmuted be curvilinear, the points, tangents, and other right lines, by means of which the curve line is to be defined, muſt be transferred.

TRANSOM, among Builders, the piece that is framed acroſs a double light window.

TRANSOM, among Mathematicians, denotes the vane of a croſs-ſtaff; being a wooden member fixed acroſs it, with a ſquare upon which it ſlides, &c.

TRANSPARENCY, or TRANSLUCENCY, in Phyſics, a quality in certain bodies, by which they give paſſage to the rays of light.

The Tranſparency of natural bodies, as glaſs, water, air, &c, is aſcribed by ſome, to the great number and ſize of the pores or interſtices between the particles of thoſe bodies. But this account is very defective; for the moſt ſolid and opaque body in nature, that we know of, contains a great deal more pores than it does matter; ſurely a great deal more than is neceſſary for the paſſage of ſo very fine and ſubtle a body as light.

Ariſtotle, Des Cartes, &c, make Tranſparency to conſiſt in ſtraightneſs or rectilineal direction of the pores; by means of which, ſay they, the rays can make their way through, without ſtriking againſt the ſolid parts, and ſo being reflected back again. But this account, Newton ſhews, is imperfect; the quantity of pores in all bodies being ſufficient to tranſmit all the rays that fall upon them, however thoſe pores be ſituated with reſpect to each other.

The reaſon then why all bodies are not Tranſparent, is not to be aſcribed to their want of rectilineal pores; but either to the unequal denſity of the parts, or to the pores being filled with ſome foreign matters, or to their being quite empty, by means of which the rays, in paſſing through, undergoing a great variety of reflections and refractions, are perpetually diverted different ways, till at length falling on ſome of the ſolid parts of the body, they are extinguiſhed and abſorbed.

Thus cork, paper, wood, &c, are opake; while glaſs, diamonds, &c, are Tranſparent; and the reaſon is, that in the neighbourhood of parts equal in denſity with reſpect to each other, as theſe latter bodies, the attraction being equal on every ſide, no reflection or refraction enſues: but the rays which entered the firſt ſurface of the body proceed quite through it without interruption, thoſe few only excepted that chance to meet with the ſolid parts: but in the neighbourhood of parts that differ much in denſity, ſuch as the parts of wood and paper are, both in reſpect of themſelves and of the air, or the empty ſpace in their pores; as the attraction is very unequal, the reflections and refractions muſt be very great; and therefore the rays will not be able to make their way through ſuch bodies, but will be variouſly deflected, and at length quite ſtopped. See OPACITY.

TRANSPOSITION, in Algebra, is the bringing any term of an equation over to the other ſide of it. Thus, if $a + x = c$, and you make $x = c - a$, then a is ſaid to be Tranſpoſed.

This operation is to be performed in order to bring all the known terms to one ſide of the equation, and all thoſe that are unknown to the other ſide of it; and every term thus Tranſpoſed muſt always have its ſign changed,

changed, from + to −, or from − to +; which in fact is no more than ſubtracting or adding ſuch term on both ſides of the equation. See REDUCTION of Equations.

TRANSVERSE-*Axis*, or *Diameter*, in the Conic Sections, is the firſt or principal diameter, or axis. See AXIS, DIAMETER, and LATUS TRANSVERSUM.

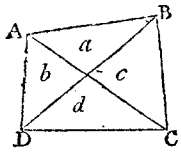
In an ellipſe the Tranſverſe is the longeſt of all the diameters; but the ſhorteſt of all in the hyperbola; and in the parabola the diameters are all equal, or at leaſt in a ratio of equality.

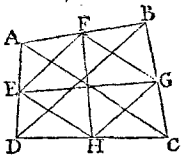
TRAPEZIUM, in Geometry, a plane figure contained under four right lines, of which both the oppoſite pairs are not parallel.—When this figure has two of its ſides parallel to each other, it is ſometimes called a *trapezoid*.—The chief properties of the Trapezium are as follow:

1. Any three ſides of a Trapezium taken together, are greater than the third ſide.

2. The two diagonals of any Trapezium divide it into four proportional triangles, *a*, *b*, *c*, *d*. That is, the triangle $a : b :: c : d$.

3. The ſum of all the four inward angles, A, B, C, D, taken together, is equal to 4 right angles, or 360°.



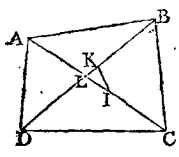


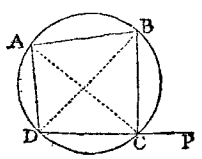
4. In a Trapezium ABCD, if all the ſides be biſected, in the points E, F, G, H, the figure EFGH formed by joining the points of biſection will be a parallelogram, having its oppoſite ſides parallel to the correſponding diagonals of the Trapezium, and the area of the ſaid inſcribed parallelogram is juſt equal to half the area of the Trapezium.

5. The ſum of the ſquares of the diagonals of the Trapezium, is equal to twice the ſum of the ſquares of the diagonals of the parallelogram, or of the two lines drawn to biſect the oppoſite ſides of the Trapezium. That is, $AC^2 + BD^2 = 2EG^2 + 2FH^2$.

6. In any Trapezium, the ſum of the ſquares of all the four ſides, is equal to the ſum of the ſquares of the two diagonals together with 4 times the ſquare of the line KI joining their middle points. That is, (firſt fig. below)

$$AB^2 + BC^2 + CD^2 + DA^2 = AC^2 + BD^2 + 4IK^2.$$





7. In any Trapezium, the ſum of the two diagonals, is leſs than the ſum of any four lines that can be drawn, to the four angles, from any point within the figure, beſide the interſection of the diagonals.

8. The area of any Trapezium, is equal to half the rectangle or product under either diagonal and the ſum of the two perpendiculars drawn upon it from the two oppoſite angles.

9. The area of any Trapezium may alſo be found thus: Multiply the two diagonals together, then that product, multiplied by the fine of their angle of interſection, to the radius 1, will be the area. That is,

$$AC \times BD \times \text{fin. } \angle L = \text{area.}$$

10. The ſame area will be otherwiſe found thus: Square each ſide of a Trapezium, add the ſquares of each pair of oppoſite ſides together, ſubtract the leſs ſum from the greater, multiply the remainder by the tangent of the angle of interſection of the diagonals (to radius 1), and $\frac{1}{4}$ of the product will be the area. That is, $(\overline{AB^2 + DC^2} - \overline{AD^2 + BC^2}) \times \frac{1}{4}\text{tang. } \angle L =$ area.

11. The area of a Trapezoid, or one that has two ſides parallel, is equal to the rectangle or product under the ſum of the two parallel ſides and the perpendicular diſtance between them.

12. If a Trapezium be inſcribed in a circle; the ſum of any two oppoſite angles is equal to two right angles; and if the ſum of two oppoſite angles be equal to two right angles, the ſum of the other two will alſo be equal to two right angles, and a circle may be deſcribed about it; and farther, if one ſide, as DC, be produced out, the external angle will be equal to the interior oppoſite angle. That is, (laſt fig. above)

$$\angle A + \angle C = \angle B + \angle D = 2 \text{ right angles,}$$
$$\text{and } \angle A = \angle BCP.$$

13. If a Trapezium be inſcribed in a circle; the rectangle of the two diagonals, is equal to the ſum of the two rectangles contained under the oppoſite ſides. That is,

$$AC \times BD = AB \times DC + AD \times BC.$$

14. If a Trapezium be inſcribed in a circle; its area may be found thus: Multiply any two adjacent ſides together, and the other two ſides together; then add theſe two products together, and multiply the ſum by the fine of the angle included by either of the pairs of ſides that are multiplied together, and half this laſt product will be the area. That is, the area is equal either

$$\text{to } (AB \times AD + CB \times CD) \times \tfrac{1}{2}\text{ fin. } \angle A \text{ or } \angle C,$$
$$\text{or } (AB \times BC + AD \times DC) \times \tfrac{1}{2}\text{ fin. } \angle B \text{ or } \angle D.$$

15. Or, when the Trapezium can be inſcribed in a circle, the area may be otherwiſe found thus: Add all the four ſides together, and take half the ſum; then from this half ſubtract each ſide ſeverally; multiply the four remainders continually together, and the ſquare root of the laſt product will be the area.

16. Laſtly, the area of the Trapezium inſcribed in a circle may be otherwiſe found thus:

Put

Put $m = AB \times BC + AD \times DC$,
$n = BA \times AD + BC \times CD$,
$p = AB \times DC + AD \times BC$,
r = radius of the circumſcribing circle,

then $\frac{\sqrt{mnp}}{4r}$ = the area of the Trapezium.

TRAPEZOID, ſometimes denotes a trapezium that has two of its ſides parallel to each other; and ſometimes an irregular ſolid figure, having four ſides not parallel to each other.

TRAVERSE, in Gunnery, is the turning a piece of ordnance about, as upon a centre, to make it point in any particular direction.

TRAVERSE, in Fortification, denotes a trench with a little parapet, ſometimes two, one on each ſide, to ſerve as a cover from the enemy that might come in flank.

TRAVERSE, in a wet foſs, is a ſort of gallery, made by throwing fauciſſons, joiſts, faſcines, ſtones, earth, &c, into the foſs, oppoſite the place where the miner is to be put, in order to fill up the ditch, and make a paſſage over it.

TRAVERSE alſo denotes a wall of earth, or ſtone, raiſed acroſs a work, to ſtop the ſhot from rolling along it.

TRAVERSE alſo ſometimes ſignifies any retrenchment, or line fortified with faſcines, barrels or bags of earth, or gabions.

TRAVERSE, in Navigation, is the variation or alteration of a ſhip's courſe, occaſioned by the ſhifting of the winds, or currents, &c; or a Traverſe is a compound courſe, conſiſting of ſeveral different courſes and diſtances.

TRAVERSE *Sailing*, is the method of working, or calculating, Traverſes or compound courſes, ſo as to bring them into one, &c.

Traverſe Sailing is uſed when a ſhip, having ſailed from one port towards another, whoſe courſe and diſtance from the former is known, is by reaſon of contrary winds, or other accidents, forced to ſhift and ſail upon ſeveral courſes, which are to be brought into one courſe, to learn, after ſo many turnings and windings, the true courſe and diſtance made good, or the true point the ſhip is arrived at; and ſo to know what muſt be the new courſe and diſtance to the intended port.

To Conſtruct a Traverſe. Aſſume a convenient point or centre, to begin at, to repreſent the place ſailed from. From that point as a centre, with the chord of 60°, deſcribe a circle, which quarter with two perpendicular lines interſecting in the centre, one to repreſent the meridian, or north-and-ſouth line, and the other the eaſt-and-weſt line. From the interſections of theſe lines with the circle, ſet off upon the circumference, the arcs or degrees, taken from the chords, for the ſeveral courſes that have been ſailed upon, marking the points they reach to in the circumference with the figures for the order or number of the courſes, 1, 2, 3, 4, &c; and from the centre draw lines to theſe ſeveral points in the circumference, or conceive them to be drawn. Upon the firſt of theſe lines lay off the firſt diſtance ſailed; from the extremity of this diſtance draw a line parallel to the ſecond radius, or line drawn in the circle, upon which lay off the 2d diſtance; through the end of this 2d diſtance draw a line parallel to the 3d radius, for the direction of the 3d courſe, and upon it lay off the 3d diſtance; and ſo on, through all the courſes and diſtances. This done, draw a line from the centre to the end of the laſt diſtance, which will be the whole diſtance made good, and it will cut the circle in a point ſhewing the courſe made good: Laſtly, draw a line from the end of the laſt diſtance to the point repreſenting the port bound to, and it will ſhew the diſtance and courſe yet to be ſailed, to gain that port.

To work a Traverſe, or to compute it by the Traverſe Table of Difference of Latitude and Departure.

Make a little tablet with 6 columns; the 1ſt for the courſes, the 2d for the diſtances, the 3d for the northing, the 4th for the ſouthing, the 5th for the eaſting, and the 6th for the weſting; firſt entering the ſeveral courſes and diſtances, in ſo many lines, in the 1ſt and 2d columns. Then, from the Traverſe table, take out the quantity of the northings or ſouthings, and eaſtings or weſtings, anſwering to the ſeveral given courſes and diſtances, entering them on their correſponding lines, and in the proper columns of eaſting, weſting, northing, and ſouthing. This done, add up into one ſum the numbers in each of theſe laſt four columns, which will give four ſums ſhewing the whole quantity of eaſting, weſting, northing, and ſouthing made good; then take the difference between the whole eaſting and weſting, and alſo between the northing and ſouthing, ſo ſhall theſe ſhew the ſpaces made good in theſe two directions, viz, eaſt or weſt, and north or ſouth; which being compared with the given difference of latitude and departure, will ſhew thoſe yet to be made good in ſailing to the deſired port, and thence the courſe and diſtance to it.

Example. A ſhip from the latitude 28° 32′ north, bound to a port diſtant 100 miles, and bearing NE by N, has run the following courſes and diſtances, viz, 1ſt, NW by N diſt. 20 miles; 2d, SW 40 miles; 3d, NE by E 60 miles; 4th, SE 55 miles; 5th, W by S 41 miles; 6th, ENE 66 miles. Required her preſent latitude, with the direct courſe and diſtance made good, and thoſe for the port bound to.

The numbers being taken out of the Traverſe table, and entered oppoſite the ſeveral courſes and diſtances, the tablet will be as here follows:

Courſes.	Diſt.	North.	South.	Eaſt.	Weſt.
NW by N	20	16·6	.	.	11·1
SW	40	.	28·3	.	28·3
NE by E	60	33·3	.	49·9	.
SE	55	.	38·9	38·9	.
W by S	41	.	8·0	.	40·2
ENE	66	25·3	.	61·0	.
		75·2	75·2	149·8	79·6
		75·2		79·6	
		0		70·2	Dep.

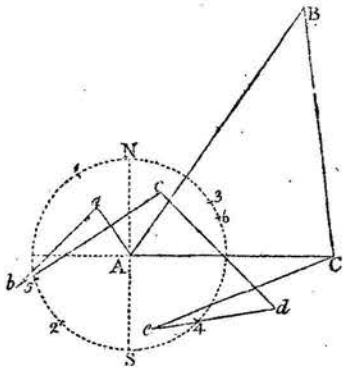
where the ſums of the northings and ſouthings, being both alike, 75·2, ſhews that the ſhip is come to the ſame parallel of latitude ſhe ſet out from. And the difference between the ſums of the eaſtings and weſtings, ſhews that the ſhip is 70·2 miles more to the eaſtward, that being the greater. Conſequently the courſe made good is due eaſt, and the diſtance is 70·2 miles.

But, by the Traverſe table, the northing and eaſting to the propoſed courſe NE by N, and diſtance 100, are thus, viz, northing 83·1 and eaſting 55·6.

diff. from made good		0	and eaſting	70·2
give - -	northing	83·1	and weſting	14·6

yet to be made good to arrive at the intended port; and therefore, by finding theſe in the Traverſe table, anſwering to them are the intended courſe and diſtance, viz, diſtance 85, and courſe N 10° W.

The geometrical conſtruction, according to the method before deſcribed, gives the figure as below: where A is the port ſet out from, B is the port bound to,



C is the place come to, by ſailing the ſeveral courſes and diſtances A*a*, *ab*, *bc*, *cd*, *de*, and *e*C; then CB is the diſtance to be ſailed to arrive at the port B, and its courſe, or direction with the meridian, is nearly 10°, or the angle ACB, made with the eaſt-and-weſt line, nearly 80°.—*Note*, the radii from the centre to the ſeveral points in the circumference, are omitted, to prevent a confuſion in the figure.

TRAVERSE-*Board*, in a ſhip, a ſmall round board, hanging up in the ſteerage, and pierced full of holes in lines ſhewing the points of the compaſs: upon which, by moving a ſmall peg from hole to hole, the ſteerſman keeps an account how many glaſſes, that is half hours, the ſhip ſteers upon any point.

TRAVERSE-*Table*, in Navigation, is the ſame with a table of difference of latitude and departure; being the difference of latitude and departure ready calculated to every point, half point, quarter point, degree, &c, of the quadrant; and for every diſtance, up to 50 or 100 or 120, &c. Though it may ſerve for any greater diſtance whatever, by adding two or more together; or by taking their halves, thirds, fourths, &c, and then doubling, tripling, quadrupling, &c, the difference of latitude and departure found to thoſe parts of the diſtance.

This table is one of the moſt neceſſary and uſeful things a navigator has occaſion for; for by it he can readily reduce all his courſes and diſtances, run in the ſpace of 24 hours, into one courſe and diſtance; whence he finds the latitude he is in, and the departure from the meridian.

One of the beſt tables of this kind is in Robertſon's Navigation, at the end of book 7, vol. 1. The diſtances are there carried to 120, for the ſake of more eaſy ſubdiviſions; and it is divided into two parts; the firſt containing the courſes for every quarter point of the compaſs, and the 2d adapted to every 15′, or quarter of a degree, in the quadrant. See TRAVERSE *Sailing*.

A ſpecimen of ſuch a Traverſe Table is the following, otherwiſe called a Table of Difference of Latitude and Departure. The diſtances are placed at top and bottom of the columns, from 1 to 10; but may be extended to any quantity by multiplying the parts, and taking out at ſeveral times. The courſes, or angles of a right-angled triangle, are in a column, on both ſides, each in two parts, the one containing the even points and quarter points, and the other whole degrees, as far as to 45°, or half the quadrant, on the left-hand ſide, and the other half quadrant, from 45° to 90°, returned upwards from bottom to top on the right-hand ſide. The correſponding Difference of Latitude and Departure are in two columns below or above the diſtances, viz, below them when the courſe or angle is within 45°, or found on the left-hand ſide; but above them when between 45 and 90°, or found on the right-hand ſide.

The ſame table ſerves alſo to work all caſes of right-angled triangles, for any other purpoſes. For example, Suppoſe a given courſe be 15°, and diſtance 35 miles, to find the correſponding difference of latitude and the departure: Or, in a right-angled triangle, given the hypotenuſe 35, and one angle 15°, to find the two legs.

Here, the diſtance 3 in the table muſt be accounted 30, moving the decimal point proportionally or one place in the other numbers; and thoſe numbers taken out at twice, viz, once from the columns under 3 for the 30, and the other from the columns under the diſtance 5. Thus, on the line of 15°, and under the

	Diſt.		*Lat.*		*Dep.*
	30	are	28·978	and	7·765
	5	are	4·830	and	1·294
theref. for	35	are	33·808	and	9·059

So that the other two legs of the triangle are 33·808 and 9·059.—If the courſe had been 75°, or the complement of the former, which is only the other angle of the ſame triangle, and which is found on the ſame line of the table, but on the right-hand ſide of it: then the numbers in the columns will be the ſame as before, and will give the ſame ſums for the two legs of the triangle, only with the contrary names, as to Latitude and Departure, which change places.

A TABLE *of the Difference of Latitude and Departure, for Degrees and Quarter Points.*

TREBLE, in Muſic, the higheſt or acuteſt of the four parts in ſymphony, or that which is heard the cleareſt and ſhrilleſt in a concert. In the like ſenſe we ſay, a Treble violin, Treble hautboy, &c.

In vocal muſic, the Treble is uſually committed to boys and girls; their proper part being the Treble.

The Treble is divided into firſt or higheſt Treble, and ſecond or baſs Treble. The half Treble is the ſame with the counter-tenor.

TRENCHES, in Fortification, are ditches which the beſiegers cut to approach more ſecurely to the place attacked; whence they are called *lines of approach*. Their breadth is 8 or 10 feet, and depth 6 or 7.

They ſay, *mount the Trenches*, that is, go upon duty in them. To *relieve the Trenches*, is to relieve ſuch as have been upon duty there. The enemy is ſaid to have *cleared the Trenches*, when he has driven away or killed the ſoldiers who guarded them.

Tail of the TRENCH, is the place where it was begun. And the *Head* is the place where it ends.

Opening of the TRENCHES, is when the beſiegers firſt begin to work upon them, or to make them; which is uſually done in the night.

TREPIDATION, in the Ancient Aſtronomy, denotes what they call a libration of the 8th ſphere; or a motion which the Ptolomaic ſyſtem attributed to the firmament, to account for certain almoſt inſenſible changes and motions obſerved in the axis of the world; by means of which the latitudes of the fixed ſtars come to be gradually changed, and the ecliptic ſeems to approach reciprocally, firſt towards one pole, then towards the other.

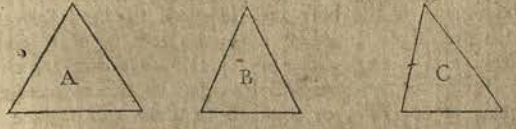
This motion is alſo called the *motion of the firſt libration*.

TRET, in Commerce, is an allowance made for the waſte, or the duſt, that may be mixed with any commodity; which is always 4 pounds on every 104 pounds weight. See TARE.

TRIANGLE, in Geometry, a figure bounded or contained by three lines or ſides, and which conſequently has three angles, from whence the figure takes its name.

Triangles are either plane or ſpherical or curvilinear. Plane when the three ſides of the Triangle are right lines; but ſpherical when ſome or all of them are arcs of great circles on the ſphere.

Plane Triangles take ſeveral denominations, both from the relation of their angles, and of their ſides, as below. And 1ſt with regard to the ſides.



An *Equilateral Triangle*, is that which has all its three ſides equal to one another; as A.

An *Iſoſceles* or *Equicrural Triangle*, is that which has two ſides equal; as B.

A *Scalene Triangle* has all its ſides unequal; as C.

Again, with reſpect to the Angles.

A *Rectangular* or *Right-angled Triangle*, is that which has one right angle; as D.

An *Oblique Triangle* is that which has no right angle, but all oblique ones; as E or F.

An *Acutangular* or *Oxygone Triangle*, is that which has three acute angles; as E.

An *Obtuſangular* or *Amblygone Triangle*, is that which has an obtuſe angle; as F.

A *Curvilinear* or *Curvilineal Triangle*, is one that has all its three ſides curve lines.

A *Mixtilinear Triangle* is one that has its ſides ſome of them curves, and ſome right lines.

A *Spherical Triangle* is one that has its ſides, or at leaſt ſome of them, arcs of great circles of the ſphere.

Similar Triangles are ſuch as have the angles in the one equal to the angles in the other, each to each.

The *Baſe* of a Triangle, is any ſide on which a perpendicular is drawn from the oppoſite angle, called the *vertex*; and the two ſides about the perpendicular, or the vertex, are called the *legs*.

The Chief Properties of Plane Triangles, are as follow, viz, In any plane Triangle,

1. The greateſt ſide is oppoſite to the greateſt angle, and the leaſt ſide to the leaſt angle, &c. Alſo, if two ſides be equal, their oppoſite angles are equal; and if the Triangle be equilateral, or have all its ſides equal, it will alſo be equiangular, or have all its angles equal to one another.

2. Any ſide of a Triangle is leſs than the ſum, but greater than the difference, of the other two ſides.

3. The ſum of all the three angles, taken together, is equal to two right angles.

4. If one ſide of a Triangle be produced out, the external angle, made by it and the adjacent ſide, is equal to the ſum of the two oppoſite internal angles.

5. A line drawn parallel to one ſide of a Triangle, cuts the other two ſides proportionally, the correſponding ſegments being proportional, each to each, and to the whole ſides; and the Triangle cut off is ſimilar to the whole Triangle.

If a perpendicular be let fall from any angle of a Triangle, as a vertical angle, upon the oppoſite ſide as a baſe; then

6. The rectangle of the ſum and difference of the ſides, is equal to twice the rectangle of the baſe and the diſtance of the perpendicular from the middle of the baſe.—Or, which is the ſame thing in other words,

7. The difference of the ſquares of the ſides, is equal to the difference of the ſquares of the ſegments of the baſe. Or, as the baſe is to the ſum of the ſides, ſo is the difference of the ſides, to the difference of the ſegments of the baſe.

8. The rectangle of the legs or ſides, is equal to the rectangle of the perpendicular and the diameter of the circumſcribing circle.

If a line be drawn biſecting any angle, to the baſe or oppoſite ſide; then,

9. The

9. The ſegments of the baſe, made by the line biſecting the oppoſite angle, are proportional to the ſides adjacent to them.

10. The ſquare of the line biſecting the angle, is equal to the difference between the rectangle of the ſides and the rectangle of the ſegments of the baſe.

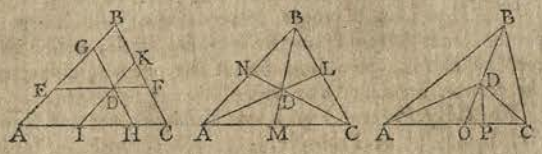
If a line be drawn from any angle to the middle of the oppoſite ſide, or biſecting the baſe; then

11. The ſum of the ſquares of the ſides, is equal to twice the ſum of the ſquares of half the baſe and the line biſecting the baſe.

12. The angle made by the perpendicular from any angle and the line drawn from the ſame angle to the middle of the baſe, is equal to half the difference of the angles at the baſe.

13. If through any point D, within a Triangle ABC, three lines EF, GH, IK, be drawn parallel to the three ſides of the Triangle; the continual products or ſolids made by the alternate ſegments of theſe lines will be equal; viz,

$$DE \times DK \times DH = DG \times DF \times DI.$$



14. If three lines AL, BM, CN, be drawn from the three angles through any point D within a Triangle, to the oppoſite ſides; the ſolid products of the alternate ſegments of the ſides are equal; viz,
AN × BL × CM = AM × CL × BN, (2d fig. above).

15. Three lines drawn from the three angles of a Triangle to biſect the oppoſite ſides, or to the middle of the oppoſite ſides, do all interſect one another in the ſame point D, and that point is the centre of gravity of the Triangle, and the diſtance AD of that point from any angle as D, is equal to double the diſtance DL from the oppoſite ſide; or one ſegment of any of theſe lines is double the other ſegment: moreover the ſum of the ſquares of the three biſecting lines, is ¾ of the ſum of the ſquares of the three ſides of the Triangle.

16. Three perpendiculars biſecting the three ſides of a Triangle, all interſect in one point, and that point is the centre of the circumſcribing circle.

17. Three lines biſecting the three angles of a Triangle, all interſect in one point, and that point is the centre of the inſcribed circle.

18. Three perpendiculars drawn from the three angles of a Triangle, upon the oppoſite ſides, all interſect in one point.

19. If the three angles of a Triangle be biſected by the lines AD, BD, CD (3d fig. above), and any one as BD be continued to the oppoſite ſide at O, and DP be drawn perp. to that ſide; then is
∠ADO = ∠CDP, or ∠ADP = ∠CDO.

20. Any Triangle may have a circle circumſcribed about it, or touching all its angles, and a circle inſcribed within it, or touching all its ſides.

21. The ſquare of the ſide of an equilateral Triangle, is equal to 3 times the ſquare of the radius of its circumſcribing circle.

22. If the three angles of one Triangle be equal to the three angles of another Triangle, each to each; then thoſe two Triangles are ſimilar, and their like ſides are proportional to one another, and the areas of the two Triangles are to each other as the ſquares of their like ſides.

23. If two Triangles have any three parts of the one (except the three angles), equal to three correſponding parts of the other, each to each; thoſe two Triangles are not only ſimilar, but alſo identical, or having all their ſix correſponding parts equal, and their areas equal.

24. Triangles ſtanding upon the ſame baſe, and between the ſame parallels, are equal; and Triangles upon equal baſes, and having equal altitudes, are equal.

25. Triangles on equal baſes, are to one another as their altitudes: and Triangles of equal altitudes, are to one another as their baſes; alſo equal Triangles have their baſes and altitudes reciprocally proportional.

26. Any Triangle is equal to half its circumſcribing parallelogram, or half the parallelogram on the ſame or an equal baſe, and of the ſame or equal altitude.

27. Therefore the area of any Triangle is found, by multiplying the baſe by the altitude, and taking half the product.

28. The area is alſo found thus: Multiply any two ſides together, and multiply the product by the ſine of their included angle, to radius 1, and divided by 2.

29. The area is alſo otherwiſe found thus, when the three ſides are given: Add the three ſides together, and take half their ſum; then from this half ſum ſubtract each ſide ſeverally, and multiply the three remainders and the half ſum continually together; then the ſquare root of the laſt product will be the area of the Triangle.

30. In a right-angled Triangle, if a perpendicular be let fall from the right angle upon the hypothenuſe, it will divide it into two other Triangles ſimilar to one another, and to the whole Triangle.

31. In a right-angled Triangle, the ſquare of the hypothenuſe is equal to the ſum of the ſquares of the two ſides; and, in general, any figure deſcribed upon the hypothenuſe, is equal to the ſum of two ſimilar figures deſcribed upon the two ſides.

32. In an iſoſceles Triangle, if a line be drawn from the vertex to any point in the baſe; the ſquare of that line together with the rectangle of the ſegments of the baſe, is equal to the ſquare of the ſide.

33. If one angle of a Triangle be equal to 120°; the ſquare of the baſe will be equal to the ſquares of both the ſides, together with the rectangle of thoſe ſides; and if thoſe ſides be equal to each other, then the ſquare of the baſe will be equal to three times the ſquare of one ſide, or equal to 12 times the ſquare of the perpendicular from the angle upon the baſe.

34. In the ſame Triangle, viz, having one angle equal to 120°; the difference of the cubes of the ſides, about that angle, is equal to a ſolid contained by the difference of the ſides and the ſquare of the baſe; and the ſum of the cubes of the ſides, is equal to a ſolid contained by the ſum of the ſides and the difference between

between the ſquare of the baſe and twice the rectangle of the ſides.

There are many other properties of Triangles to be found among the geometrical writers; ſo Gregory St. Vincent has written a folio volume upon Triangles; there are alſo ſeveral in his Quadrature of the circle. See alſo other properties under the article TRIGONOMETRY.

For the properties of ſpherical Triangles, ſee SPHERICAL *Triangles*.

Solution of TRIANGLES. See TRIGONOMETRY.

TRIANGLE, in Aſtronomy, one of the 48 ancient conſtellations, ſituated in the northern hemiſphere. There is alſo the *Southern Triangle* in the ſouthern hemiſphere, which is a modern conſtellation. The ſtars in the Northern Triangle are, in Ptolomy's catalogue 4, in Tycho's 4, in Hevelius's 12, and in the Britiſh catalogue 16.

The ſtars in the Southern Triangle are, in Sharp's catalogue, 5.

Arithmetical TRIANGLE, a kind of numeral Triangle, or Triangle of numbers, being a table of certain numbers diſpoſed in form of a Triangle. It was ſo called by Paſcal; but he was not the inventor of this table, as ſome writers have imagined, its properties having been treated of by other authors, ſome centuries before him, as is ſhewn in my Mathematical Tracts, vol. 1, pa. 69 &c.

The form of the Triangle is as follows:

1					
1	1				
1	2	1			
1	3	3	1		
1	4	6	4	1	
1	5	10	10	5	1
1	6	15	20	&c	
1	7	21	&c		
1	8	&c			
1	9				

And it is conſtructed by adding always the laſt two numbers of the next two preceding columns together, to give the next ſucceeding column of numbers.

The firſt vertical column conſiſts of units; the 2d a ſeries of the natural numbers 1, 2, 3, 4, 5, &c; the 3d a ſeries of Triangular numbers 1, 3, 6, 10, &c; the 4th a ſeries of pyramidal numbers, &c. The oblique diagonal rows, deſcending from left to right, are alſo the ſame as the vertical columns. And the numbers taken on the horizontal lines are the co-efficients of the different powers of a binomial. Many other properties and uſes of theſe numbers have been delivered by various authors, as may be ſeen in the Introduction to my Mathematical Tables, pages 7, 8, 75, 76, 77, 89, 2d edition.

After theſe, Paſcal wrote a treatiſe on the Arithmetical Triangle, which is contained in the 5th volume of his works, publiſhed at Paris and the Hague in 1779, in 5 volumes, 8vo.

In this publication is alſo a deſcription, taken from the 1ſt volume of the French Encyclopedie, art. *Arithmetique Machine*, of that admirable machine invented by Paſcal at the age of 19, furniſhing an eaſy and expeditious method of making all ſorts of arithmetical calculations without any other aſſiſtance than the eye and the hand.

TRIANGULAR, relating to a triangle; as

TRIANGULAR *Canon*, tables relating to trigonometry; as of ſines, tangents, ſecants, &c.

TRIANGULAR *Compaſſes*, are ſuch as have three legs or feet, by which any triangle, or three points, may be taken off at once. Theſe are very uſeful in the conſtruction of maps, globes, &c.

TRIANGULAR *Numbers*, are a kind of polygonal numbers; being the ſums of arithmetical progreſſions, which have 1 for the common difference of their terms.

Thus, from theſe arithmeticals 1 2 3 4 5 6, are formed the Triang. Numb. 1 3 6 10 15 21, or the 3d column of the arithmetical triangle abovementioned.

The ſum of any number n of the terms of the Triangular numbers, 1, 3, 6, 10, &c, is $=$

$$\frac{n^3}{6} + \frac{n^2}{2} + \frac{n}{3}, \text{ or } \frac{n}{1} \times \frac{n+1}{2} \times \frac{n+2}{3}$$

which is alſo equal to the number of ſhot in a triangular pile of balls, the number of rows, or the number in each ſide of the baſe, being n.

The ſum of the reciprocals of the Triangular ſeries, infinitely continued, is equal to 2; viz,

$$1 + \tfrac{1}{3} + \tfrac{1}{6} + \tfrac{1}{10} + \tfrac{1}{15} \text{ &c} = 2.$$

For the rationale and management of theſe numbers, ſee Malcolm's Arith. book 5, ch. 2; and Simpſon's Algeb. ſec. 15.

TRIANGULAR *Quadrant*, is a ſector furniſhed with a looſe piece, by which it forms an equilateral triangle. Upon it is graduated and marked the calendar, with the ſun's place, and other uſeful lines; and by the help of a ſtring and a plummet, with the diviſions graduated on the looſe piece, it may be made to ſerve for a quadrant.

TRIBOMETER, in Mechanics, a term applied by Muſſchenbroek to an inſtrument invented by him for meaſuring the friction of metals. It conſiſts of an axis formed of hard ſteel, paſſing through a cylindrical piece of wood: the ends of the axis, which are highly poliſhed, are made to reſt on the poliſhed ſemicircular cheeks of various metals, and the degree of friction is eſtimated by means of a weight ſuſpended by a fine ſilken ſtring or ribband over the wooden cylinder. For a farther deſcription and the figure of this inſtrument, with the reſults of various experiments performed with it, ſee Muſſchenb. Introd. ad Phil. Nat. vol. 1, p. 151.

TRIDENT, is a particular kind of parabola, uſed by Deſcartes in conſtructing equations of 6 dimenſions. See the article *Carteſian* PARABOLA.

TRIGLYPH, in Architecture, is a member of the Doric Frize, placed directly over each column, and at equal diſtances in the intercolumnation, having two entire glyphs or channels engraven in it, meeting in an angle, and ſeparated by three legs from the two demi-channels of the ſides.

TRIGON, a figure of three angles, or a triangle.

TRIGON, in Aſtrology. See TRIPLICITY.

TRIGON, in Aſtronomy, denotes an aſpect of two planets when they are 120 degrees diſtant from each other; called alſo a Trine, being the 3d part of 360 degrees.—The Trigons of Mars and Saturn are by aſtrologers held malific or malignant aſpects.

TRIGON, in Dialling, is an inſtrument of a triangular form.

TRIGON, in Muſic, denoted a muſical inſtrument, uſed among the ancients. It was a kind of triangular lyre, or harp, invented by Ibycus; and was uſed at feaſts, being played on by women, who ſtruck it either with a quill, or beat it with ſmall rods of different lengths and weights, to occaſion a diverſity in the ſounds.

TRIGONAL *Numbers*. See TRIANGULAR *Numbers*.

TRIGONOMETER *Armillary*. See ARMILLARY *Trigonometer*.

TRIGONOMETRY, the art of meaſuring the ſides and angles of triangles, either plane or ſpherical, from whence it is accordingly called either Plane Trigonometry, or Spherical Trigonometry.

Every triangle has 6 parts, 3 ſides, and 3 angles; and it is neceſſary that three of theſe parts be given, to find the other three. In ſpherical Trigonometry, the three parts that are given, may be of any kind, either all ſides, or all angles, or part the one and part the other. But in plane Trigonometry, it is neceſſary that one of the three parts at leaſt be a ſide, ſince from three angles can only be found the proportions of the ſides, but not the real quantities of them.

Trigonometry is an art of the greateſt uſe in the mathematical ſciences, eſpecially in aſtronomy, navigation, ſurveying, dialling, geography, &c, &c. By it, we come to know the magnitude of the earth, the planets and ſtars, their diſtances, motions, eclipſes, and almoſt all other uſeful arts and ſciences. Accordingly we find this art has been cultivated from the earlieſt ages of mathematical knowledge.

Trigonometry, or the reſolution of triangles, is founded on the mutual proportions which ſubſiſt between the ſides and angles of triangles; which proportions are known by finding the relations between the radius of a circle and certain other lines drawn in and about the circle, called *chords*, *ſines*, *tangents*, and *ſecants*. The ancients Menelaus, Hipparchus, Ptolomy, &c, performed their Trigonometry, by means of the chords. As to the ſines, and the common theorems relating to them, they were introduced into Trigonometry by the Moors or Arabians, from whom this art paſſed into Europe, with ſeveral other branches of ſcience. The Europeans have introduced, ſince the 15th century, the tangents and ſecants, with the theorems relating to them. See the hiſtory and improvements at large, in the Introduction to my Mathematical Tables.

The proportion of the ſines, tangents, &c, to their radius, is ſometimes expreſſed in common or natural numbers, which conſtitute what we call the *tables of natural ſines, tangents, and ſecants*. Sometimes it is expreſſed in logarithms, being the logarithms of the ſaid natural ſines, tangents, &c; and theſe conſtitute the table of *artificial ſines*, &c. Laſtly, ſometimes the proportion is not expreſſed in numbers; but the ſeveral ſines, tangents, &c, are actually laid down upon lines of ſcales; whence the *line of ſines*, of *tangents*, &c. See SCALE.

In Trigonometry, as angles are meaſured by arcs of a circle deſcribed about the angular point, ſo the whole circumference of the circle is divided into a great number of parts, as 360 degrees, and each degree into 60 minutes, and each minute into 60 ſeconds, &c; and then any angle is ſaid to conſiſt of ſo many degrees, minutes and ſeconds, as are contained in the arc that meaſures the angle, or that is intercepted between the legs or ſides of the angle.

Now the ſine, tangent, and ſecant, &c, of every degree and minute, &c, of a quadrant, are calculated to the radius 1, and ranged in tables for uſe; as alſo the logarithms of the ſame; forming the triangular canon. And theſe numbers, ſo arranged in tables, form every ſpecies of right-angled triangles, ſo that no ſuch triangle can be propoſed, but one ſimilar to it may be there found, by comparison with which, the propoſed one may be computed by analogy or proportion.

As to the ſcales of chords, ſines, tangents, &c, uſually placed on inſtruments, the method of conſtructing them is exhibited in the ſcheme annexed to the article SCALE; which, having the names added to each, needs no farther explanation.

There are uſually three methods of reſolving triangles, or the caſes of Trigonometry; viz, geometrical conſtruction, arithmetical computation, and inſtrumental operation. In the 1ſt method, the triangle in queſtion is conſtructed by drawing and laying down the ſeveral parts of their magnitudes given, viz, the ſides from a ſcale of equal parts, and the angles from a ſcale of chords, or other inſtrument; then the unknown parts are meaſured by the ſame ſcales, and ſo they become known.

In the 2d method, having ſtated the terms of the proportion according to rule, which terms conſiſt partly of the numbers of the given ſides, and partly of the ſines, &c, of angles taken from the tables, the proportion is then reſolved like all other proportions, in which a 4th term is to be found from three given terms, by multiplying the 2d and 3d together, and dividing the product by the firſt. Or, in working with the logarithms, adding the log. of the 2d and 3d terms together, and from the ſum ſubtracting the log. of the 1ſt term, then the number anſwering to the remainder is the 4th term ſought.

To work a caſe inſtrumentally, as ſuppoſe by the log. lines on one ſide of the two-foot ſcales: Extend the compaſſes from the 1ſt term to the 2d, or 3d, which happens to be of the ſame kind with it; then that extent will reach from the other term to the 4th. In this operation, for the ſides of triangles, is uſed the line of numbers (marked Num.); and for the angles, the line of ſines or tangents (marked ſin. and tan.) according as the proportion reſpects ſines or tangents.

In every caſe of triangles, as has been hinted before, there

there must be three parts, one at least of which must be a side. And then the different circumstances, as to the three parts that may be given, admit of three cases or varieties only; viz,

1st. When two of the three parts given, are a side and its opposite angle.—2d, When there are given two sides and their contained angle.—3d, And thirdly, when the three sides are given.

To each of these cases there is a particular rule, or proportion, adapted, for resolving it by.

1st. *The Rule for the 1st Case*, or that in which, of the three parts that are given, an angle and its opposite side are two of them, is this, viz, That the sides are proportional to the sines of their opposite angles,

That is,

As one side given :
To the sine of its opposite angle : :
So is another side given :
To the sine of its opposite angle.

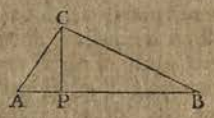
Or,

As the sine of an angle given :
To its opposite side : :
So is the sine of another angle given :
To its opposite side.

So that, to find an angle, we must begin the proportion with a given side that is opposite to a given angle; and to find a side, we must begin with an angle opposite to a given side.

Ex. Suppose, in the triangle ABC, there be given

AB = 365 feet,
AC = 154·33 f.
∠C = 98° 3′
to find the other side, and the angles.



1. *Geometrically, by Construction.*

Draw AC = 154·33 from a scale of equal parts: Make the angle C = 98° 3′, producing CB indefinitely: With centre A, and radius 365 feet, cross CB in B: Then join AB, and the figure is constructed. Then, by measuring the unknown angles and side, the former by the line of cords or otherwise, and the side by the line of equal parts, they will be found, as near as they can be measured, as below, viz,

BC = 310; the ∠A = 57° ¼; and ∠B = 24° ¾.

2. *Arithmetically, by Tables of Logs.*

As AB	= 365	log.	2·5622929
To AC	= 154·33		2·1884504
So sin. ∠C =	98° 3′ or 81° 57′		9·9956993
To sin. ∠B =	24° 45′		9·6218568

the sum 122 48
taken from 180 00
leaves ∠A 57 12

Then, again,

As sin. ∠C =	98° 3′	log.	9·9956993
To AB	= 365		2·5622929
So sin. ∠A =	57° 12′		9·9245721
To BC	= 309·86		2·4911657

3. *Instrumentally, by Gunter's Lines.*

In the first proportion, Extend the compasses from 365 to 154½ on the line of numbers; and that extent will reach, upon the line of sines, from 82° to 24¾, which gives the angle B. And, in the second proportion, Extend from 98° to 57¼ on the sines; and that extent will reach, upon the numbers, from 365 to 310, or the side BC nearly.

2d *Case*, when there are Given two Sides and their contained angle, to find the rest, the rule is this:

As the sum of the two given sides :
Is to the difference of the sides : :
So is the tang. of half the sum of the two opposite angles, or cotangent of half the given angle :
To tang. of half the diff. of those angles.

Then the half diff. added to the half sum, gives the greater of the two unknown angles; and subtracted, leaves the less of the two angles.

Hence, the angles being now all known, the remaining 3d side will be found by the former case.

Ex. Suppose, in the triangle ABC, there be given
the side AC = 154·33
the side BC = 309·86
the included ∠C = 98° 3′
to find the other side and the angles.

1. *Geometrically.*—Draw two indefinite lines making the angle C = 98° 3′: upon these lines set off CA = 154½, and CB = 310: Join the points A and B, and the figure is made. Then, by measurement, as before, we find the

∠A = 57¼; ∠B 24¾; and side AB = 365.

2. *By Logarithms.*

As CB + CA	= 464·19	log.	2·6666958
To CB − CA	= 155·53		2 1918142
So tan. ½A + ½B	= 40° 58½′		9·9387803
To tan. ½A − ½B	= 16 13½		9·4638987

sum gives ∠A 57 12
diff. gives ∠B 24 45

Then,

As sin. ∠B =	24° 45′	log.	9·6218612
To side AC =	154·33		2·1884504
So sin. ∠C =	98° 3′, or 81° 57		9·9956993
To side AB =	365		2·5622885

3. *Instrumentally.*—Extend the compasses from 464 to 155½ upon the line of numbers; then that extent will reach, upon the line of tangents, from 41° to 16°¾. Then, in the 2d proportion, extend the compasses from 24°¾ to 82° on the sines; and that extent

will reach, upon the numbers, from $154\frac{1}{3}$ to 365, which is the third side.

3d *Case*, is when the three sides are given, to find the three angles; and the method of resolving this case is, to let a perpendicular fall from the greatest angle, upon the opposite side or base, dividing it into two segments, and the whole triangle into two smaller right-angled triangles: then it will be,

As the base, or sum of the two segments:
Is to the sum of the other two sides :
So is the difference of those sides :
To the difference of the segments of the base.

Then half this difference of the two segments added to the half sum, or half the base, gives the greater segments, and subtracted, gives the less. Hence, in each of the two right-angled triangles, there are given the hypotenuse, and the base, besides the right angle, to find the other angles by the 1st case.

Ex. In the trangle ABC, suppose there are given the three sides, to find the three angles, viz,

AB = 365
AC = 154·33 } to find the angles.
BC = 309·86

1. *Geometrically.*—Draw the base AB = 365: with the radius $154\frac{1}{3}$ and centre A describe an arc; and with the radius 310 and centre B describe another arc, cutting the former in C; then join AC and BC, and the triangle is constructed. And by measuring the angles, they are found, viz.

$\angle A = 57°\frac{1}{4}$; $\angle B = 24°\frac{3}{4}$; $\angle C = 98°$ nearly.

2. *Arithmetically.*—Having let fall the perpendicular CP, dividing the base into the two segments AP, PB, and the given triangle ABC into the two right-angled triangles ACP, BCP. Then,

As AB	= 365	- - log.	2·5622929
To CB + CA	= 464·19	- - -	2·6666958
So CB − CA	= 155·53	- - -	2·1918142
To BP − PA	= 197·80	- - -	2·2962171
its half	= 98·90		
$\frac{1}{2}$AB	= 182·50		
sum BP	= 281·40		
dif. AP	= 83·60		

Then, in the triangle APC, right-angled at P,

As AC	= 154·33	- - log.	2·1884504
To sin. ∠P	= 90°	- - - -	10·0000000
So AP	= 83·6	- - -	1·9222063
To sin. ∠ACP	= 32° 48′	- - -	9·7337559
its comp. ∠A	= 57° 12		

And in the triangle BPC, right-angled at P,

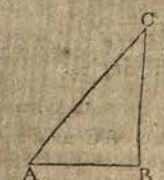
As BC	= 309·86	- - log.	2·4911655
To sin. ∠P	= 90°	- - -	10·0000000
So BP	= 281·4	- - -	2·4493241
To sin. ∠BCP	= 65° 15′	- -	9·9581586
its comp. ∠B	= 24 45		
Also to ∠ACP	= 32 48		
add ∠BCP	= 65 15		
makes ∠ACB	= 98 3		

3. *Instrumentally.*—In the 1st proportion, Extend the compasses from 365 to 464 on the line of numbers, and that extent will reach, on the same line, from $155\frac{1}{2}$ to 197·8 nearly.—In the 2d proportion, Extend the compasses from $154\frac{1}{3}$ to 83·6 on the line of numbers, and that extent will reach, on the lines, from 90° to $32°\frac{3}{4}$ nearly.—In the 3d proportion, Extend the compasses from 310 to 281[illegible] on the line of numbers; then that extent will reach, on the lines, from 90° to $65°\frac{1}{4}$.

The foregoing three cases include all the varieties of plane triangles that can happen, both of right and oblique-angled triangles. But beside these, there are some other theorems that are useful upon many occasions, or suited to some particular forms of triangles, which are often more expeditious in use than the foregoing general ones; one of which, for right-angled triangles, as the case for which it serves so often occurs, may be here inserted, and is as follows.

Case 4. When, in a right-angled triangle, there are given the angles and one leg, to find the other leg, or the hypothenuse. Then it will,

As radius :
To given leg AB : :
So tang. adjacent ∠A :
To the opp. leg BC, and : :
So sec. of same ∠A :
To hypot. AC .



Ex. In the triangle ABC, right-angled at B,

Given the leg AB = 162
and the ∠A = 53° 7′ 48″ } to find BC and AC.
conseq. ∠C = 36 52 12

1. *Geometrically.*—Draw the leg AB = 162: Erect the indefinite perpendicular BC: Make the angle A = $53°\frac{1}{8}$, and the side AC will cut BC in C, and form the triangle ABC. Then, by measuring, there will be found AC = 270, and BC = 216.

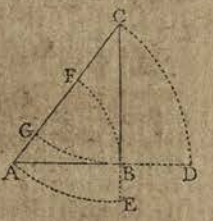
2. *Arithmetically.*

As radius	= 10	- - log.	10·0000000
To AB	= 162	- - -	2·2095150
So tan. ∠A	= 53° 7′ 48″		10·1249372
To BC	= 216	- -	2·3344522
So sec. ∠A	= 53° 7′ 48″	- -	10·2218477
To AC	= 270	- - -	2·4533627

3. *Instrumentally.*

3. *Inſtrumentally.*—Extend the compaſſes from 45° at the end of the tangents (the radius) to the tangent of 53° ½; then that extent will reach, on the line of numbers, from 162 to 216, for BC. Again, extend the compaſſes from 36° 52′ to 90 on the ſines; then that extent will reach, on the line of numbers, from 162 to 270 for AC.

Note, another method, by making every ſide radius, is often added by the authors on Trigonometry, which is thus: The given right-angled triangle being ABC, make firſt the hypotenuſe AC radius, that is, with the extent of AC as a radius, and each of the centres A and C, deſcribe ares CD and AE; then it is evident that each leg will repreſent the ſine of its oppoſite angle, viz, the leg BC the ſine of the arc CD or of the angle A, and the leg AB the ſine of the arc AE or of the angle C. Again, making either leg radius, the other leg will repreſent the tangent of its oppoſite angle, and the hypotenuſe the ſecant of the ſame angle; thus, with radius AB and centre A deſcribing the arc BF, BC repreſents the tangent of that arc, or of the angle A, and the hypotenuſe AC the ſecant of the ſame; or with the radius BC and centre C deſcribing the arc BG, the other leg AB is the tangent of that arc BG, or of the angle C, and the hypotenuſe CA the ſecant of the ſame.



And then the general rule for all theſe caſes is this, viz, that the ſides bear to each other the ſame proportions as the parts or things which they repreſent. And this is called making every ſide radius.

Spherical TRIGONOMETRY, is the reſolution and calculation of the ſides and angles of ſpherical triangles, which are made by three interſecting arcs of great circles on a ſphere. Here, any three of the ſix parts being given, even the three angles, the reſt can be found; and the ſides are meaſured or eſtimated by degrees, minutes, and ſeconds, as well as the angles.

Spherical Trigonometry is divided into right-angled and oblique-angled, or the reſolution of right and oblique-angled ſpherical triangles. When the ſpherical triangle has a right angle, it is called a right-angled triangle, as well as in plane triangles; and when a triangle has one of its ſides equal to a quadrant of a circle, it is called a quadrantal triangle.

For the reſolution of ſpherical Triangles, there are various theorems and proportions, which are ſimilar to thoſe in plane Trigonometry, by ſubſtituting the ſines of ſides inſtead of the ſides themſelves, when the proportion reſpects ſines; or tangents of the ſides for the ſides, when the proportion reſpects tangents, &c; ſome of the principal of which theorems are as follow:

Theor. 1. In any ſpherical triangle, the ſines of the ſides are proportional to the ſines of their oppoſite angles.

Theor 2. In any right-angled triangle,

As radius :
To ſine of one ſide : :
So tang. of the adjacent angle :
To tang. of the oppoſite ſide.

Theor. 3. If a perpendicular be let fall from any angl upon the baſe or oppoſite ſide of a ſpherical triangle it will be,

As the ſine of the ſum of the two ſides :
To the ſine of their difference : :
So cotan. ½ ſum angles at the vertex :
To tang. of half their difference.

Theor. 4.

As tang. half ſum of the ſides :
To tang. half their difference : :
So tang. ½ ſum ∠s at the baſe :
To tang. half their difference.

Theor. 5.

As cotan. ½ ſum of ∠s at the baſe :
To tang. half their difference : :
So tang. ½ ſum of ∠s at the vertex :
To tang. half their difference.

Theor. 6.

As tang. ½ ſum ſegments of baſe :
To tang. half ſum of the ſides : :
So tang. half difference of the ſides :
To tang. ½ diff. ſegments of baſe.

Theor. 7.

As ſin. ſum of ∠s at the baſe :
To ſine of their difference : :
So tang. ½ ſum ſegments of baſe :
To tang. of half their difference.

Theor. 8.

As ſin. ſum of ſegments of baſe :
To ſine of their difference : :
So ſin. ſum of angles at the vertex :
To ſine of their difference.

Theor. 9.

As ſine of the baſe :
To ſine of the vertical angle : :
So ſin. of diff. ſegments of the baſe :
To ſin. diff. ∠s at vertex, when the perp. falls within : :

Or ſo ſin. ſum ſegments of baſe :
To ſin. ſum vertical ∠s, where the perp. falls without.

Theor. 10.

As coſin. half ſum of the two ſides :
To coſine of half their difference : :
So cotang. of half the included angle :
To tang. half ſum of oppoſite angles.

Theor. 11.

As ſin. of half ſum of two ſides :
To ſine of half their difference : :
So cotang. half the included angle :
To tang. ½ diff. of the oppoſ. angles,

Theor.

Theor. 12.

As cosin. half sum of two angles :
To cosine of half their difference ::
So tang. of half the included side :
To tang. $\frac{1}{2}$ sum of the opposite sides.

Theor. 13.

As sin. half sum of two angles :
To sine of half their difference ::
So tang. half the included side :
To tang. $\frac{1}{2}$ diff. of the opposite sides.

Theor. 14. In a right-angled triangle,

As sin. sum of hypot. and one side :
To sin. of their difference ::
So radius squared :
To square of tang. $\frac{1}{2}$ contained angle.

Theor. 15. In any spherical triangle;
The product of the sines of two sides and of the cosine of the included angle, added to the product of the cosines of those sides, is equal to the cosine of the third side; the radius being 1.

Theor. 16. In any spherical triangle;
The product of the sines of two angles and of the cosine of the included side, minus the product of the cosines of those angles, is equal to the cosine of the third angle; the radius being 1.

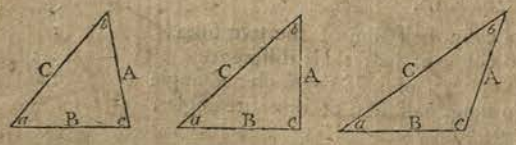
By some or other of these theorems may all the cases of spherical triangles be resolved, both right-angled and oblique: viz, the cases of right-angled triangles by the 1st and 2d theorems, and the oblique triangles by some of the other theorems.

In treatises on Trigonometry are to be found many other theorems, as well as synopses or tables of all the cases, with the theorem that is peculiar or proper to each. See the Introduction to my Mathematical Tables, p. 155 &c; or Robertson's Navigation, vol. 1, p. 162. See also Napier's Catholic or Universal Rule, in this Dictionary.

To the foregoing Theorems may be added the following synopsis of rules for resolving all the cases of plane and spherical triangles, under the title of

Trigonometrical Rules.

1. In a right-lined triangle, whose sides are A, B, C, and their opposite angles a, b, c; having given any three of these, of which one is a side; to find the rest.



Put s for the sine, s′ the cosine, t the tangent, and t′ the cotangent of an arch or angle, to the radius r; also L for a logarithm, and L′ its arithmetical complement. Then

Case 1. When three sides A, B, C, are given.

Put $P = \frac{1}{2}.\ A + B + C$ or semiperimeter.

Then s. $\frac{1}{2}c = r\sqrt{\frac{\overline{P-A} \times \overline{P-B}}{A \times B}}$.

And s′ $\frac{1}{2}c = r\sqrt{\frac{P \times \overline{P-C}}{A \times B}}$.

L. s. $\frac{1}{2}c = \frac{1}{2}$ (L. $\overline{P-A}$ + L. $\overline{P-B}$ + L′A + L′B),

L′s. $\frac{1}{2}c = \frac{1}{2}$ (L. P + L. $\overline{P-C}$ + L′A + L′B).

Note, When A = B, then

s. $\frac{1}{2}c = \frac{C}{A} \times \frac{r}{2}$. And s′ $\frac{1}{2}c = r\sqrt{\frac{A^2 - \frac{1}{4}C^2}{A^2}}$.

Case 2. Given two sides A, B, and their included angle c.

Put $s = 90° - \frac{1}{2}c$, and t. $d = \frac{A-B}{A+B} \times$ t. s;

then $a = s + d$; and $b = s - d$. And

$$C = \sqrt{\frac{4AB + s^2\frac{1}{2}c}{rr} + \overline{A-B}^2}.$$

Or in logarithms, putting L. Q = 2 L. $\overline{A-B}$, and L. R = L. 2A + L. 2B + 2 L. s. $\frac{1}{2}c$ − 20, we shall have L. C = $\frac{1}{2}$ L. $\overline{Q+R}$.

If the angle c be right, or = 90°; then

$$\text{t. } a = \frac{A}{B}r;\quad \text{t. } b = \frac{B}{A}r;$$

$$C = \frac{r}{\text{s. } a}A, \text{ or} = \frac{r}{\text{s. } b}B, \text{ or} = \sqrt{A^2 + B^2}.$$

If A = B; we shall have $a = b = 90° - \frac{1}{2}c$, and $C = \frac{\text{s. } \frac{1}{2}c}{r} \times 2A$.

Case 3. When a side and its opposite angle are among the terms given.

Then $\frac{A}{\text{s. } a} = \frac{B}{\text{s. } b} = \frac{C}{\text{s. } c}$; from which equations any term wanted may be found.

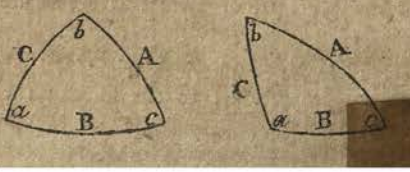
When an angle, as a, is 90°, and A and C are given, then

$$B = \sqrt{A^2 - C^2} = \sqrt{\overline{A+C} \times \overline{A-C}}.$$

And L. B = $\frac{1}{2}$ (L. $\overline{A+C}$ + L. $\overline{A-C}$).

Note, When two sides A, B, and an angle a opposite to one of them, are given; if A be less than B, then b, c, C have each two values; otherwise, only one value.

II. In a spherical triangle, whose three sides are A, B, C, and their opposite angles a, b, c; any three of these six terms being given, to find the rest.



Case 1. Given the three sides A, B, C.

Calling 2P the perim. or $P = \frac{1}{2}.\overline{A + B + C}$.

Then $s.\frac{1}{2}c = r\sqrt{\frac{s.\overline{P - A} \times s.\overline{P - B}}{s.A \times s.B}}$

And $s'\frac{1}{2}c = r\sqrt{\frac{s.P \times s.\overline{P - C}}{s.A \times s.B}}$.

$L.s.\frac{1}{2}c = \frac{1}{2}(L.s.\overline{P-A} + L.s.\overline{P-s} + L's.A + L's.B)$

$L.s'c = \frac{1}{2}(L.s.P + L.s.\overline{P-C} + L's.A + L's.B)$.

And the same for the other angles.

Case 2. Given the three angles.

Put $2p = a + b + c$. Then

$s.\frac{1}{2}C = r\sqrt{\frac{s'p \times s'\overline{p - c}}{s.a \times s.b}}$. And

$s'\frac{1}{2}C = r\sqrt{\frac{s'\overline{p-a} \times s'\overline{p-b}}{s.a \times s.b}}$.

$L.s.\frac{1}{2}C = \frac{1}{2}(L.s'p + Ls'\overline{p-c} + L's.a + L's.B)$

$L.s'\frac{1}{2}C = \frac{1}{2}(L.s'\overline{p-a} + L.s'\overline{p-b} + L's.a + Ls'.b)$

And the same for the other sides.

Note. The sign $\rhd$ signifies greater than, and $\lhd$ less; also $\backsim$ the difference.

Case 3. Given A, B, and included angle *c*.

To find an angle *a* opposite the side A,

let $r : s'c :: t.A : t.M$, like or unlike A,
as *c* is $\rhd$ or $\lhd 90°$; also $N = B \backsim M$:
then $s.N : s.M :: t.c : t.a$, like or unlike
c as M is $\rhd$ or $\lhd$ B.

Or let $s'\frac{1}{2}.\overline{A + B} : s'\frac{1}{2}.\overline{A \backsim B} :: t'\frac{1}{2}c : t.M$,
which is $\rhd$ or $\lhd 90°$ as A + B is $\rhd$ or $\lhd 180°$;

and $s.\frac{1}{2}.\overline{A+B} : s.\overline{A \backsim B} :: t'\frac{1}{2}c : t.N, \rhd 90°$.
then $a = M + N$; and $b = M - N$.

Again let $r : s'c :: t.A : t.M$, like or unlike A as *c*
is $\rhd$ or $\lhd 90°$; and $N = B \backsim M$.

Then $s'M : s'N :: s'A, s'C$, like or unlike
N as *c* is $\rhd$ or $\lhd 90°$. Or,

$$s.\tfrac{1}{2}C = \sqrt{\frac{s.A \times s.B \times s^2\frac{1}{2}c}{rr} + s^2\tfrac{1}{2}.A \backsim B}.$$

In logarithms, put $L.Q = 2L.s.\frac{1}{2}\overline{A \backsim B}$; and
$L.R = L.s.A + L.s.B + 2L.s.\frac{1}{2}c - 20$; then
$L.s.\frac{1}{2}C = \frac{1}{2}L.\overline{Q + R}$.

Case 4. Given *a*, *b*, and included side C.

First, let $r : s'C :: t.a : t'm$, like or unlike *a* as C is
$\rhd$ or $\lhd 90°$; also $n = b \backsim m$.

Then $s'n : s'm :: t.C : t.A$, like or unlike *n* as *a* is
$\rhd$ or $\lhd 90°$.

Or, let $s'\frac{1}{2}\overline{a+b} : s'\frac{1}{2}.\overline{a \backsim b} :: t.\frac{1}{2}C : t.M$, $\rhd$ or $\lhd$
$90°$ as $a + b$ is $\rhd$ or $\lhd 180°$;

and $s.\frac{1}{2}\overline{a+b} : s\,\frac{1}{2}\overline{a \backsim b} :: t.\frac{1}{2}C : tN, \rhd 90°$;
then $A = M \pm N$; and $B = M \mp N$.

Again, let $r : s'C :: t.a : t'm$, like or unlike *a* as C is
$\rhd$ or $\lhd 90°$;
and $n = b \backsim m$;

then $s.m. : s.n. :: s'a : s'c$, like or unlike *a* as
m is $\rhd$ or $\lhd b$.

Case 5. Given A, B, and an opposite angle *a*.

1st. $s.A : s.a. :: s.B : s.b, \rhd$ or $\lhd 90°$.

2nd. Let $r : s'B :: t.a : t'm$, like or unlike s as *a*
is $\rhd$ or $\lhd 90°$;

and $t.A : t.B :: s'm : s'n$, like or unlike A as *a* is
$\rhd$ or $\rhd 90°$:

then $c = m \pm n$, two values also.

3dly. Let $r : s'a :: t.B : t.M$, like or unlike B as
a is $\rhd$ or $\lhd 90°$;

and $s'B : s'A :: s'M : s'N$, like or unlike A as *a* is
$\rhd$ or $\lhd 90°$:

then $C = M \pm N$, two values also.

But if A be equal to B, or to its supplement, or between B and its supplement; then is *b* like to B: also *c* is $= m \mp n$, and $C = M \pm N$, as B is like or unlike *a*.

Case 6. Given *a*, *b*, and an opposite side A.

1st. $s.a. : s.A :: s.b : s.B, \rhd$ or $\lhd 90°$.

2nd. Let $r : s'b :: t.A :$ to tM, like or unlike *b*
as A is $\rhd$ or $\lhd 90°$;

and $t.a : t.b :: s.M : s.N, \rhd$ or $\lhd 90°$:
then $C = M \mp N$, as *a* is like or unlike *b*.

3dly. Let $r : s'A :: t.b : t'm$, like or unlike *b* as
A $\rhd$ or $\lhd 90°$;

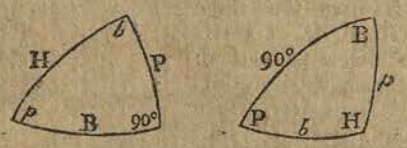
and $s'b : s'a :: s.m. : s.n, \rhd$ or $\lhd 90°$:
then $c = m \pm n$, as *a* is like or unlike *b*.

But if A be equal to B, or to its supplement, or between B and its supplement; then B is unlike *b*, and only the less values of N, *n*, are possible.

Note, When two sides A, B, and their opposite angles *a*, *b*, are known; the third side C, and its opposite angle *c*, are readily found thus:

$s.\frac{1}{2}\overline{a \backsim b} : s.\frac{1}{2}.\overline{a+b} :: t.\frac{1}{2}\overline{A \backsim B} : t.\frac{1}{2}C$.

$s.\frac{1}{2}.\overline{A \backsim B} : s.\frac{1}{2}\overline{A+B} :: t.\frac{1}{2}.\overline{a \backsim b} : t.\frac{1}{2}c$.



III. In a right-angled spheric triangle, where H is the hypotenuse, or side opposite the right angle, B, P the other two sides, and *b*, *p* their opposite angles; any two of these five terms being given, to find the rest; the cases, with their solutions, are as in the following Table.

The ſame Table will alſo ſerve for the quadrantal triangle, or that which has one ſide = 90°, H being the angle oppoſite that ſide, B, P the other two angles, and *b*, *p* their oppoſite ſides: obſerving, inſtead of H, to take its ſupplement: and mutually change the terms *like* and *unlike* for each other where H is concerned.

Caſe	Given	Req^{d}	SOLUTIONS.
1	H B	*b* *p* P	s. H. : *r* :: s B : s*b*, and is like B *r* : t'H :: t. B : s'*p* s'B : *r* :: s'H : s'P } , ▷ or ◁ 90° as H is like or unlike B
2	H *b*	B P *p*	*r* : s'H :: s.*b* : s.B, like *b* *r* : s'*b* :: t.H : t.P *r* : s'H :: t.*b* : t'*p* } , ▷ or ◁ 90° as H is like or unlike *b*
3	B *b*	H P *p*	s.*b* : *r* :: s.B : s.H *r* : t.B :: t'*b* : s.P s'B : *r* :: s'*b* : s.*p* } , each ▷ or ◁ 90° ; both values true
4	B *p*	H *b* *p*	*r* : t'B :: s'*p* : t'H, ▷ or ◁ 90 as B is like or unlike *p* *r* : s'B :: s.*p* : s'*b*, like B *r* : s.B :: t.*p* : t.P, like *p*
5	B P	H *b* *p*	*r* : s'B :: s'P : s'H, ▷ or ◁ 90° as B is like or unlike P *r* : s.P :: t'B : t'*b*, like B *r* : s.B :: t'P : t'*p*, like P
6	*b* *p*	H B P	*r* : t'*b* :: t'*p* : s'H, ▷ or ◁ 90° as *b* is like or unlike *p* s.*p* : *r* :: s'*b* : s'B like *b* s.*b* : *r* :: s'*p* : s'P like *p*

The following Propoſitions and Remarks, concerning Spherical Triangles, (ſelected and communicated by the reverend Nevil Maſkelyne, D. D. Aſtronomer Royal, F. R. S.) will alſo render the calculation of them perſpicuous, and free from ambiguity.

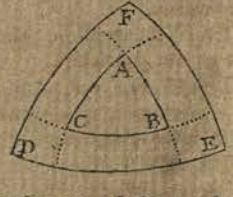
" 1. A ſpherical triangle is equilateral, iſoſceles, or ſcalene, according as it has its three angles all equal, or two of them equal, or all three unequal; and *vice verſa*.

2. The greateſt ſide is always oppoſite the greateſt angle, and the ſmalleſt ſide oppoſite the ſmalleſt angle.

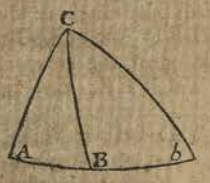
3. Any two ſides taken together, are greater than the third.

4. If the three angles are all acute, or all right, or all obtuſe; the three ſides will be, accordingly, all leſs than 90°, or equal to 90°, or greater than 90°; and *vice verſa*.

5. If from the three angles A, B, C, of a triangle ABC, as poles, there be deſcribed, upon the ſurface of the ſphere, three arches of a great circle DE, DF, FE, forming by their interſections a new ſpherical triangle DEF; each ſide of the new triangle will be the ſupplement of the angle at its pole; and each angle of the ſame triangle, will be the ſupplement of the ſide oppoſite to it in the triangle ABC.



6. In any triangle ABC, or A*b*C, right angled in A, 1ſt, The angles at the hypotenuſe are always of the ſame kind as their oppoſite ſides; 2dly, The hypotenuſe is leſs or greater than a quadrant, according as the ſides including the right angle are of the ſame or different kinds; that is to ſay, according as theſe ſame ſides are either both acute or both obtuſe, or as one is acute and the other obtuſe. And, *vice verſa*, 1ſt, The ſides including the right angle, are always of the ſame kind as their oppoſite angles: 2dly, The ſides including the right angle will be of the ſame or different kinds, according as the hypotenuſe is leſs or more than 90°; but one at leaſt of them will be of 90°, if the hypotenuſe is ſo."



TRILATERAL, three-ſided, a term applied to all figures of three ſides, or triangles.

TRILLION, in Arithmetic, the number of a million of billions, or a million of million of millions.

TRIMMERS, in Architecture, pieces of timber framed at right-angles to the joiſts, againſt the ways for chimneys to ſupport the hearths, and the well-holes for ſtairs.

TRINE *Dimenſion*, or *threefold dimenſion*, includes length, breadth, and thickneſs. The Trine dimenſion is peculiar to bodies or ſolids.

TRINE, in Aſtrology, is the aſpect or ſituation of one planet with reſpect to another, when they are diſtant

tant $\frac{1}{3}$ part of the circle, or 4 ſigns, or 120 degrees. It is alſo called trigon, and is denoted by the character $\triangle$.

TRINITY *Sunday*, is the next after Whitſunday; ſo called, becauſe on that day was anciently held a feſtival (as it ſtill continues to be in the Romiſh Church) in honour of the Holy Trinity.—The obſervance of this feſtival was firſt enjoined by the 6th canon of the council of Arles, in 1260; and John the 22d, who diſtinguiſhed himſelf ſo much by his opinion concerning the beatific viſion, it is ſaid, fixed the office for this feſtival in 1334.

TRINODA, or TRINODIA *Terræ*, in ſome ancient writers, denotes the quantity of 3 perches of land.

TRINOMIAL, in Algebra, is a quantity, or a root, conſiſting of three parts or terms, connected together by the ſigns + or −: as $a + b - c$, or $x + y + z$.

TRIO, in Muſic, a part of a concert in which three perſons ſing; or rather a muſical compoſition conſiſting of 3 parts.—Trios are the fineſt kind of muſical compoſition, and pleaſe moſt in concerts.

TRIOCTILE, in Aſtrology, an aſpect or ſituation of two planets, with regard to the earth, when they are 3 octants, or $\frac{3}{8}$ of a circle, which is 135°, diſtant from each other.—This aſpect, which ſome call the *ſeſquiquadrans*, is one of the new aſpects added to the old ones by Kepler.

TRIONES, in Aſtronomy, a ſort of conſtellation, or aſſemblage of 7 ſtars in the Urſa Major, popularly called *Charles's Wain*.—From the *Septem Triones* the north pole takes the denomination *Septentrio*.

TRIPARTITION, is a diviſion by 3, or the taking of the 3d part of any number or quantity.

TRIPLE, threefold. See RATIO and SUBTRIPLE.

TRIPLE, in Muſic, is one of the ſpecies of meaſure or time, and is taken from hence, that the whole, or half meaſure, is diviſible into 3 equal parts, and is beaten accordingly.

TRIPLICATE *Ratio*, is the ratio which cubes, or any ſimilar ſolids, bear to each other; and is the cube of the ſimple ratio, or this twice multiplied by itſelf. Thus 1 to 8 is the Triplicate ratio of 1 to 2, and 1 to 27 Triplicate of 1 to 3.

TRIPLICITY, or TRIGON, with Aſtrologers, is a diviſion of the 12 ſigns, according to the number of the 4 elements, earth, water, air, fire; each diviſion conſiſting of 3 ſigns, making the earthly Triplicity, the watery Triplicity, the airy Triplicity, and the fiery Triplicity.

Triplicity is ſometimes confounded with trine aſpect; though they are, ſtrictly ſpeaking, very different things; as Triplicity is only uſed with regard to the ſigns, and trine with regard to the planets. The ſigns of Triplicity are thoſe which are of the ſame nature, and not thoſe that are in trine aſpect: thus Aries, Leo, and Sagittary are ſigns of Triplicity, becauſe thoſe ſigns are, by theſe writers, all ſuppoſed fiery.

The ſigns in each of the four Triplicities, are as follow:

Earthly.	*Watery.*	*Airy.*	*Fiery.*
♉ Taurus.	♋ Cancer.	♊ Gemini.	♈ Aries.
♍ Virgo.	♏ Scorpio.	♎ Libra.	♌ Leo.
♑ Capricorn.	♓ Piſces.	♒ Aquarius.	♐ Sagittary.

TRIS-DIAPASON, or *Triple Diapaſon Chord*, in Muſic, is what is otherwiſe called a *triple eighth*.

TRISECTION, the dividing a thing into three equal parts. The term is chiefly uſed in Geometry, for the diviſion of an angle into three equal parts. The *Triſection of an angle* geometrically, is one of thoſe great problems whoſe ſolution has been ſo much ſought for by mathematicians, for 2000 years paſt; being, in this reſpect, on a footing with the famous quadrature of the circle, and the duplicature of the cube.

The Ancients Triſected an angle by means of the conic ſections, and the book of Inclinations; and Pappus enumerates ſeveral ways of doing it, in the 4th book of his Mathematical Collections, prop. 31, 32, 33, 34, 35, &c. He farther obſerves, that the problem of Triſecting an angle, is a ſolid problem, or a problem of the 3d degree, being expreſſed by the reſolution of a cubic equation, in which way it has been reſolved by Vieta, and others of the Moderns. See his Angular Sections, with thoſe of other authors, and the Triſection in particular by cubic equations, as in Guiſne's Application of Algebra to Geometry, in l'Hoſpital's Conic Sections, and in Emerſon's Trigonometry, book 1, ſec. 4. The cubic equation by which the problem of Triſection is reſolved, is as follows: Let c denote the chord of a given arc, or angle, and x the cord of the 3d part of the ſame, to the radius 1; then is

$$x^3 - 3x = -c,$$

by the reſolution of which cubic equation is found the value of x, or the chord of the 3d part of the given arc or angle, whoſe chord is c; and the reſolution of this equation, by Cardan's rule, gives the chord

$$x = \sqrt[3]{\frac{-c + \sqrt{c^2 - 4}}{2}} + \frac{1}{\sqrt[3]{\frac{-c + \sqrt{c^2 - 4}}{2}}},$$

$$\text{or } x = \sqrt[3]{\frac{-c + \sqrt{c^2 - 4}}{2}} + \sqrt[3]{\frac{-c - \sqrt{c^2 - 4}}{2}}$$

TRISPAST, or TRISPASTON, in Mechanics, a machine with 3 pulleys, or an aſſemblage of 3 pulleys, for raiſing great weights; being a lower ſpecies of the polyſpaſton.

TRITE, in Muſic, the 3d muſical chord in the ſyſtem of the Ancients.

TRITONE, in Muſic, a falſe concord, conſiſting of three tones, or a greater third, and a greater tone. Its ratio or proportion in numbers, is that of 45 to 32.

TROCHILE, in Architecture, is that hollow ring, or cavity, which runs round a column next to the tore.

TROCHLEA, in Mechanics, one of the mechanic powers, more uſually called the pulley.

TROCHOID, in the Higher Geometry, a curve described by a point in any part of the radius of a wheel, during its rotatory and progreſſive motions. This is the ſame curve as what is more uſually called the *Cycloid*, where the conſtruction and properties of it are ſhewn.

TRONE *Weight*, was the ſame with what we now call *Troy Weight*.

TRONE *Pound*, in Scotland, contains 20 Scotch ounces. Or becauſe it is uſual to allow one to the ſcore, the Trone-pound is commonly 21 ounces.

TRONE-*Stone*, in Scotland, according to Sir John Skene, contains 19½ pounds.

TROPHY, in Architecture, an ornament which repreſents the trunk of a tree, charged or encompaſſed all around with arms or military weapons, both offenſive and defenſive.

TROPICAL, ſomething relating to the Tropics. As, TROPICAL-*Winds*. See WIND, and TRADE-*Winds*.

TROPICAL *Year*, the ſpace of time during which the ſun paſſes round from a tropic, till his return to it again. See YEAR.

TROPICS, in Aſtronomy, two fixed circles of the ſphere, drawn parallel to the equator, through the ſolſtitial points, or at ſuch diſtance from the equator, as is equal to the ſun's greateſt receſs or declination, or to the obliquity of the ecliptic.

Of the two Tropics, that on the north ſide of the equator, paſſes through the firſt point of Cancer, and is therefore called the *Tropic of Cancer*. And the other on the ſouth ſide, paſſing through the firſt point of Capricorn, is called the *Tropic of Capricorn*.

To determine the diſtance between the two Tropics, and thence the ſun's greateſt declination, or the obliquity of the ecliptic; obſerve the ſun's meridian altitude, both in the ſummer and winter ſolſtice, and ſubtract the latter from the former, ſo ſhall the remainder be the diſtance between the two Tropics; and the half of this will be the quantity of the greateſt declination, or the obliquity of the ecliptic; the medium of which is now 23° 28′ nearly.

TROPICS, in Geography, are two leſſer circles of the globe, drawn parallel to the equator through the beginnings of Cancer and Capricorn, being in the planes of the celeſtial Tropics, and conſequently at 23° 28′ diſtance either way from the equator.

TROY-*Weight*, anciently called *Trone weight*, is ſuppoſed to be taken from a weight of the ſame name in France, and that from the name of the town of Troyes there.

The original of all weights uſed in England, was a corn or grain of wheat gathered out of the middle of the ear, and, when well dried, 32 of them were to make one pennyweight. 20 pennyweights 1 ounce, and 12 ounces 1 pound Troy. Vide Statutes of 51 Hen. III; 31 Ed. I. and 12 Hen. VII.

But afterward it was thought ſufficient to divide the ſaid pennyweight into 24 equal parts, called grains, being the leaſt weight now in common uſe; ſo that the diviſions of Troy weight now are theſe:

24 grains	= 1 pennyweight	*dwt.*
20 pennyweights	= 1 ounce	*oz.*
12 ounces	= 1 pound	*lb.*

By Troy-weight are weighed jewels, gold, ſilver, and all liquors.

TRUCKS, among Gunners, are the ſmall wooden wheels fixed on the axletrees of gun carriages, eſpecially thoſe for ſhip ſervice, to move them about by.

TRUE *Conjunction*, in Aſtronomy. See *True* CONJUNCTION.

TRUE *Place of a Planet or Star*, is a point in the heavens ſhewn by a right line drawn from the centre of the earth, through the centre of the ſtar or planet.

TRUMPET, *Liſtening or Hearing*, is an inſtrument invented by Joſeph Landini, to aſſiſt the hearing of perſons dull of that faculty, or to aſſiſt us to hear perſons who ſpeak at a great diſtance.

Inſtruments of this kind are formed of tubes, with a wide mouth, and terminating in a ſmall canal, which is applied to the ear. The form of theſe inſtruments evidently ſhews how they conduce to aſſiſt the hearing; for the greater quantity of the weak and languid pulſes of the air being received and collected by the large end of the tube, are reflected to the ſmall end, where they are collected and condenſed; thence entering the ear in this condenſed ſtate, they ſtrike the tympanum with a greater force than they could naturally have done from the ear alone.

Hence it appears, that a ſpeaking Trumpet may be applied to the purpoſe of a hearing Trumpet, by turning the wide end towards the ſound, and the narrow end to the ear.

Speaking TRUMPET, is a tube of a conſiderable length, from 6 to 15 feet, uſed for ſpeaking with to make the voice be heard to a greater diſtance.

This tube, which is made of tin, is ſtraight throughout its length, but opening to a large aperture outwards, and the other end terminating in a proper ſhape and ſize to receive both the lips in the act of ſpeaking, the ſpeaker puſhing his voice or the ſound outwards, by which means it may be heard at the diſtance of a mile or more.

The invention of this Trumpet is held to be modern, and has been aſcribed to Sir Samuel Moreland, who called it the *tuba ſtentorophonica*, and in a work of the ſame name, publiſhed at London in 1671, that author gave an account of it, and of ſeveral experiments made with it. With one of theſe inſtruments, of 5½ feet long, 21 inches diameter at the greater end, and 2 inches at the ſmaller, tried at Deal-Caſtle, the ſpeaker was heard to the diſtance of 3 miles, the wind blowing from the ſhore.

But it ſeems that Kircher has a better title to the invention; for it is certain that he had ſuch an inſtrument before ever Moreland thought of his. That author, in his Phonurgia Nova, publiſhed in 1673, ſays, that the tromba, publiſhed laſt year in England, he invented 24 years before, and publiſhed in his Muſurgia. He adds, that Jac. Albanus Ghibbiſius and Fr. Eſchinardus aſcribe it to him; and that G. Schottus teſtifies of him, that he had ſuch an inſtrument in his chamber in the

Roman

Roman college, with which he could call to, and receive anſwers from the porter.

But, conſidering how famous the tube or horn of Alexander the Great was, it is rather ſtrange that the Moderns ſhould pretend to the invention. With his ſtentorophonic horn or tube he uſed to ſpeak to his army, and make himſelf be diſtinctly heard, it is ſaid, 100 ſtadia or furlongs. A figure of this tube is preſerved in the Vatican; and it is nearly the ſame as that now in uſe. See STENTOROPHONIC.

The principle of this inſtrument is obvious; for as ſound is ſtronger in proportion to the denſity of the air, it follows that the voice in paſſing through a tube, or Trumpet, muſt be greatly augmented by the conſtant reflection and agitation of the air through the length of the tube, by which it is condenſed, and its action on the external air greatly increaſed at its exit from the tube.

It has been found, that a man ſpeaking through a tube of 4 feet long, may be underſtood at the diſtance of 500 geometrical paces; with a tube 16½ feet, at the diſtance of 1800 paces; and with a tube 24 feet long, at more than 2500 paces.

Although ſome advantage in heightening the ſound, both in ſpeaking and hearing, be derived from the ſhape of the tube, and the width of the outer end, yet the effect depends chiefly upon its length. As to the form of it, ſome have aſſerted that the beſt figure is that which is formed by the revolution of a parabola about its axis; the mouth-piece being placed in the focus of the parabola, and conſequently the ſonorous rays reflected parallel to the axis of the tube. But Mr. Martin obſerves, that this parallel reflection is by no means eſſential to increaſing the ſound: on the contrary, it prevents the infinite number of reflections and reciprocations of ſound, in which, according to Newton, its augmentation chiefly conſiſts; the augmentation of the impetus of the pulſes of air being proportional to the number of repercuſſions from the ſides of the tube, and therefore to its length, and to ſuch a figure as is moſt productive of them. Hence he infers, that the parabolic Trumpet is the moſt unfit of any for this purpoſe; and he endeavours to ſhew, that the logarithmic or logiſtic curve gives the beſt form, viz, by a revolution about its axis. Martin's Philoſ. Brit. vol. 2, pa. 248, 3d edit.

But Caſſegrain is of opinion that an hyperbola, having the axis of the tube for an aſymptote, is the beſt figure for this inſtrument. Muſſchenb. Intr. ad Phil. Nat. tom. 2, pa. 926, 4to.

For other conſtructions of Speaking Trumpets, by Mr. Conyers, ſee Philoſ. Tranſ. numb. 141, for 1678.

TRUNCATED *Pyramid* or *Cone*, is the fruſtum of one, being the part remaining at the bottom, after the top is cut off by a plane parallel to the baſe. See FRUSTUM.

TRUNNIONS, of a piece of ordnance, are thoſe knobs or ſhort cylinders of metal on the ſides, by which it reſts on the cheeks of the carriage.

TRUNNION-*Ring*, is the ring about a cannon, next before the Trunnions.

TSCHIRNHAUSEN (ERNFROY WALTER), an ingenious mathematician, lord of Killingſwald and of Stolzenberg in Luſatia, where he was born in 1651. After having ſerved as a volunteer in the army of Holland in 1672, he travelled into moſt parts of Europe, as England, Germany, Italy, France, &c. He went to Paris for the third time in 1682; where he communicated to the Academy of Sciences, the diſcovery of the curves called, from him, Tſchirnhauſen's Cauſtics; and the Academy in conſequence elected the inventor one of its foreign members. On returning to Italy, he was deſirous of perfecting the ſcience of optics; for which purpoſe he eſtabliſhed two glaſs-works, from whence reſulted many new improvements in dioptrics and phyſics, particularly the noted burning-glaſs which he preſented to the regent.—It was to him too that Saxony owed its porcelane manufactory.

Content with the enjoyment of literary fame, Tſchirnauſen refuſed all other honours that were offered him. Learning was his ſole delight. He ſearched out men of talents, and gave them encouragement. He was often at the expence of printing the uſeful works of other men, for the benefit of the public; and died, beloved and regretted, the 11th of September 1708.

Tſchirnauſen wrote, *De Medicina Mentis & Corporis*, printed at Amſterdam in 1687. And the following memoirs were printed in the volumes of the Academy of Sciences.

1. Obſervations on Burning Glaſſes of 3 or 4 feet diameter: vol. 1699.

2. Obſervations on the Glaſs of a Teleſcope, convex on both ſides, of 32 feet focal diſtance; 1700.

3. On the Radii of Curvature, with the finding the Tangents, Quadratures, and Rectifications of many curves; 1701.

4. On the Tangents of Mechanical Curves; 1702.

5. On a method of Quadratures; 1702.

TUBE, a pipe, conduit, or canal; being a hollow cylinder, either of metal, wood, glaſs, or other matter, for the conveyance of air, or water, &c.

The term is chiefly applied to thoſe uſed in phyſics, aſtronomy, anatomy, &c. On other ordinary occaſions, we more uſually ſay *pipe*.

In the memoirs of the French Academy of Sciences, Varignon has given a treatiſe on the proportions for the diameters of tubes, to give any particular quantities of water. The reſult of his paper gives theſe two analogies, viz, that the diminutions of the velocity of water, occaſioned by its friction againſt the ſides of Tubes, are as the diameters; the Tubes being ſuppoſed equally long: and the quantities of water iſſuing out at the Tubes, are as the ſquare roots of their diameters, deducting out of them the quantity that each is diminiſhed.

TUBE, in Aſtronomy, is ſometimes uſed for teleſcope; but more properly for that part of it into which the lenſes are fitted, and by which they are directed and uſed.

TUESDAY, the 3d day of the week, ſo called from Tueſco, one of the Saxon Gods, ſimilar to Mars; for which reaſon the aſtronomical mark for this day of the week, is ♂.

TUMBREL, is a kind of carriage with two wheels, uſed either in Huſbandry for dung, or in Artillery to carry the tools of the pioneers, &c, and ſometimes likewiſe the money of an army.

TUN, is a meaſure for liquids, as wine, oil, &c.

The Engliſh Tun contains 2 pipes, or 4 hogſheads, or 252 gallons.

TUNE, or TONE, in Muſic, is that property of ſounds by which they come under the relation of acute and grave.

If two or more ſounds be compared together in this relation, they are either equal or unequal in the degree of Tune: ſuch as are equal, are called *uniſons*. The unequal conſtitute what are called *intervals*, which are the differences of Tone between ſounds.

Sonorous bodies are found to differ in Tone: 1ſt, According to the different kinds of matter; thus the ſound of a piece of gold, is much graver than that of a piece of ſilver of the ſame ſhape and dimenſions. 2d, According to the different quantities of the ſame matter in bodies of the ſame figure; as a ſolid ſphere of braſs of 1 foot diameter, ſounds acuter than a ſphere of braſs of 2 feet diameter.

But the meaſures of Tone are only to be ſought in the relations of the motions that are the cauſe of ſound, which are moſt diſcernible in the vibration of chords. Now, in general, we find that in two chords, all things being equal, excepting the tenſion, the thickneſs, or the length, the Tones are different; which difference can only be in the velocity of their vibratory motions, by which they perform a different number of vibrations in the ſame time; as it is known that all the ſmall vibrations of the ſame chord are performed in equal times. Now the frequenter or quicker thoſe vibrations are, the more acute is the Tone; and the ſlower and fewer they are in the ſame ſpace of time, by ſo much the more grave is the Tone. So that any given note of a Tune is made by one certain meaſure of velocity of vibrations, that is, ſuch a certain number of vibrations of a chord or ſtring, in ſuch a certain ſpace of time, conſtitutes a determinate Tone.

This theory is ſtrongly ſupported by the beſt and lateſt writers on muſic, Holder, Malcolm, Smith, &c, both from reaſon and experience. Dr. Wallis, who owns it very reaſonable, adds, that it is evident the degrees of acuteneſs are reciprocally as the lengths of the chords; though, he ſays, he will not poſitively affirm that the degrees of acuteneſs anſwer the number of vibrations, as their only true cauſe: but his diffidence ariſes from hence, that he doubts whether the thing has been ſufficiently confirmed by experiment.

TUNNAGE. See TONNAGE.

TURN, is uſed for a circular motion; in which ſenſe it agrees with revolution.

TURN, in Clock or Watch-work, particularly denotes the revolution of a wheel or pinion.

In calculation, the number of Turns which the pinion hath, is denoted in common arithmetic thus, 5) 60 (12, where the pinion 5, playing in a wheel of 60, moves round 12 times in one Turns of the wheel. Now by knowing the number of Turns which any pinion hath, in one Turn of the wheel it works in, you may eaſily find how many Turns a wheel or pinion has at a greater diſtance; as the contrat-wheel, crown-wheel, &c, by multiplying together the quotients, and the number produced is the number of Turns, as in the example here annexed: the firſt of theſe three numbers has 11 Turns, the next 9, and the laſt 8; if you multiply 11 by 9, it produces 99; that is, in one Turn of the wheel 55, there are 99 Turns of the ſecond pinion 5, or the wheel 40, which runs concentrical or on the ſame arbor with the ſecond pinion 5: and if you again multiply 99 by the laſt quotient 8, it produces 792, which is the number of Turns the third pinion 5 hath. See CLOCK-*work*, and PINION.

5)	55	(11
5)	45	(9
5)	40	(8

TURNING *to windward*, in Sea Language, denotes that operation in ſailing when a ſhip endeavours to make a progreſs againſt the direction of the wind, by a compound courſe, inclined to the place of her deſtination.—This method of navigation is otherwiſe called *plying to windward*.

TUSCAN *Order*, in Architecture, is the firſt, the ſimpleſt, and the ſtrongeſt or moſt maſſive of any. Its column has 7 diameters in height; and its capital, baſe, and entablement, have no ornaments, and but few mouldings.

TWELFTH-*Day*, the feſtival of the Epiphany, or the manifeſtation of Chriſt to the Gentiles, ſo called, as being the Twelfth day, excluſive, from the nativity or Chriſtmas-day; of courſe it falls always on the 6th day of January.

TWILIGHT, in Aſtronomy, is that faint light which is perceived before the ſun-riſing, and after ſun-ſetting. The Twilight is occaſioned by the earth's atmoſphere refracting the rays of the ſun, and reflecting them among its particles.

The depreſſion of the ſun below the horizon, at the beginning of the morning, and end of the evening Twilight, has been variouſly ſtated, at different ſeaſons, and by different obſervers: by Alhazen it was obſerved to be 19°; by Tycho 17°; by Rothman 24°; by Stevinus 18°; by Caſſini 15°; by Riccioli, at the time of the equinox in the morning 16°, in the evening 20°½; in the ſummer ſolſtice in the morning 21° 25′, and in the winter 17° 15′. Whence it appears that the cauſe of the Twilight is variable; but, or a medium, about 18° of the ſun's depreſſion will ſerve tolerably well for our latitude, for the beginning and end of Twilight, and according to which Dr. Long, (in his Aſtronomy, vol. 1, pa. 258) gives the following Table, of the duration of Twilight, in different latitudes, and for ſeveral different declinations of the ſun.

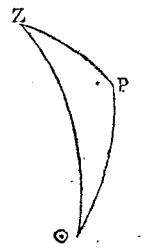
Latitude.

Latitude.	0	10	20	30	40	45	50	52½	55	60	65	70	75	80	85	90
☉ Enters ♋	h m 1 18	h m 1 21	h m 1 28	h m 1 41	h m 2 8	h m 2 39	h m w n	h m w n	h m w n	h m w n	h m w n	h m c d	h m c d	h m c d	h m c d	h m c d
♊ ♌	1 16	1 19	1 25	1 36	1 58	2 19	3 3	w n	w n	w n	w n	c d	c d	c d	c d	c d
♉ ♍	1 13	1 15	1 20	1 28	1 43	1 55	2 12	2 25	2 41	3 55	w n	w n	w n	c d	c d	c d
♈ ♎	1 12	1 13	1 17	1 24	1 35	1 44	1 55	2 2	2 10	2 33	3 8	4 18	w n	w n	w n	w. n
♓ ♏	1 13	1 14	1 18	1 24	1 35	1 43	1 54	2 0	2 8	2 27	2 56	8 41	5 2	17 32	w n	w n
♒ ♐	1 16	1 17	1 21	1 28	1 40	1 49	2 1	2 8	2 18	2 43	3 26	11 38	11 14	10 32	8 38	c n
♑	1 18	1 19	1 23	1 30	1 43	1 53	2 6	2 15	2 26	2 57	4 4	10 24	9 30	7 46	c n	c. n

Where *c d* ſignify that it is then continual day, *c n* continual night, and *w n* that the Twilight laſts the whole night.

Prob.—To find the Beginning or End of Twilight.

In this problem, there are given the ſides of an oblique ſpherical triangle, to find an angle; viz, given the ſide ZP the colatitude of the place; P☉ the codeclination, or polar diſtance; and Z☉ the zenith diſtance, which is always equal to 108°, viz, 90° from the zenith to the horizon, and 18° more for the ſun's diſtance below the horizon. For example, ſuppoſe the place London in latitude 51° 32′, and the time the 1ſt of May, when the ſun's declination is 15° 12′ north. Here then ZP = 38° 28′ the complement of 51° 32′, and P☉ = 74° 48′, the complement of 15° 12′. Then the calculation is as follows.



$$P\odot = 74^\circ\ 48'$$
$$PZ = 38\ 28$$
$$P\odot - PZ = 36\ 20 = D$$
$$Z\odot = 108\ 00$$
$$Z\odot + D = 144\ 20 \quad | \quad 72^\circ\ 10' = \tfrac{1}{2}\,\overline{Z\odot + D}$$
$$Z\odot - D = 71\ 40 \quad | \quad 35\ 50 = \tfrac{1}{2}\,\overline{Z\odot - D}$$

Then,

Co-ar. ſin. polar diſt.	= 74° 48′	0·01547
Co-ar. ſin. colat.	= 38 28	0·20617
Sine ½ $\overline{Z\odot + D}$	= 72 10	9·97861
Sine ½ $\overline{Z\odot - D}$	= 35 50	9·76747
Sum of theſe four logs.		19·96772
Half ſum gives	74° 28½′	9·98386

Which doubled gives 148 57 for the angle ZPO.

This 148° 57′ reduced to time, at the rate of 15° per hour, gives 9ʰ 55ᵐ 48ˢ, either before or after noon; that is, the twilight begins at 2ʰ 4ᵐ 12ˢ in the morning, and ends at 9ʰ 55ᵐ 48ˢ in the evening on the given day at London.

TWINKLING *of the Stars*, denotes that tremulous motion which is obſerved in the light proceeding from the fixed ſtars.

This Twinkling in the ſtars has been variouſly accounted for. Alhazen, a Mooriſh philoſopher of the 12th century, conſiders refraction as the cauſe of this phenomenon.

Vitello, in his Optics, (compoſed before the year 1270) pa. 449, aſcribes the Twinkling of the ſtars to the motion of the air, in which the light is refracted; and he obſerves, in confirmation of this hypotheſis, that they Twinkle ſtill more when they are viewed in water put into motion.

Dr. Hook (Microgr. pa. 231, &c) aſcribes this phenomenon to the inconſtant and unequal refraction of the rays of light, occaſioned by the trembling motion of the air and interſperſed vapours, in conſequence of variable degrees of heat and cold in the air, producing correſponding variations in its denſity, and alſo of the action of the wind, which muſt cauſe the ſucceſſive rays to fall upon the eye in different directions, and conſequently upon different parts of the retina at different times, and alſo to hit and miſs the pupil alternately; and this alſo is the reaſon, he ſays, why the limbs of the ſun, moon, and planets appear to wave or dance.

Theſe tremors of the air are manifeſt to the eye by the tremulous motion of ſhadows caſt from high towers; and by looking at objects through the ſmoke of a chimney, or through ſteams of hot water, or at objects ſituated beyond hot ſands, eſpecially if the air be moved tranſverſely over them. But when ſtars are ſeen through teleſcopes that have large apertures; they Twinkle but little, and ſometimes not at all. For, as Newton has obſerved, (Opt. pa. 98) the rays of light which paſs through different parts of the aperture, tremble each of them apart, and by means of their various, and contrary tremors, fall at one and the ſame time

time upon different points in the bottom of the eye, and their trembling motions are too quick and confused to be feparately perceived. And all thefe illuminated points conftitute one broad lucid point, compofed of thofe many trembling points confufedly and infenfibly mixed with one another by very fhort and fwift tremors, and fo caufe the ftar to appear broader than it is, and without any trembling of the whole.

Dr. Jurin, in his Eflay upon Diftinct and Indiftinct Vifion, has recourfe to Newton's hypothefis of fits of eafy refraction and reflection for explaining the Twinkling of the ftars: thus, he fays, if the middle part of the image of a ftar be changed from light to dark, and the adjacent ring at the fame time be changed from dark to light, as muft happen from the leaft motion of the eye towards or from the ftar, this will occafion fuch an appearance as Twinkling.

Mr. Michell (Philof. Tranf. vol. 57, pa. 262) fuppofes that the arrival of fewer or more rays at one time, efpecially from the fmaller or more remote fixed ftars, may make fuch an unequal impreffion on the eye, as may at leaft have fome fhare in producing this effect: fince it may be fuppofed that even a fingle particle of light is fufficient to make a fenfible impreffion on the organs of fight; fo that very few particles arriving at the eye in a fecond of time, perhaps not more than three or four, may be fufficient to make an object conftantly vifible. See LIGHT.

Hence, he fays, it is not improbable that the number of the particles of light which enter the eye in a fecond of time, even from Syrius himfelf, may not exceed 3 or 4 thoufand, and from ftars of the 2d magnitude they may probably not exceed 100. Now the apparent increafe and diminution of the light, which we obferve in the Twinkling of the ftars, feem to be repeated at intervals not very unequal, perhaps about 4 or 5 times in a fecond. He therefore thought it reafonable to fuppofe, that the inequalities which will naturally arife from the chance of the rays coming fometimes a little denfer, and fometimes a little rarer, in fo fmall a number of them, as muft fall upon the eye in the 4th or 5th part of a fecond, may be fufficient to account for this appearance.

Since thefe obfervations were publifhed however, Mr. Michell (as we are informed by Dr. Prieftley in his Hift. of Light, pa. 495) has entertained fome fufpicion, that the unequal denfity of light does not contribute to this effect in fo great a degree as he had imagined; efpecially as he has obferved that even Venus does fometimes Twinkle. This he once obferved her to do remarkably when fhe was about 6 degrees high, though Jupiter, which was then about 16 degrees high, and was fenfibly lefs luminous, did not Twinkle at all. If, notwithftanding the great number of rays which doubtlefs come to the eye from fuch a furface as this planet prefents, its appearance be liable to be affected in this manner, it muft be owing to fuch undulations in the atmofphere, as will probably render the effect of every other caufe altogether infenfible.

Muffchenbroek fufpects (Introd. ad Phil. Nat. vol. 2, fect. 1741, pa. 707) that the Twinkling of the ftars arifes from fome affection of the eye, as well as the ftate of the atmofphere. For, fays he, in Holland, when the weather is frofty, and the fky very clear, the ftars Twinkle moft manifeftly to the naked eye, though not in telefcopes; and fince he does not fuppofe there is any great exhalation, or dancing of the vapour, at that time, he queftions whether the vivacity of the light, affecting the eye, may not be concerned in the phenomenon.

But this philofopher might have fatisfied himfelf with refpect to this hypothefis, by looking at the ftars near the zenith, when the light traverfes but a fmall part of the atmofphere, and therefore might be expected to affect the eye moft fenfibly. For he would have found that they do not Twinkle near fo much as they do near the horizon, when much more of their light is intercepted by the atmofphere.

Some aftronomers have lately endeavoured to explain the Twinkling of the fixed ftars, by the extreme minutenefs of their apparent diameter; fo that they fuppofe the light of them is intercepted by every mote that floats in the air. To this purpofe Dr. Long obferves (Aftron. vol. 1, pa. 170) that our air near the earth is fo full of various kinds of particles, which are in continual motion, that fome one or other of them is perpetually paffing between us and any ftar we look at, which makes us every moment alternately fee it and lofe fight of it: and this Twinkling of the ftars, he fays, is greateft in thofe that are neareft the horizon, becaufe they are viewed through a great quantity of thick air, where the intercepting particles are moft numerous; whereas ftars that are near the zenith do not Twinkle fo much, becaufe we do not look at them through fo much thick air, and therefore the intercepting particles, being fewer, come lefs frequently before them. With refpect to the planets, it is obferved that, becaufe they are much nearer to us than the ftars, they have a fenfible apparent magnitude, fo that they are not covered by the fmall particles floating in the atmofphere, and therefore do not Twinkle, but fhine with a fteady light.

The fallacy of this hypothefis appears from the obfervation of Mr. Michell, that no object can hide a ftar from us that is not large enough to exceed the apparent diameter of the ftar, by the diameter of the pupil of the eye; fo that if a ftar were even a mathematical point, or of no diameter, the interpofing object muft ftill be equal in fize to the pupil of the eye; and indeed it muft be large enough to hide the ftar from both eyes at the fame time.

The principal caufe therefore of the Twinkling of the ftars, is now acknowledged to be the unequal refraction of light, in confequence of inequalities and undulations in the atmofphere.

Befides a variation in the quantity of light, it may here be added, that a momentary change of colour has likewife been obferved in fome of the fixed ftars. Mr. Melville (Edinb. Eflays, vol. 2, pa. 81) fays, that when one looks fteadfaftly at Sirius, or any bright ftar, not much elevated above the horizon, its colour feems not to be conftantly white, but appears tinctured, at every Twinkling, with red and blue. Mr. Melville could not entirely fatisfy himfelf as to the caufe of this phenomenon;

nomenon; obſerving that the ſeparation of the colours by the refractive power of the atmoſphere, is probably too ſmall to be perceived. Mr. Michell's hypotheſis above mentioned, though not adequate to the explication of the Twinkling of the ſtars, may pretty well account for this circumſtance. For the red and blue rays being much fewer than thoſe of the intermediate colours, and therefore much more liable to inequalities from the common effect of chance, a ſmall exceſs or defect in either of them will make a very ſenſible difference in the colour of the ſtars.

TYCHONIC *Syſtem*, or *Hypotheſis*, is an order or arrangement of the heavenly bodies, of an intermediate nature between the Copernican and Ptolomaic; and is ſo called from its inventor Tycho Brahe. See SYSTEM.

TYMPAN, or TYMPANUM, in Architecture, is the area of a pediment, being that part which is on a level with the naked of the frize. Or it is the ſpace included between the three cornices of a triangular pediment, or the two cornices of a circular one.

TYMPAN is alſo uſed for that part of a pedeſtal called the *trunk* or *dye*.

TYMPAN, among Joiners, is alſo applied to the pannels of doors.

TYMPAN *of an Arch*, is a triangular ſpace or table in the corners of ſides of an arch, uſually hollowed and enriched, ſometimes with branches of laurel, olive-tree, or oak; or with trophies, &c; ſometimes with flying figures, as fame, &c; or ſitting figures, as the cardinal virtues.

TYMPAN, in Mechanics, is a kind of wheel placed round an axis, or cylindrical beam, on the top of which are two levers, or fixed ſtaves, for more eaſily turning the axis about, in order to raiſe a weight. The Tympanum is much the ſame with the peritrochium; but that the cylinder of the axis of the peritrochium is much ſhorter and leſs than the cylinder of the Tympanum.

TYMPANUM of a machine, is alſo uſed for a hollow wheel, in which people or animals walk, to turn it; ſuch as that of ſome cranes, calenders, &c.

TYR, in the Ethiopian Calendar, the name of the 5th month of the Ethiopian year. It commences on the 25th of December of the Julian year.

TYSHAS, among the Ethiopians, the name of the 4th month of their year, commencing the 27th of November in the Julian year.

U AND V.

V Is a numeral letter, in the Roman numeration, denoting 5 or five. And with a daſh over the top thus $\overline{V}$, it denoted 5000.

VACUUM, in Phyſics, a ſpace empty or devoid of all matter.

Whether there be any ſuch thing in nature as an abſolute Vacuum; or whether the univerſe be completely full, and there be an abſolute plenum; is a queſtion that has been agitated by the philoſophers of all ages.

The Ancients, in their controverſies, diſtinguiſhed two kinds; a *Vacuum coacervatum*, and a *Vacuum interſperſum*, or *diſſeminatum*.

VACUUM *Coacervatum*, is conceived as a conſiderably large ſpace deſtitute of matter; ſuch, for inſtance, as there would be, ſhould God annihilate all the air, and other bodies, within the walls of a chamber.

The exiſtence of ſuch a Vacuum is maintained by the Pythagoreans, Epicureans, and the Atomiſts or Corpuſcularians; moſt of whom aſſert, that ſuch a Vacuum actually exiſts without the limits of the ſenſible world. But the modern Corpuſcularians, who hold a *Vacuum coacervatum*, deny that appellation; as conceiving that ſuch a Vacuum muſt be infinite, eternal, and uncreated.

According then to the later philoſophers, there is no Vacuum coacervatum without the bounds of the ſenſible world; nor would there be any other Vacuum, provided God ſhould annihilate divers contiguous bodies, than what amounts to a mere privation, or nothing; the dimenſions of ſuch a ſpace, which the Ancients held to be real, being by theſe held to be mere negations; that is, in ſuch a place there is ſo much length, breadth, and depth wanting, as a body muſt have to fill it. To ſuppoſe then, that when all the matter in a chamber is annihilated, there ſhould yet be real dimenſions, is to ſuppoſe, ſay they, corporeal dimenſions without body; which is abſurd.

The Carteſians however deny any *Vacuum coacervatum* at all, and aſſert that if God ſhould immediately annihilate all the matter, for example in a chamber, and prevent the ingreſs of any other matter, the conſequence would be, that the walls would become contiguous, and include no ſpace at all. They add, that if there be no matter in a chamber, the walls cannot be conceived otherwiſe than as contiguous; thoſe things being

being ſaid to be contiguous, between which there is not any thing intermediate: but if there be no body between, there is, ſay they, no extenſion between; extenſion and body being the ſame thing: and if there be no extenſion between, then the walls are contiguous; and where is the Vacuum?——But this reaſoning, or rather quibbling, is founded on the miſtake, that body and extenſion are the ſame thing.

VACUUM *Diſſeminatum*, or *Interſperſum*, is that ſuppoſed to be naturally interſperſed in and among bodies, in the interſtices between different bodies, and in the pores of the ſame body.

It is this kind of Vacuum which is chiefly conteſted among the modern philoſophers; the Corpuſcularians ſtrenuouſly aſſerting it; and the Peripatetics and Carteſians as tenaciouſly denying it. See CARTESIAN and LEIBNITZIAN.

The great argument urged by the Peripatetics againſt a Vacuum interſperſum, is, that there are divers bodies frequently ſeen to move contrary to their own nature and inclination; and that for no other apparent reaſon, but to avoid a Vacuum: whence they conclude, that nature abhors a Vacuum; and give us a new claſs of motions aſcribed to the *fuga vacui* or nature's flying a Vacuum. Such, they ſay, is the riſe of water in a ſyringe, upon the drawing up of the piſton; and ſuch is the aſcent of water in pumps, and the ſwelling of the fleſh in a cupping glaſs, &c.—But ſince the weight, elaſticity, &c, of the air have been aſcertained by ſure experiments, thoſe motions and effects are univerſally, and juſtly, aſcribed to the gravity and preſſure of the atmoſphere.

The Carteſians deny, not only the actual exiſtence, but even the poſſibility of a Vacuum; and that on this principle, that extenſion being the eſſence of matter, or body, wherever extenſion is, there is matter; but mere ſpace, or vacuity, is ſuppoſed to be extended; therefore it is material. Whoever aſſerts an empty ſpace, ſay they, conceives dimenſions in that ſpace, i. e. he conceives an extended ſubſtance in it; and therefore he denies a Vacuum, at the ſame time that he admits it.—But Deſcartes, if we may believe ſome accounts, rejected a Vacuum from a complaiſance to the taſte which prevailed in his time, againſt his own firſt ſentiments; and among his familiar friends he uſed to call his ſyſtem his philoſophical romance.

On the other hand, the corpuſcular authors prove, not only the poſſibility, but the actual exiſtence, of a Vacuum, from divers conſiderations; particularly from the conſideration of motion in general; and that of the planets, comets, &c, in particular; as alſo from the fall of bodies; from the vibration of pendulums; from rarefaction and condenſation; from the different ſpecific gravities of bodies; and from the diviſibility of matter into parts.

1. Firſt, there could be no linear or progreſſive motion without a Vacuum; for if all ſpace were full of matter, no body could be moved out of its place, for want of another place unoccupied, to move into. And this argument was ſtated even by Lucretius.

2 The motions of the planets and comets alſo prove a Vacuum. Thus, Newton argues, "that there is no ſuch fluid medium as æther," (to fill up the porous parts of all ſenſible bodies, and ſo make a plenum), ſeems probable; becauſe the planets and comets proceed with ſo regular and laſting a motion, through the celeſtial ſpaces; for hence it appears that thoſe celeſtial ſpaces are void of all ſenſible reſiſtance, and conſequently of all ſenſible matter. Conſequently if the celeſtial region were as denſe as water, or as quickſilver, they would reſiſt almoſt as much as water or quickſilver; but if they were perfectly denſe, without any interſperſed vacuity, though the matter were ever ſo fluid and ſubtile, they would reſiſt more than quickſilver does: a perfectly ſolid globe, in ſuch a medium, would loſe above half its motion, in moving 3 lengths of its diameter; and a globe not perfectly ſolid, ſuch as the bodies of the planets and comets are, would be ſtopped ſtill ſooner. Therefore, that the motion of the planets and comets may be regular, and laſting, it is neceſſary that the celeſtial ſpaces be void of all matter; except perhaps ſome few and much rarefied effluvia of the planets and comets, and the paſſing rays of light."

3. The ſame great author alſo deduces a Vacuum from the conſideration of the weights of bodies; thus: "All bodies about the earth gravitate towards it; and the weights of all bodies, equally diſtant from the earth's centre, are as the quantities of matter in thoſe bodies. If the æther therefore, or any other ſubtile matter, were altogether deſtitute of gravity, or did gravitate leſs than in proportion to the quantity of its matter; becauſe (as Ariſtotle, Deſcartes, and others, argue) it differs from other bodies only in the form of matter; the ſame body might, by the change of its form, gradually be converted into a body of the ſame conſtitution with thoſe which gravitate moſt in proportion to the quantity of matter: and, on the other hand, the heavieſt bodies might gradually loſe their gravity, by gradually changing their form; and ſo the weights would depend upon the forms of bodies, and might be changed with them; which is contrary to all experiment."

4. The deſcent of bodies proves, that all ſpace is not equally full; for the ſame author goes on, "If all ſpaces were equally full, the ſpecific gravity of that fluid with which the region of the air would, in that caſe, be filled, would not be leſs than the ſpecific gravity of quickſilver or gold, or any other the moſt denſe body; and therefore neither gold, nor any other body, could deſcend in it. For bodies do not deſcend in a fluid, unleſs that fluid be ſpecifically lighter than the body. But by the air-pump we can exhauſt a veſſel, till even a feather ſhall fall with a velocity equal to that of gold in the open air; and therefore the medium through which this feather falls, muſt be much rarer than that through which the gold falls in the other caſe. The quantity of matter therefore in a given ſpace may be diminiſhed by rarefaction: and why may it not be diminiſhed ad infinitum? Add, that we conceive the ſolid particles of all bodies to be of the ſame denſity; and that they are only rarefiable by means of their pores; and hence a Vacuum evidently follows."

5. "That there is a Vacuum, is evident too from the vibrations of pendulums: for ſince thoſe bodies, in places out of which the air is exhauſted, meet with no reſiſtance to retard their motion, or ſhorten their vibrations; it is evident that there is no ſenſible matter in thoſe ſpaces, or in the occult pores of thoſe bodies."

6. That

6. That there are interſperſed vacuities, appears from matter's being actually divided into parts, and from the figures of thoſe parts; for, on ſuppoſition of an abſolute plenum, we do not conceive how any part of matter could be actually divided from that next adjoining, any more than it is poſſible to divide actually the parts of abſolute ſpace from one another: for by the actual diviſion of the parts of a continuum from one another, we conceive nothing elſe underſtood, but the placing of thoſe parts at a diſtance from one another, which in the continuum were at no diſtance from one another: but ſuch diviſions between the parts of matter muſt imply vacuities between them.

7. As for the figures of the parts of bodies, upon the ſuppoſition of a plenum, they muſt either be all rectilinear, or all concavo-convex; otherwiſe they would not adequately fill ſpace; which we do not find to be true in fact.

8. The denying a Vacuum ſuppoſes what it is impoſſible for any one to prove to be true, viz, that the material world has no limits.

However, we are told by ſome, that it is impoſſible to conceive a Vacuum. But this ſurely muſt proceed from their having imbibed Deſcartes's doctrine, that the eſſence of body is conſtituted by extenſion; as it would be contradictory to ſuppoſe ſpace without extenſion. To ſuppoſe that there are fluids penetrating all bodies and repleniſhing ſpace, which neither reſiſt nor act upon bodies, merely in order to avoid admitting a Vacuum, is feigning two ſorts of matter, without any neceſſity or foundation; or is tacitly giving up the queſtion.

Since then the eſſence of matter does not conſiſt in extenſion, but in ſolidity, or impenetrability, the univerſe may be ſaid to conſiſt of ſolid bodies moving in a Vacuum: nor need we at all fear, leſt the phenomena of nature, moſt of which are plauſibly accounted for from a plenum, ſhould become inexplicable when the plenitude is ſet aſide. The principal ones, ſuch as the tides; the ſuſpenſion of the mercury in the barometer; the motion of the heavenly bodies, and of light, &c, are more eaſily and ſatisfactorily accounted for from other principles.

VACUUM *Boileanum*, is uſed to expreſs that approach to a real Vacuum, which we arrive at by means of the air-pump. Thus, any thing put in a receiver ſo exhauſted, is ſaid to be put *in vacuo*: and thus moſt of the experiments with the air-pump are ſaid to be performed *in vacuo*, or *in vacuo Boileano*.

Some of the principal phenomena obſerved of bodies in vacuo, are; that the heavieſt and lighteſt bodies, as a guinea and a feather, fall here with equal velocity: —that fruits, as grapes, cherries, peaches, apples, &c, kept for any time in vacuo, retain their nature, freſhneſs, colour, &c, and thoſe withered in the open air recover their plumpneſs in vacuo:—all light and fire become immediately extinct in vacuo:—little or no ſound is heard from a bell rung in vacuo:—a bladder half full of air, will diſtend the bladder, and lift up 40 pound weight in vacuo:—moſt animals ſoon expire in vacuo.

By experiments made in 1704, Dr. Derham found that animals which have two ventricals, and no foramen ovale, as birds, dogs, cats, mice, &c, die in leſs than half a minute; counting from the firſt exſuction: a mole died in one minute; a bat lived 7 or 8. Inſects, as waſps, bees, graſshoppers, &c, ſeemed dead in two minutes; but after being left in vacuo 24 hours, they came to life again in the open air: ſnails continued 24 hours in vacuo, without appearing much incommoded. —Seeds planted in vacuo do not grow: Small beer dies, and loſes all its taſte, in vacuo: And air ruſhing through mercury into a Vacuum, throws the mercury in a kind of ſhower upon the receiver, and produces a great light in a dark room.

The air-pump can never produce a perfect Vacuum; as is evident from its ſtructure, and the manner of its working: in effect, every exſuction only takes away a part of the air; ſo that there is ſtill ſome left after any finite number of exſuctions. For the air-pump has no longer any effect but while the ſpring of the air remaining in the receiver is able to lift up the valves; and when the rarefaction is come to that degree, you can come no nearer to a Vacuum; unleſs perhaps the air valves can be opened mechanically, independent of the ſpring of the air, as it is ſaid they are in ſome new improved air-pumps.

Torricellian VACUUM, is that made in the barometer tube, between the upper end and the top of the mercury. This is perhaps never a perfect and entire Vacuum; as all fluids are found to yield or to riſe in elaſtic vapours, on the removal of the preſſure of the atmoſphere. See TORRICELLIAN, and BAROMETER.

VALVE, in Hydraulics, Pneumatics, &c, is a kind of lid or cover to a tube or veſſel, contrived to open one way; but which, the more forcibly it is preſſed the other way, the cloſer it ſhuts the aperture: ſo that it either admits the entrance of a fluid into the tube, or veſſel, and prevents its return; or permits it to eſcape, and prevents its re-entrance.

Valves are of great uſe in the air-pump, and other wind machines; in which they are uſually made of pieces of bladder. In hydraulic engines, as the emboli of pumps, they are moſtly of ſtrong leather, of a round figure, and fitted to ſhut the apertures of the barrels or pipes. Sometimes they are made of two round pieces of leather encloſed between two others of braſs; having divers perforations, which are covered with another piece of braſs, moveable upwards and downwards, on a kind of axis, which goes through the middle of them all. Sometimes they are made of braſs, covered over with leather, and furniſhed with a fine ſpring, which gives way upon a force applied againſt it; but upon the ceaſing of that, returns the Valve over the aperture. See PUMP. See alſo Deſaguliers' Exper. Philoſ. vol. 2, p. 156, and p. 180.

VANE, in a ſhip, &c, a thin ſlip of ſome kind of matter, placed on high in the open air, turning eaſily round on an axis or ſpindle, and veered about by the wind, to ſhew its direction or courſe.

VANES, in Mathematical or Philoſophical Inſtruments, are ſights made to ſlide and move upon croſs-ſtaves, fore-ſtaves, quadrants, &c.

VAPOUR, in Meteorology, a watery exhalation raiſed up either by the heat of the ſun, or any other heat, as fire, &c. Vapour is conſidered as a thin veſicle of water, or other humid matter, filled or inflated with air; which, being rarefied to a certain degree by the action of heat, aſcends to ſome height in the atmo-

atmoſphere, where it is ſuſpended, till it returns in form of rain, ſnow, or the like. An aſſemblage of a number of particles or veſicles of vapour, conſtitutes what is called a cloud.

Some uſe the term Vapour indifferently, for all fumes emitted, either from moiſt bodies, as fluids of any kind; or from dry bodies, as ſulphur, &c. But Newton, and other authors, better diſtinguiſh between humid and dry fumes, calling the latter *exhalations*.

For the manner in which Vapours are raiſed, and again precipitated, ſee CLOUD, DEW, RAIN, BAROMETER, and particularly EVAPORATION.

It may here be added, with reſpect to the principles of ſolution adopted to account for evaporation, and largely illuſtrated under that article, that Dr. Halley, about the beginning of the preſent century, ſeems to have been acquainted with the ſolvent power of air on water; for he ſays, that ſuppoſing the earth to be covered with water, and the ſun to move diurnally round it, the air would of itſelf imbibe a certain quantity of aqueous Vapours, and retain them like ſalts diſſolved in water; and that the air warmed by the ſun would ſuſtain a greater proportion of Vapours, as warm water will hold more diſſolved ſalts; which would be diſcharged in dews, ſimilar to the precipitation of ſalts on the cooling of liquors. Philoſ. Tranſ. Abr. vol. 2, p. 127.

Mr. Eeles, in 1755, endeavoured to account for the aſcent of Vapour and exhalation, and their ſuſpenſion in the atmoſphere, by means of the electric fire. The ſun, he acknowledges, is the great agent in detaching Vapour and exhalations from their maſſes, whether he acts immediately by himſelf, or by his rendering the electric fire more active in its vibrations: but their ſubſequent aſcent he attributes entirely to their being rendered ſpecifically lighter than the lower air, by their conjunction with electrical fire: each particle of Vapour, with the electrical fluid that ſurrounds it, occupying a greater ſpace than the ſame weight of air. Mr. Eeles alſo endeavours to ſhew, that the aſcent and deſcent of Vapour, attended by this fire, are the cauſe of all the winds, and that they furniſh a ſatisfactory ſolution of the general phenomena of the weather and barometer. Philoſ. Tranſ. vol. 49, pa. 124.

Dr. Darwin, in 1757, publiſhed remarks on the theory of Mr. Eeles, with a view of confuting it; and attempting to account for the aſcent of Vapours, by conſidering the power of expanſion which the conſtituent parts of ſome bodies acquire by heat, and alſo that ſome bodies have a greater affinity to heat, or acquire it ſooner, and retain it longer, than others. On theſe principles, he thinks, it is eaſily underſtood how water, whoſe parts appear from the æolipile to be capable of immeaſurable expanſion, ſhould by heat alone become ſpecifically lighter than the common atmoſphere. A ſmall degree of heat is ſufficient to detach or raiſe the Vapour of water from the maſs to which it belongs; and the rays of the ſun communicate heat only to thoſe bodies by which they are refracted, reflected, or obſtructed, whence, by their impulſe, a motion or vibration is cauſed in the parts of ſuch bodies. Hence he infers, that the ſpherickes of Vapour will, by refracting the ſolar rays, acquire a conſtant heat, though the ſurrounding atmoſphere remain cold. If it be aſked, how clouds are ſupported in the abſence of the ſun? It muſt be remembered, that large maſſes of Vapour muſt for a conſiderable time retain much of the heat they have acquired in the day; at the ſame time reflecting how ſmall a quantity of heat was neceſſary to raiſe them, and that doubtleſs even a leſs will be ſufficient to ſupport them; as from the diminiſhed preſſure of the atmoſphere at a given height, a leſs power may be able to continue them in their preſent ſtate of rarefaction; and laſtly, that clouds of particular ſhapes will be ſuſtained or elevated by the motion they acquire from winds. Philoſ. Tranſ. vol. 50, p. 246.

For the Effect of Vapour in the Formation of Springs, &c, ſee SPRING, and RIVER.

The quantity of Vapour raiſed from the ſea by the warmth of the ſun, muſt be far greater than is commonly imagined. Dr. Halley has attempted to eſtimate it. For the reſult of his calculations, ſee EVAPORATION.

VARIABLE, in Geometry and Analytics, is a term applied by mathematicians, to ſuch quantities as are conſidered in a Variable or changeable ſtate, either increaſing or decreaſing. Thus, the abſciſſes and ordinates of an ellipſis, or other curve line, are Variable quantities; becauſe theſe vary or change their magnitude together, the one at the ſame time with the other. But ſome quantities may be Variable by themſelves alone, or while thoſe connected with them are conſtant: as the abſciſſes of a parallelogram, whoſe ordinates may be conſidered as all equal, and therefore conſtant. Alſo the diameter of a circle, and the parameter of a conic ſection, are *conſtant*, while their abſciſſes are *Variable*.

Variable quantities are uſually denoted by the laſt letters of the alphabet, x, y, z, &c; while the conſtant ones are denoted by the leading letters, a, b, c, &c.

Some authors, inſtead of *Variable* and *conſtant* quantities, uſe the terms *fluent* and *ſtable* quantities.

The indefinitely ſmall quantity by which a Variable quantity is continually increaſed or decreaſed, in very ſmall portions of time, is called the *differential*, or *increment* or *decrement*. And the rate of its increaſe or decreaſe at any point, is called its *fluxion*; while the Variable quantity itſelf is called the *fluent*. And the calculation of theſe, is the ſubject of the new *Methodus Differentialis*, or *Doctrine of Fluxions*.

VARENIUS (BERNARD), a learned Dutch geographer and phyſician, of the laſt century, who was author of the beſt mathematical treatiſe on Geography, intitled, *Geographia Univerſalis*, in qua affectiones generalis Telluris explicantur. This excellent work has been tranſlated into all languages, and was honoured by an edition, with improvements, by Sir Iſaac Newton, for the uſe of his academical ſtudents at Cambridge.

VARIATION, *of Quantities*, in Algebra. See CHANGES, and COMBINATION.

VARIATION, in Aſtronomy.—*The Variation of the Moon*, called by Bulliald, the *Reflection of her Light*, is the third inequality obſerved in the moon's motion; by which, when out of the quadratures, her true place differs from her place twice equated. See PLACE, EQUATION, &c.

Newton makes the moon's variation to ariſe partly from the form of her orbit, which is an ellipſis; and partly

partly from the inequality of the ſpaces, which the moon deſcribes in equal times, by a radius drawn to the earth.

To find the Greateſt Variation. Obſerve the moon's longitude in the octants; and to the time of obſervation compute the moon's place twice equated; then the difference between the computed and obſerved place, is the greateſt Variation.

Tycho makes the greateſt Variation 40′ 30″; and Kepler makes it 51′ 49″.—But Newton makes the greateſt Variation, at a mean diſtance between the ſun and the earth, to be 35′ 10″: at the other diſtances, the greateſt Variation is in a ratio compounded of the duplicate ratio of the times of the moon's ſynodical revolution directly, and the triplicate ratio of the diſtance of the ſun from the earth inverſely. And therefore in the ſun's apogee, the greateſt Variation is 33′ 14″, and in his perigee 37′ 11″; provided that the eccentricity of the ſun be to the tranſverſe ſemidiameter of the orbis magnus, as $16\frac{15}{16}$ to 1000. Or, taking the mean motions of the moon from the ſun, as they are ſtated in Dr. Halley's tables, then the greateſt Variation at the mean diſtance of the earth from the ſun will be 35′ 7″, in the apogee of the ſun 33′ 27″, and in his perigee 36′ 51″. Philoſ. Nat. Princ. pr. 29, lib. 3.

VARIATION, in Geography, Navigation, &c, a term applied to the deviation of the magnetic needle, or compaſs, from the true north point, either towards the eaſt or weſt; called alſo the *declination.* Or the Variation of the compaſs is properly defined, the angle which a magnetic needle, ſuſpended at liberty, makes with the meridian line on an horizontal plane; or an arch of the horizon, comprehended between the true and the magnetic meridians.

In the ſea-language, the Variation is uſually called *north-eaſting*, or *north-weſting*.

All magnetic bodies are found to range themſelves, in ſome ſort, according to the meridian; but they ſeldom agree preciſely with it: in one place they decline, from the north toward the eaſt, in another toward the weſt; and that too differently at different times.

The Variation of the compaſs could not long remain a ſecret, after the invention of the compaſs itſelf: accordingly Ferdinand, the ſon of Columbus, in his life written in Spaniſh, and printed in Italian at Venice in 1571, aſſerts, that his father obſerved it on the 14th of September 1492: though others ſeem to attribute the diſcovery of it to Sebaſtian Cabat, a Venetian, employed in the ſervice of our king Henry VII, about the year 1500.—It now appears however, that this Variation or declination of the needle was known even ſome centuries earlier, though it does not appear that the uſe of the needle itſelf in navigation was then known. For it ſeems there is in the library of the univerſity of Leyden, a ſmall manuſcript tract on the Magnet, in Latin, written by one Peter Adſiger, bearing date the 8th of Auguſt 1269; in which the declination of the needle is particularly mentioned. Mr. Cavallo has printed the chief part of this letter in the Supplement to his Treatiſe on Magnetiſm, with a tranſlation; and I think it is to be wiſhed he had printed the whole of ſo curious a paper. The curioſity of this letter, ſays Mr. Cavallo, conſiſts in its containing almoſt all that is at preſent known of the ſubject, at leaſt the moſt remarkable parts of it, mixed however with a good deal of abſurdity. The laws of magnetic attraction, and of the communication of that power to iron, the directive property of the natural magnet, as well as of the iron that has been touched by it, and even the declination of the magnetic needle, are clearly and unequivocally mentioned in it.

As this Variation differs in different places, Gonzales d'Oviedi found there was none at the Azores; from whence ſome geographers thought fit in their maps to make the firſt meridian paſs through one of theſe iſlands: it not being then known that the Variation altered in time. See MAGNET; alſo Gilbert De Magnete, Lond. 1600, p. 4 and 5; or Purchas's Pilgrims, Lond. 1625, book 2, ſect. 1.

Various are the hypotheſes that have been framed to account for this extraordinary phenomenon: we ſhall only notice ſome of the latter, and more probable: juſt premiſing, that Robert Norman, the inventor of the Dipping-needle, diſputes againſt Cortes's notion, that the Variation was cauſed by a point in the heavens; contending that it ſhould be ſought for in the earth, and propoſes how to diſcover its place.

The firſt is that of Gilbert (De Magnete, lib. 4, p. 151 &c), which is followed by Cabeus, &c. This notion is, that it is the earth, or land, that draws the needle out of its meridian direction: and hence they argue, that the needle varied more or leſs, as it was more or leſs diſtant from any great continent; and conſequently that if it were placed in the middle of an ocean, equally diſtant from equal tracts of land on each ſide, eaſtward and weſtward, it would not decline either to the one or the other, but point exactly north and ſouth. Thus, ſay they, in the Azores iſlands, which are equally diſtant from Africa on the eaſt, and America on the weſt, there is no Variation: but as you ſail from thence towards Africa, the needle begins to decline toward the eaſt, and that ſtill more and more till you reach the ſhore. If you proceed ſtill farther eaſtward, the declination gradually diminiſhes again, by reaſon of the land left behind on the weſt, which continues to draw the needle. The ſame holds till you arrive at a place where the tracts of land on each ſide are equal; and there again the Variation will be nothing. But the misfortune is, the law does not hold univerſally; for multitudes of obſervations of the Variation, in different parts, made and collected by Dr. Halley, overturn the whole theory.

Others therefore have recourſe to the frame and compages of the earth, conſidered as interſperſed with rocks and ſhelves, which being generally found to run towards the polar regions, the needle comes to have a general tendency that way; but it ſeldom happens that their direction is exactly in the meridian, and the needle has conſequently, for the moſt part, ſome Variation.

Others hold that divers parts of the earth have different degrees of the magnetic virtue, as ſome are more intermixed with heterogeneous matters, which prevent the free action or effect of it, than others are.

Others again aſcribe all to magnetic rocks and iron mines, which, affording more of the magnetic matter than other parts, draw the needle more.

Laſtly, others imagine that earthquakes, or high tides, have diſturbed and diſlocated ſeveral conſiderable parts of the earth, and ſo changed the magnetic axis of the globe, which was originally the ſame with the axis of the earth itſelf.

But none of theſe theories can be the true one; for ſtill that great phenomenon, the *Variation of the Variation*, i. e. the continual change of the declination, in one and the ſame place, is not accountable for, on any of theſe foundations, nor is it even conſiſtent with them.

Doctor Hook communicated to the Royal Society, in 1674, a theory of the Variation; the ſubſtance of which is, that the magnet has its peculiar pole, diſtant 10 degrees from the pole of the earth, about which it moves, ſo as to make a revolution in 370 years: whence the Variation, he ſays, has altered of late about 10 or 11 minutes every year, and will probably ſo continue to do for ſome time, when it will begin to proceed ſlower and ſlower, till at length it become ſtationary and retrograde, and ſo return back again. Birch's Hiſt. of the Royal Society, vol. 3, p. 131.

Dr. Halley has given a new ſyſtem, the reſult of numerous obſervations, and even of a number of voyages made at the public expence on this account. The light which this author has thrown upon this obſcure part of natural hiſtory, is very great, and of important conſequence in navigation, &c. In this ſyſtem he has reduced the ſeveral Variations in divers places to a preciſe rule, or order, which before appeared all precarious and arbitrary.

His theory will therefore deſerve a more ample detail. The obſervations it is built upon, as laid down in the Philoſ. Tranſ. number 148, or Abr. vol. 2, p. 610, are as follow:

Obſerved Variations of the Needle in divers places, and at divers times.

Upon

Upon theſe obſerved Variations Dr. Halley makes ſeveral remarks, as to the Variation in different parts of the world at the time of his writing, eaſtward and weſtward, and the ſituation and direction of the lines or places of no Variation: from the whole he deduces the following theory.

Dr. *Halley's Theory of the Variation of the Needle.* That the whole globe of the earth is one great magnet, having four magnetical poles, or points of attraction; near each pole of the equator two; and that in thoſe parts of the world which lie nearly adjacent to any one of theſe magnetic poles, the needle is governed by it; the neareſt pole being always predominant over the more remote.

The pole which at preſent is neareſt to us, he conjectures to lie in or near the meridian of the Land's-end of England, and not above 7° from the north pole: by this pole, the Variations in all Europe and Tartary, and the North Sea, are chiefly governed; though ſtill with ſome regard to the other northern pole, whoſe ſituation is in the meridian paſſing about the middle of California, and about 15° from the north pole of the world, to which the needle has chiefly reſpect in all North America, and in the two oceans on either ſide of it, from the Azores weſtward to Japan, and farther.

The two ſouthern magnetic poles, he imagines, are rather more diſtant from the ſouth pole of the world; the one being about 16° from it, on a meridian 20° to the weſtward of the Magellanic Streights, or 95° weſt from London: this pole commands the needle in all South America, in the Pacific Ocean, and the greateſt part of the Ethiopic Ocean. The other magnetic pole ſeems to have the greateſt power, and the largeſt dominion of all, as it is the moſt remote from the pole of the world, being little leſs than 20° diſtant from it, in the meridian which paſſes through New Holland, and the iſland Celebes, about 120° eaſt from London: this pole is predominant in the ſouth part of Africa, in Arabia, and the Red Sea, in Perſia, India, and its iſlands, and all over the Indian ſea, from the Cape of Good Hope eaſtward, to the middle of the Great South Sea that divides Aſia from America.

Such, he obſerves, ſeems to be the preſent diſpoſition of the magnetic virtue thoughout the whole globe of the earth. It is then ſhewn how this hypotheſis accounts for all the Variations that have been obſerved of late, and how it anſwers to the ſeveral remarks drawn from the table.

It is there inferred that from the whole it appears, that the direction of the needle, in the temperate and frigid zones, depends chiefly upon the counterpoiſe of the forces of two magnetic poles of the ſame nature: as alſo why, under the ſame meridian, the Variation ſhould be in one place 29½ degrees weſt, and in another 20½ degrees eaſt.

In the torrid zone, and particularly about the equator, reſpect muſt be had to all the four poles, and their poſitions muſt be well conſidered, otherwiſe it will not be eaſy to determine what the Variation ſhould be, the neareſt pole being always ſtrongeſt; yet ſo however as to be ſometimes counterbalanced by the united forces of two more remote ones. Thus, in ſailing from St. Helena, by the iſle of Aſcenſion, to the equator, on the north-weſt courſe, the Variation is very little eaſterly, and unalterable in that whole track; becauſe the South-American pole (which is much the neareſt in the aforeſaid places), requiring a great eaſterly variation, is counterpoiſed by the contrary attraction of the North-American and the Aſiatic ſouth poles; each of which ſingly is, in theſe parts, weaker than the American ſouth pole; and upon the north-weſt courſe the diſtance from this latter is very little varied; and as you recede from the Aſiatic ſouth pole, the balance is ſtill preſerved by an acceſs towards the North-American pole. In this caſe no notice is taken of the European north pole; its meridian being a little removed from thoſe of theſe places, and of itſelf requiring the ſame Variations which are here found.

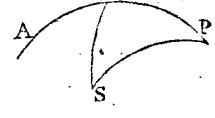
After the ſame manner may the Variations in other places about the equator be accounted for, upon Dr. Halley's hypotheſis.

To obſerve the Variation of the Needle. Draw a meridian line, as directed under MERIDIAN; then a ſtile being erected in the middle of it, place a needle upon it, and draw the right line which it hangs over. Thus will the quantity of the Variation appear.

Or thus: As the former method of finding the Variation cannot be applied at ſea, others have been deviſed, the principal of which are as follow. Suſpend a thread and plummet over the compaſs, till the ſhadow paſs through the centre of the card; obſerve the rhumb, or point of the compaſs which the ſhadow touches when it is the ſhorteſt. For the ſhadow is then a meridian line; and conſequently the Variation is ſhewn.

Or thus: Obſerve the point of the compaſs upon which the ſun, or ſome ſtar, riſes and ſets; biſect the arch intercepted between the riſing and ſetting, and the line of biſection will be the meridian line; conſequently the Variation is had as before. The ſame may alſo be obtained from two equal altitudes of the ſame ſtar, obſerved either by day or night. Or thus: Obſerve the rhumb upon which the ſun or ſtar riſes and ſets; and from the latitude of the place find the eaſtern or weſtern amplitude: for the difference between the amplitude, and the diſtance of the rhumb obſerved, from the eaſtern rhumb of the card, is the Variation ſought.

Or thus: Obſerve the altitude of the ſun, or ſome ſtar S, whoſe declination is known; and note the rhumb in the compaſs to which it then correſponds. Then in the triangle ZPS, are known three ſides, viz, PZ the colatitude, PS the codeclination, and ZS the coaltitude; the angle PZS is thence found by ſpherical trigonometry; the ſupplement to which, viz AZS, is the azimuth from the ſouth. Then the difference between the azimuth and the obſerved diſtance of the rhumb from the ſouth, is the Variation ſought. See *Azimuth* COMPASS.



The uſe of the Variation is to correct the courſes a ſhip has ſteered by the compaſs, which muſt always be done before they are worked, or calculated.

VARIATION *of the Variation*, is a gradual and continual change in the Variation, obſerved in any place, by which the quantity of the Variation is found to be different at different times.

This Variation, according to Henry Bond (in his *Longitude found*, Lond. 1670, pa. 6) "was firſt found to decreaſe by Mr. John Mair; 2dly, by Mr. Edmund Gunter: 3dly, by Mr. Henry Gellibrand; 4thly, by myſelf (Henry Bond) in 1640; and laſtly, by Dr. Robert Hook, and others, in 1665;" which they found out by comparing together obſervations made at the ſame place, at different times. The diſcovery was ſoon known abroad; for Kircher, in his treatiſe intitled Magnes, firſt printed at Rome in 1641, ſays that our countryman Mr. John Greaves had informed him of it, and then he gives a letter of Merſenne's, containing a diſtinct account of it.

This continual change in the Variation, is gradual and univerſal, as appears by numerous obſervations. Thus, the Variation was,

At Paris, according to Orontius Finæus,

in 1550	8°	0′E.
in 1640	3	0 E.
in 1660	0	0
in 1681	2	2W.
in 1759	18	10W.
in 1760	18	20W.

M. De la Lande (Expoſition du Calcul Aſtronomique) obſerves, that the Variation has changed, at Paris, 26° 20′ in the ſpace of 150 years, allowing that in 1610 the Variation was 8° E: and ſince 1740 the needle, which was always uſed by Maraldi, is more than 3° advanced toward the weſt, beyond what it was at that period; which is a change after the rate nearly of 9′½ per year.

At Cape d'Agulhas, in 1600, it had no Variation; (whence the Portugueſe gave it that name);

in 1622 it was	2°W.	
in 1675	8	W.
in 1692	11	W.

which is a change of nearly 8′ per year.

At St. Helena, the Variation,

in 1600 was	8°	0′	E.
in 1623	6	0	E.
in 1677	0	40	E.
in 1692	1	0	W.

which is a change of nearly 5′½ per year.

At Cape Comorin, the Variation,

in 1620 was	14°	20′	W.
in 1680	8	44	W.
in 1688	7	30	W.

which is a change of nearly 6′½ per year.

At London, the Variation,

in 1580 was	11°	15′	E.
in 1622	6	0	E.
in 1634	4	5	E.
in 1657	0	0	
in 1672	2	30	W.
in 1692	6	0	W.
in 1723	14	17	W.
in 1747	17	40	W.
in 1780	22	41	W.

which is a change after the rate of 10′ per year, upon a courſe of exactly 200 years. See Philoſ. Tranſ. No. 148 and No. 383, or Abr. vol. 2, p. 615, and vol. 7, p. 290; and Philoſ. Tranſ. vol. 45, p. 280, and vol. 66, p. 393. On the ſubject of the Variation, ſee alſo Norman's New Attractive 1614; Burrows's Diſcovery of the Variation 1581; Bond's Longitude found, 1676; &c.

Mr. Thomas Harding, in the Tranſactions of the Royal Iriſh Academy, vol. 4, has given obſervations on the Variation of the magnetic needle, at Dublin, which are rather extraordinary. He ſays the change in the Variation at that place is *uniform*. That from the year 1657, in which the Variation was nothing (the ſame as at London in that year), it has been going on at the medium rate of 12′ 20″ annually, and was in May 1791, 27° 23′ weſt: exceeding that at London now by 3 or 4 degrees. He brings proof of his aſſertion of the uniformity of the Variation, from different authentic records, and ſtates the operations by which it is calculated. He concludes with recommending accuracy in marking the exiſting Variation when maps are made, as not only conducing to the exact definition of boundaries, but as laying the beſt foundation for a diſcovery of the longitude by ſea or land.

Theory of the Variation of the Variation. According to Dr. Halley's theory, this change in the Variation of the compaſs, is ſuppoſed owing to the difference of velocity in the motions of the internal and external parts of the globe. From the obſervations that have been cited, it ſeems to follow, that all the magnetical poles have a motion weſtward, but yet not exactly round the axis of the earth, for then the Variations would continue the ſame in the ſame parallel of latitude, contrary to experience.

From the diſagreement of ſuch a ſuppoſition with experiments therefore, the learned author of the theory invented the following hypotheſis: The external parts of the globe he conſiders as the ſhell, and the internal as a nucleus, or inner globe; and between the two he conceives a fluid medium. That inner earth having the ſame common centre and axis of diurnal rotation, may revolve with our earth every 24 hours: Only the outer ſphere having its turbinating motion ſomewhat ſwifter or ſlower than the internal ball; and a very minute difference in length of time, by many repetitions, becoming ſenſible; the internal parts will gradually recede from the external, and they will appear to move, either eaſtward or weſtward, by the difference of their motions.

Now, ſuppoſing ſuch an internal ſphere, having ſuch a motion, the two great difficulties in the former hypotheſis are eaſily ſolved; for if this exterior ſhell of earth be a magnet, having its pole at a diſtance from the poles of diurnal rotation; and if the internal nucleus be likewiſe a magnet, having its poles in two other places, diſtant alſo from the axis; and theſe latter, by a ſlow gradual motion, change their place in reſpect of the external, a reaſonable account may then be given of the four magnetical poles before mentioned, and alſo of the changes of the needle's Variation.

The author thinks that two of theſe poles are fixed, and the other two moveable; viz, that the fixed poles are the poles of the external cortex or ſhell of the earth;

earth; and the other the poles of the magnetical nucleus, included and moveable within the former. From the obſervations he infers, that the motion is weſtwards, and conſequently that the nucleus has not preciſely attained the ſame velocity with the exterior parts in their diurnal rotation; but ſo very nearly equals it, that in 365 revolutions the difference is ſcarcely ſenſible.

That there is any difference of this kind, ariſes from hence, that the impulſe by which the diurnal motion was impreſſed on the earth, was given to the external parts, and from thence in time communicated to the internal; but ſo as not yet perfectly to equal the velocity of the firſt motion impreſſed on the ſuperficial parts of the globe, and ſtill preſerved by them.

As to the preciſe period, obſervations are wanting to determine it, though the author thinks we may reaſonably conjecture that the American pole has moved weſtward 46° in 90 years, and that its whole period is performed in about 700 years.

Mr. Whiſton, in his New Laws of Magnetiſm, raiſes ſeveral objections againſt this theory. See MAGNETISM.

M. Euler, too, the ſon of the celebrated mathematician of that name, has controverted and cenſured Dr. Halley's theory. He thinks, that two magnetic poles, placed on the ſurface of the earth, will ſufficiently account for the Variation: and he then endeavours to ſhew, how we may determine the declination of the needle, at any time, and on every part of the globe, from this hypotheſis. For the particulars of this reaſoning, ſee the Hiſtoire de l'Academie des Sciences & Belles Lettres of Berlin, for 1757; alſo Mr. Cavallo's Treatiſe on Magnetiſm, p. 117.

Variation of the Needle by Heat and Cold.—There is a ſmall Variation of the Variation of the magnetic needle, amounting only to a few minutes of a degree in the ſame place, at different hours of the ſame day, which is only diſcoverable by nice obſervations. Mr. George Graham made ſeveral obſervations of this kind in the years 1722 and 1723, profeſſing himſelf altogether ignorant of the cauſe of the phenomena he obſerved. Philoſ. Tranſ. No. 383, or Abr. vol. 7, p. 290.

About the year 1750, Mr. Wargentin, ſecretary of the Swediſh Academy of Sciences, took notice both of the regular diurnal Variation of the needle, and alſo of its being diſturbed at the time of the aurora borealis, as recorded in the Philoſ. Tranſ. vol. 47, p. 126.

About the year 1756, Mr. Canton commenced a ſeries of obſervations, amounting to near 4000, with an excellent Variation-compaſs, of about 9 inches diameter. The number of days on which theſe obſervations were made, was 603, and the Diurnal Variation on 574 of them was regular, ſo as that the abſolute Variation of the needle weſtward was increaſing from about 8 or 9 o'clock in the morning, till about 1 or 2 in the afternoon, when the needle became ſtationary for ſome time; after that, the abſolute Variation weſtward was decreaſing, and the needle came back again to its former ſituation, or nearly ſo, in the night, or by the next morning. The Diurnal Variation is irregular when the needle moves ſlowly eaſtward in the latter part of the morning, or weſtward in the latter part of the afternoon; alſo when it moves much either way after night, or ſuddenly both ways in a ſhort time. Theſe irregularities ſeldom happen more than once or twice in a month, and are always accompanied, as far as Mr. Canton obſerved, with an aurora borealis.

Mr. Canton lays down and evinces, by experiment, the following principle, viz, that the attractive power of the magnet (whether natural or artificial) will decreaſe while the magnet is heating, and increaſe while it is cooling. He then proceeds to account for both the regular and irregular Variation. It is evident, he ſays, that the magnetic parts of the earth in the north, on the eaſt ſide, and on the weſt ſide of the magnetic meridian, equally attract the north end of the needle. If then the eaſtern magnetic parts be heated faſter by the ſun in the morning, than the weſtern parts, the needle will move weſtward, and the abſolute Variation will increaſe: when the attracting parts of the earth on each ſide of the magnetic meridian have their heat increaſing equally, the needle will be ſtationary, and the abſolute Variation will then be greateſt; but when the weſtern magnetic parts are either heating faſter, or cooling ſlower, than the eaſtern, the needle will move eaſtward, or the abſolute Variation will decreaſe; and when the eaſtern and weſtern magnetic parts are cooling equally faſt, the needle will again be ſtationary, and the abſolute Variation will then be leaſt.

By this theory, the Diurnal Variation in the ſummer ought to exceed that in winter; and accordingly it is found by obſervation, that the Diurnal Variation in the months of June and July is almoſt double of that in December and January.

The irregular Diurnal Variation muſt ariſe from ſome other cauſe than that of heat communicated by the ſun; and here Mr. Canton has recourſe to ſubterranean heat, which is generated without any regularity as to time, and which will, when it happens in the north, affect the attractive power of the magnetic parts of the earth on the north end of the needle. That the air neareſt the earth will be moſt warmed by the heat of it, is obvious; and this has been often noticed in the morning, before day, by means of thermometers at different diſtances from the ground. Philoſ. Tranſ. vol. 48, pa. 526.

Mr. Canton has annexed to his paper on this ſubject, a complete year's obſervations; from which it appears, that the Diurnal Variation increaſes from January to June, and decreaſes from June to December. Philoſ. Tranſ. vol. 51, pa. 398.

It has alſo been obſerved, that different needles, eſpecially if touched with different loadſtones, will differ a few minutes in their Variation. See Poleni Epiſt. Phil. Tranſ. num. 421.

Dr. Lorimer (in the Supp. to Cavallo's Magnetiſm) adduces ſome ingenious obſervations on this ſubject. It muſt be allowed, ſays he, according to the obſervations of ſeveral ingenious gentlemen, that the collective magnetiſm of this earth ariſes from the magnetiſm of all the ferruginous bodies contained in it, and that the magnetic poles ſhould therefore be conſidered as the centres of the powers of thoſe magnetic ſubſtances. Theſe poles muſt therefore change their places according as the magnetiſm of ſuch ſubſtances is affected; and if with

with Mr. Canton we allow, that the general cauſe of the Diurnal Variation ariſes from the ſun's heat in the forenoon and afternoon of the ſame day, it will naturally occur, that the ſame cauſe, being continued, may be ſufficient to produce the general Variation of the magnetic needle for any number of years. For we muſt conſider, that ever ſince any attentive obſervations have been made on this ſubject, the natural direction of the magnetic needle in Europe has been conſtantly moving, from weſt to eaſt, and that in other parts of the world it has continued its motion with equal conſtancy.

As we muſt therefore admit, ſays Dr. Lorimer, that the heat in the different ſeaſons depends chiefly on the ſun, and that the months of July and Auguſt are commonly the hotteſt, while January and February are the coldeſt months of the year; and that the temperature of the other months falls into the reſpective intermediate degrees; ſo we muſt conſider the influence of heat upon magnetiſm to operate in the like manner, viz, that for a ſhort time it ſcarcely manifeſts itſelf; yet in the courſe of a century, the conſtancy and regularity of it becomes ſufficiently apparent. It would therefore be idle to ſuppoſe, that ſuch an influence could be derived from an uncertain or fortuitous cauſe. But if it be allowed to depend upon the conſtancy of the ſun's motion, and this appears to be a cauſe ſufficient to explain the phenomena, we ſhould (agreeably to Newton's firſt law of philoſophizing) look no farther.

As we therefore conſider, ſays he, the magnetic powers of the earth to be concentrated in the magnetic poles, and that there is a diurnal Variation of the magnetic needle, theſe poles muſt perform a ſmall diurnal revolution proportional to ſuch Variation, and return again to the ſame point nearly. Suppoſe then that the ſun in his diurnal revolution paſſes along the northern tropic, or along any parallel of latitude between it and the equator, when he comes to that meridian in which the magnetic pole is ſituated, he will be much nearer to it, than in any other; and in the oppoſite meridian he will of courſe be the fartheſt from it. As the influence of the ſun's heat will therefore act moſt powerfully at the leaſt, and leſs forcibly at the greateſt diſtance, the magnetic pole will conſequently deſcribe a figure ſomething of the elliptical kind; and as it is well known that the greateſt heat of the day is ſome time after the ſun has paſſed the meridian, the longeſt axis of this elliptical figure will lie north-eaſterly in the northern, and ſouth-eaſterly in the ſouthern hemiſphere. Again, as the influence of the ſun's heat will not from thoſe quarters have ſo much power, the magnetic poles cannot be moved back to the very ſame point, from which they ſet out; but to one which will be a little more northerly and eaſterly, or more ſoutherly and eaſterly, according to the hemiſpheres in which they are ſituated. The figures therefore which they deſcribe, may more properly be termed elliptoidal ſpirals.

In this manner the Variation of the magnetic needle in the northern hemiſphere may be accounted for. But with reſpect to the ſouthern hemiſphere we muſt recollect, that though the lines of declination in the northern hemiſphere have conſtantly moved from weſt to eaſt, yet in the ſouthern hemiſphere, it is equally certain that they have moved from eaſt to weſt, ever ſince any obſervations have been made on the ſubject. Hence then the lines of magnetic declination, or Halleyan curves, as they are now commonly called, appear to have a contrary motion in the ſouthern hemiſphere, to what they have in the northern; though both the magnetic poles of the earth move in the ſame direction, that is from weſt to eaſt.

In the northern hemiſphere there was a line of no Variation, which had eaſt Variation on its eaſtern ſide, and weſt Variation on its weſtern ſide. This line evidently moved from weſt to eaſt during the two laſt centuries; the lines of eaſt Variation moving before it, while the lines of weſt Variation followed it with a proportional pace. Theſe lines firſt paſſed the Azores or Weſtern Iſlands, then the meridian of London, and after a certain number of years ſtill later, they paſſed the meridian of Paris. But in the ſouthern hemiſphere there was another line of no Variation, which had eaſt Variation on its weſtern ſide, and weſt Variation on its eaſtern; the lines of eaſt Variation moving before it, while thoſe of the weſt Variation followed it. This line of no Variation firſt paſſed the Cape des Aiguilles, and then the Cape of Good Hope; the lines of 5°, 10°, 15°, and 20° weſt Variation following it, the ſame as was the caſe in the northern hemiſphere, but in the contrary direction.

We may juſt farther mention the idea of Dr. Gowin Knight, which was, that this earth had originally received its magnetiſm, or rather that its magnetical powers had been brought into action, by a ſhock, which entered near the ſouthern tropic, and paſſed out at the northern one. His meaning appears to have been, that this was the courſe of the magnetic fluid, and that the magnetic poles were at firſt diametrically oppoſite to each other. Though, according to Mr. Canton's doctrine, they would not have long continued ſo; for from the intenſe heat of the ſun in the torrid zone, according to the principles already explained, the north pole muſt have ſoon retired to the north-eaſtward, and the ſouth pole to the ſouth-eaſtward. It is alſo curious to obſerve, that on account of the ſouthern hemiſphere being colder upon the whole than the northern hemiſphere, the magnetic poles would have moved with unequal pace: that is, the north magnetic pole would have moved farther in any given time to the north-eaſt, than the ſouth magnetic pole could have moved to the ſouth-eaſt. And, according to the opinions of the moſt ingenious authors on this ſubject, it is generally allowed, that at this time the north magnetic pole is conſiderably nearer to the north pole of the earth, than the ſouth magnetic pole is to the ſouth pole of the earth.

It may farther be added, that ſeveral ingenious ſea officers are of opinion, that in the weſtern parts of the Engliſh Channel the Variation of the magnetic needle has already begun to decreaſe; having in no part of it ever amounted to 25°. There are however other perſons who aſſert that the Variation is ſtill increaſing in the Channel, and as far weſtward as the 15th degree of longitude and 51° of latitude, at which place they ſay that it amounts to about 30°.

Of the Variation Chart. Doctor Halley having collected a multitude of obſervations made on the Variation of the needle in many parts of the world, was hence enabled to draw, on a Mercator's chart, certain lines, ſhewing the Variation of the compaſs in all thoſe places

places over which they paſſed, in the year 1700, when he publiſhed the firſt chart of this kind, called the *Variation Chart*.

From the conſtruction of this chart it appears, that the longitude of any of thoſe places may be found by it, when the latitude and the Variation in that place are known. Thus, having found the Variation of the compaſs, draw a parallel of latitude on the chart through the latitude found by obſervation; and the point where it cuts the curved line, whoſe Variation is the ſame with that obſerved, will be the ſhip's place. A ſimilar project of thus finding the longitude, from the known latitude and inclination or dip of the needle, was before propoſed by Henry Bond, in his treatiſe intitled, The Longitude Found, printed in 1676.

This method however is attended with two conſiderable inconveniences: 1ſt, That wherever the Variation lines run eaſt and weſt, or nearly ſo, this way of finding the longitude becomes imperfect, as their interſection with the parallel of latitude muſt be very indefinite: and among all the trading parts of the world, this imperfection is at preſent found chiefly on the weſtern coaſts of Europe, between the latitudes of 45° and 53°; and on the eaſtern ſhores of North America, with ſome parts of the Weſtern Ocean and Hudſon's Bay, lying between the ſaid ſhores: but for the other parts of the world, a Variation Chart may be attended with conſiderable benefit. However, the Variation curves, when they run eaſt and weſt, may ſometimes be applied to good purpoſe in correcting the latitude, when meridian obſervations cannot be had, as it often happens on the northern coaſts of America, in the Weſtern Ocean, and about Newfoundland; for if the Variation can be obtained exactly, then the eaſt and weſt curve, anſwering to the Variation in the chart, will ſhew the latitude.

2dly, As the deviation of the magnetical meridian, from the true one, is ſubject to continual alteration, therefore a chart to which the Variation lines are fitted for any year, muſt in time become uſeleſs, unleſs new lines, ſhewing the ſtate of the Variation at that time, be drawn on the chart: but as the change in the Variation is very ſlow, therefore new Variation Charts publiſhed every 7 or 8 years, will anſwer the purpoſe tolerably well. And thus it has happened that Halley's Variation Chart has become uſeleſs, for want of encouragement to renew it from time to time.

However, in the year 1744, Mr. William Mountaine and Mr. James Dodſon publiſhed a new Variation Chart, adapted for that year, which was well received; and ſeveral inſtances of its great utility having been communicated to them, they fitted the Variation lines anew for the year 1756, and in the following year publiſhed the 3d Variation Chart, and alſo preſented to the Royal Society a curious paper concerning the Variation of the magnetic needle, with a ſet of tables annexed, containing the reſult of upwards of 50 thouſand obſervations, in ſix periodical reviews, from the year 1700 to 1756 inclusive, and adapted to every 5 degrees of latitude and longitude in the more frequented oceans; which paper and tables were printed in the Tranſactions for the year 1757.

From theſe tables of obſervations, ſuch extraordinary and whimſical irregularities occur in the Variation, that we cannot think it wholly under the direction of one general and uniform law; but rather conclude, with Dr. Gowen, in the 87th prop. of his Treatiſe upon Attraction and Repulſion, that it is influenced by various and different magnetic attractions, perhaps occaſioned by the heterogeneous compoſitions in the great magnet, the earth.

Many other obſervations on the Variation of the magnetic needle, are to be found in ſeveral volumes of the Philoſ. Tranſ. See particularly vol. 48, p. 875; vol. 50, p. 329; vol. 56, p. 220; and vol. 61, p. 422.

VARIATION *Compaſs*. See COMPASS.

VARIATION *of Curvature*, in Geometry, is uſed for that inequality or change which takes place in the curvature of all curves except the circle, by which their curvature is more or leſs in different parts of them. And this Variation conſtitutes the quality of the curvature of any line.

Newton makes the index of the inequality, or Variation of Curvature, to be the ratio of the fluxion of the radius of curvature to the fluxion of the curve itſelf: and Maclaurin, to avoid the perplexity that different notions, connected with the ſame terms, occaſion to learners, has adopted the ſame definition: but he ſuggeſts, that this ratio gives rather the Variation of the ray of curvature, and that it might have been proper to have meaſured the Variation of Curvature rather by the ratio of the fluxion of the curvature itſelf to the fluxion of the curve; ſo that, the curvature being inverſely as the radius of curvature, and conſequently its fluxion as the fluxion of the radius itſelf directly, and the ſquare of the radius inverſely, its Variation would have been directly as the meaſure of it according to Newton's definition, and inverſely as the ſquare of the radius of curvature.

According to this notion, it would have been meaſured by the angle of contact contained by the curve and circle of curvature, in the ſame manner as the curvature itſelf is meaſured by the angle of contact contained by the curve and tangent. The reaſon of this remark may appear from this example: The Variation of curvature, according to Newton's explication, is uniform in the logarithmic ſpiral, the fluxion of the radius of curvature in this figure being always in the ſame ratio to the fluxion of the curve; and yet, while the ſpiral is produced, though its curvature decreaſes, it never vaniſhes; which muſt appear a ſtrange paradox to thoſe who do not attend to the import of Newton's definition. Newton's Method of Fluxions and Inf. Series, pa. 76. Maclaurin's Flux. art. 386. Philoſ. Tranſ. num. 468, pa. 342.

The Variation of curvature at any point of a conic ſection, is always as the tangent of the angle contained by the diameter that paſſes through the point of contact, and the perpendicular to the curve at the ſame point, or to the angle formed by the diameter of the ſection, and of the circle of curvature. Hence the Variation of curvature vaniſhes at the extremities of either axis, and is greateſt when the acute angle, contained by the diameter, paſſing through the point of contact and the tangent, is leaſt.

When the conic ſection is a parabola, the Variation is

as the tangent of the angle, contained by the right line drawn from the point of contact to the focus, and the perpendicular to the curve. See CURVATURE.

From Newton's definition may be derived practical rules for the Variation of curvature, as follows:

1. Find the radius of curvature, or rather its fluxion; then divide this fluxion by the fluxion of the curve, and the quotient will give the Variation of curvature; exterminating the fluxions when neceſſary, by the equation of the curve, or perhaps by expreſſing their ratio by help of the tangent, or ordinate, or ſubnormal, &c.

2. Since $\frac{\dot{z}^3}{-\dot{x}\ddot{y}}$, or $\frac{\dot{z}^3}{-\ddot{y}}$ (putting $\dot{x} = 1$) denotes the radius of curvature of any curve z, whoſe abſciſs is x, and ordinate y; if the fluxion of this be divided by $\dot{z}$, and $\dot{z}$ and $\ddot{z}$ be exterminated, the general value of the Variation will come out $\frac{-3\dot{y}\ddot{y}^2 + \dddot{y}(1+\dot{y}^2)}{\dot{y}^2}$; then ſubſtituting the values of $\dot{y}$, $\ddot{y}$, $\dddot{y}$ (found from the equation of the curve) into this quantity, it will give the Variation ſought.

Ex. Let the curve be the parabola, whoſe equation is $ax = y^2$. Here then $2y\dot{y} = a\dot{x} = a$, and $\dot{y} = \frac{a}{2y}$; hence $\ddot{y} = \frac{-a\dot{y}}{2y\dot{y}} = \frac{-aa}{4y^3}$, and $\dddot{y} = \frac{-3aa\dot{y}}{2y^4} = \frac{3a^3}{8y^5}$. Therefore $\frac{-3\dot{y}\ddot{y}^2 + \dddot{y}(1+\dot{y}^2)}{\dot{y}^2} = -3\dot{y} + \dddot{y} \times \frac{1+\dot{y}^2}{\dot{y}^2} = \frac{-3a}{2y} + \frac{3a^3}{8y^5} \times \left(1 + \frac{aa}{4yy}\right) \times \frac{16y^6}{a^4} = \frac{6y}{a}$, the Variation ſought. Emerſon's Flux. pa. 228.

VARIGNON (PETER), a celebrated French mathematician and prieſt, was born at Caen in 1654, and died ſuddenly in 1722, at 68 years of age. He was the ſon of an architect in middling circumſtances, but had a college education, being intended for the church. An accident threw a copy of Euclid's Elements in his way, which gave him a ſtrong turn to that kind of learning. The ſtudy of geometry led him to the works of Des Cartes on the ſame ſcience, and there he was ſtruck with that new light which has, from thence, ſpread over the world.

He abridged himſelf of the neceſſaries of life to purchaſe books of this kind, or rather conſidered them of that number, as indeed they ought to be. What contributed to heighten this paſſion in him was, that he ſtudied in private; for his relations obſerving that the books he ſtudied were not ſuch as were commonly uſed by others, ſtrongly oppoſed his application to them. As there was a neceſſity for his being an eccleſiaſtic, he continued his theological ſtudies, yet not entirely ſacrificing his favourite ſubject to them.

At this time the Abbé St. Pierre, who ſtudied philoſophy in the ſame college, became acquainted with him. A taſte in common for rational ſubjects, whether phyſics or metaphyſics, and continual diſputations, formed the bonds of their friendſhip. They were mutually ſerviceable to each other in their ſtudies. The Abbé, to enjoy Varignon's company with greater eaſe, lodged him with himſelf; thus, growing ſtill more ſenſible of his merit, he reſolved to give him a fortune, that he might fully purſue his genius, and improve his talents; and, out of only 18 hundred livres a year, which he had himſelf, he conferred 300 of them upon Varignon.

The Abbé, perſuaded that he could not do better than go to Paris to ſtudy philoſophy, ſettled there in 1686, with M. Varignon, in the ſuburbs of St. Jacques. There each ſtudied in his own way; the Abbé applying himſelf to the ſtudy of men, manners, and the principles of government; whilſt Varignon was wholly occupied with the mathematics.

I, ſays Fontenelle, who was their countryman, often went to ſee them, ſometimes ſpending two or three days with them. They had alſo room for a couple of viſitors, who came from the ſame province. We joined together with the greateſt pleaſure. We were young, full of the firſt ardour for knowledge, ſtrongly united, and, what we were not then perhaps diſpoſed to think ſo great a happineſs, little known. Varignon, who had a ſtrong conſtitution, at leaſt in his youth, ſpent whole days in ſtudy, without any amuſement or recreation, except walking ſometimes in fine weather. I have heard him ſay, that in ſtudying after ſupper, as he uſually did, he was often ſurpriſed to hear the clock ſtrike two in the morning; and was much pleaſed that four hours reſt were ſufficient to refreſh him. He did not leave his ſtudies with that heavineſs which they uſually create; nor with that wearineſs that a long application might occaſion. He left off gay and lively, filled with pleaſure, and impatient to renew it. In ſpeaking of mathematics, he would laugh ſo freely, that it ſeemed as if he had ſtudied for diverſion. No condition was ſo much to be envied as his; his life was a continual enjoyment, delighting in quietneſs.

In the ſolitary ſuburb of St. Jacques, he formed however a connection with many other learned men; as Du Hamel, Du Verney, De la Hire, &c. Du Verney often aſked his aſſiſtance in thoſe parts of anatomy connected with mechanics: they examined together the poſitions of the muſcles, and their directions; hence Varignon learned a good deal of anatomy from Du Verney, which he repaid by the application of mathematical reaſoning to that ſubject.

At length, in 1687, Varignon made himſelf known to the public by a Treatiſe on New Mechanics, dedicated to the Academy of Sciences. His thoughts on this ſubject were, in effect, quite new. He diſcovered truths, and laid open their ſources. In this work, he demonſtrated the neceſſity of an equilibrium, in ſuch caſes as it happens in, though the cauſe of it is not exactly known. This diſcovery Varignon made by the theory of compound motions, and is what this eſſay turns upon.

This new Treatiſe on Mechanics was greatly admired by the mathematicians, and procured the author two conſiderable places, the one of Geometrician in the Academy of Sciences, the other of Profeſſor of Mathematics in the College of Mazarine, to which he was the firſt perſon raiſed.

Varignon catched eagerly at the Science of Infinitesimals as ſoon as it appeared in the world, and became one of its moſt early cultivators. When that ſublime and beautiful method was attacked in the Academy itſelf

ſelf (for it could not eſcape the fate of all innovations) he became one of its moſt zealous defenders, and in its favour he put a violence upon his natural character, which abhorred all contention. He ſometimes lamented, that this diſpute had interrupted him in his enquiries into the Integral Calculation ſo far, that it would be difficult for him to reſume his diſquiſition where he had left it off. He ſacrificed Infiniteſimals to the intereſt of Infiniteſimals, and gave up the pleaſure and glory of making a farther progreſs in them when called upon by duty to undertake their defence.

All the printed volumes of the Academy bear witneſs to his application and induſtry. His works are never detached pieces, but complete theories of the laws of motion, central forces, and the reſiſtance of mediums to motion. In theſe he makes ſuch uſe of his rules, that nothing eſcapes him that has any connection with the ſubject he treats.

Geometrical certainty is by no means incompatible with obſcurity and confuſion, and thoſe are ſometimes ſo great, that it is ſurpriſing a mathematician ſhould not miſs his way in ſo dark and perplexing a labyrinth. The works of M. Varignon never occaſion this diſagreeable ſurpriſe, he makes it his chief care to place every thing in the cleareſt light; he does not, as ſome great men do, conſult his eaſe by declining to take the trouble of being methodical, a trouble much greater than that of compoſition itſelf; he does not endeavour to acquire a reputation for profoundneſs, by leaving a great deal to be gueſſed by the reader.

He was perfectly acquainted with the hiſtory of mathematics. He learned it not merely out of curioſity, but becauſe he was deſirous of acquiring knowledge from every quarter. This hiſtorical knowledge is doubtleſs an ornament in a mathematician, but it is an ornament which is by no means without its utility. Indeed it may be laid down as a maxim, the more different ways the mind is occupied in, upon a ſubject, the more it improves.

Though Varignon's conſtitution did not ſeem eaſy to be impaired, aſſiduity and conſtant application brought upon him a ſevere diſeaſe in 1705. Great abilities are generally dangerous to the poſſeſſors. He was ſix months in danger, and three years in a languid ſtate, which proceeded from his ſpirits being almoſt entirely exhauſted. He ſaid that ſometimes when delirious with a fever, he thought himſelf in the midſt of a foreſt, where all the leaves of the trees were covered with algebraical calculations. Condemned by his phyſicians, his friends, and himſelf, to lay aſide all ſtudy, he could not, when alone in his chamber, avoid taking up a book of mathematics, which he hid as ſoon as he heard any perſon coming. He again reſumed the attitude and behaviour of a ſick man, and ſeldom had occaſion to counterfeit.

In regard to his character, Fontenelle obſerves, that it was at this time that a writing of his appeared, in which he cenſured Dr. Wallis for having advanced that there are certain ſpaces more than infinite, which that great geometrician aſcribes to hyperbolas. He maintained, on the contrary, that they were finite. The criticiſm was ſoftened with all the politeneſs and reſpect imaginable; but a criticiſm it was, though he had written it only for himſelf. He let M. Carré ſee it, when he was in a ſtate that rendered him indifferent about things of that kind; and that gentleman, influenced only by the intereſt of the ſciences, cauſed it to be printed in the memoirs of the Academy of Sciences, unknown to the author, who thus made an attack againſt his inclination.

He recovered from his diſeaſe; but the remembrance of what he had ſuffered did not make him more prudent for the future. The whole impreſſion of his *Projet for a New Syſtem of Mechanics*, having been ſold off, he formed a deſign to publiſh a ſecond edition of it, or rather a work entirely new, though upon the ſame plan, but more extended. It muſt be eaſy to perceive how much learning he muſt have acquired in the interval; but he often complained, that he wanted time, though he was by no means diſpoſed to loſe any. Frequent viſits, either of French or of foreigners, ſome of whom went to ſee him that they might have it to ſay that they had ſeen him; and others to conſult him and improve by his converſation: works of mathematics, which the authority of ſome, or the friendſhip he had for others, engaged him to examine, and which he thought himſelf obliged to give the moſt exact account of; a literary correſpondence with all the chief mathematicians of Europe; all theſe obſtructed the book he had undertaken to write. Thus a man acquires reputation by having a great deal of leiſure time, and he loſes this precious leiſure as ſoon as he has acquired reputation. Add to this, that his beſt ſcholars, whether in the College of Mazarine or the Royal College (for he had a profeſſor's chair in both), ſometimes requeſted private lectures of him, which he could not refuſe. He ſighed for his two or three months of vacation, for that was all the leiſure time he had in the year; no ſooner were they come but he retired into the country, where his time was entirely his own, and the days ſeemed always quickly ended.

Notwithſtanding his great deſire of peace, in the latter part of his life he was involved in a diſpute. An Italian monk, well verſed in mathematics, attacked him upon the ſubject of tangents and the angle of contact in curves, ſuch as they are conceived in the arithmetic of infinites; he anſwered by the laſt memoir he ever gave to the Academy, and the only one which turned upon a diſpute.

In the laſt two years of his life he was attacked with an aſthmatic complaint. This diſorder increaſed every day, and all remedies were ineffectual. He did not however ceaſe from any of his cuſtomary buſineſs; ſo that, after having finiſhed his lecture at the College of Mazarine, on the 22d of December 1722, he died ſuddenly the following night.

His character, ſays Fontenelle, was as ſimple as his ſuperior underſtanding could require. He was not apt to be jealous of the fame of others: indeed he was at the head of the French mathematicians, and one of the beſt in Europe. It muſt be owned however, that when a new idea was offered to him, he was too haſty to object. The fire of his genius, the various inſights into every ſubject, made too impetuous an oppoſition to thoſe that were offered; ſo that it was not eaſy to obtain from him a favourable attention.

His works that were publiſhed ſeparately, were,

1. Projet d'une Nouvelle Mechanique; 4to, Paris 1687.

2. Des Nouvelles Conjectures ſur la Peſanteur.

3. Nouvelle Mechanique ou Statique, 2 tom. 4to, 1725.

As to his memoirs in the volumes of the Academy of Sciences, they are far too numerous to be here particularized; they extend through almoſt all the volumes, down to his death in 1722.

VASA *Concordiæ*, in Hydraulics, are two veſſels, ſo-conſtructed, as that one of them, though full of wine, will not run a drop, unleſs the other, being full of water, do run alſo. Their ſtructure and apparatus may be ſeen in Wolfius, Element. Mathef. tom. 3, Hydraul.

VAULT, in Architecture, an arched roof, ſo contrived, as that the ſeveral ſtones of which it conſiſts, by their diſpoſition into the form of a curve, mutually ſuſtain each other; as the arches of bridges, &c.

Vaults are to be preferred, on many occaſions, to ſoffits, or flat ceilings, as they give a greater riſe and elevation, and are alſo more firm and durable.

The Ancients, Salmaſius obſerves, had only three kinds of vaults: the firſt the *fornix*, made cradlewiſe; the 2d, the *teſtudo*, tortoiſe-wiſe, or oven-wiſe; the 3d, the *concha*, made ſhell-wiſe.

But the Moderns ſubdivide theſe three ſorts into a great many more, to which they give different names, according to their figures and uſe: ſome are circular, others elliptical, &c.

Again, the ſweeps of ſome are larger, and others leſs portions of a ſphere: all above hemiſpheres are called *high*, or *ſurmounted Vaults*; all that are leſs than hemiſpheres, are *low*, or *ſurbaſed Vaults*, &c.

In ſome the height is greater than the diameter; in others it is leſs: there are others again quite flat, only made with haunſes; others oven-like, and others growing wider as they lengthen, like a trumpet.

Of Vaults, ſome are *ſingle*, others *double*, *croſs*, *diagonal*, *horizontal*, *aſcending*, *deſcending*, *angular*, *oblique*, *pendent*, &c, &c. There are alſo *Gothic* Vaults, with *pendentives*, &c.

Maſter VAULTS, are thoſe which cover the principal parts of buildings; in contradiſtinction from the *leſs*, or ſubordinate Vaults, which only cover ſome ſmall part; as a paſſage, a gate, &c.

Double VAULT, is ſuch a one as, being built over another, to make the exterior decoration range with the interior, leaves a ſpace between the convexity of the one, and the concavity of the other: as in the dome of St. Paul's at London, and that of St. Peter's at Rome.

VAULTS *with Compartiments*, are ſuch whoſe ſweep, or inner face, is enriched with pannels of ſculpture, ſeparated by platbands. Theſe compartiments, which are of different figures, according to the Vaults, and are uſually gilt on a white ground, are made with ſtucco, on brick Vaults; as in the church of St. Peter's at Rome; and with plaſter, on timber Vaults.

Theory of VAULTS.—In a ſemicircular Vault, or arch, being a hollow cylinder cut by a plane through its axis, ſtanding on two impoſts, and all the ſtones that compoſe it, being cut and placed in ſuch a manner, as that their joints, or beds, being prolonged, do all meet in the centre of the vault; it is evident that all the ſtones muſt be cut wedge-wiſe, or wider at top and above, than below; by virtue of which, they ſuſtain each other, and mutually oppoſe the effort of their weight, which determines them to fall.

The ſtone in the middle of the Vault, which is perpendicular to the horizon, and is called the *key of the Vault*, is ſuſtained on each ſide by the two contiguous ſtones, as by two inclined planes.

The ſecond ſtone, which is on the right or left of the key-ſtone, is ſuſtained by a third; which, by virtue of the figure of the Vault, is neceſſarily more inclined to the ſecond, than the ſecond is to the firſt; and conſequently the ſecond, in the effort it makes to fall, employs a leſs part of its weight than the firſt.

For the ſame reaſon, all the ſtones, reckoning from the key-ſtone, employ ſtill a leſs and leſs part of their weight to the laſt; which, reſting on the horizontal plane, employs no part of its weight, or makes no effort to fall, as being entirely ſupported by the impoſt.

Now a great point to be aimed at in Vaults, is, that all the ſeveral ſtones make an equal effort to fall: to effect this, it is evident that as each ſtone, reckoning from the key to the impoſt, employs a ſtill leſs and leſs part of its whole weight; the firſt only employing, for example, one-half; the 2d, one-third; the 3d, one-fourth; &c; there is no other way to make theſe different parts equal, but by a proportionable augmentation of the whole; that is, the ſecond ſtone muſt be heavier than the firſt, the third heavier than the ſecond, and ſo on to the laſt, which ſhould be vaſtly heavier.

La Hire demonſtrates what that proportion is, in which the weights of the ſtones of a ſemicircular arch muſt be increaſed, to be in equilibrio, or to tend with equal forces to fall; which gives the firmeſt diſpoſition that a vault can have. Before him, the architects had no certain rule to conduct themſelves by; but did all at random. Reckoning the degrees of the quadrant of the circle, from the key-ſtone to the impoſt; the length or weight of each ſtone muſt be ſo much greater, as it is farther from the key. La Hire's rule is, to augment the weight of each ſtone above that of the key ſtone, as much as the tangent of the arch to the ſtone exceeds the tangent of the arch of half the key. Now the tangent of the laſt ſtone becomes infinite, and conſequently the weight ſhould be ſo too; but as infinity has no place in practice, the rule amounts to this, that the laſt ſtone be loaded as much as poſſible, and the others in proportion, that they may the better reſiſt the effort which the Vault makes to ſeparate them; which is called the *ſhoot* or *drift* of the Vault.

M. Parent, and other authors, have ſince determined the curve, or figure, which the extrados or outſide of a Vault, whoſe intrados or inſide is ſpherical, ought to have, that all the ſtones may be in equilibrio.

The above rule of La Hire's has ſince been found not accurate. See ARCH, and BRIDGE. See alſo my Treatiſe on the Principles of Bridges, and Emerſon's Conſtruction of Arches.

Key of a VAULT. See KEY, and VOUSSOIR.

Reins or *fillings up of a* VAULT, are the ſides which ſuſtain it.

Pendentive of a VAULT. See PENDENTIVE.

Impoſt of a VAULT, is the ſtone upon which is laid the firſt vouſſoir, or arch-ſtone of the Vault.

VEADAR,

VEADAR, in Chronology, the 13th month of the Jewiſh eccleſiaſtical year, anſwering commonly to our March; this month is intercalated, to prevent the beginning of Niſan from being removed to the end of February.

VECTIS, in Mechanics, one of the ſimple mechanical powers, more uſually called the LEVER.

VECTOR, or *Radius Vector*, in Aſtronomy, is a line ſuppoſed to be drawn from any planet moving round a centre, or the focus of an ellipſe, to that centre, or focus. It is ſo called, becauſe it is that line by which the planet ſeems to be carried round its centre; and with which it deſcribes areas proportional to the times.

VELOCITY, or *Swiftneſs*, in Mechanics, is that affection of motion, by which a moving body paſſes over a certain ſpace in a certain time. It is alſo called celerity; and it is always proportional to the ſpace moved over in a given time, when the Velocity is uniform, or always the ſame during that time.

Velocity is either *uniform* or *variable*. *Uniform*, or equal *Velocity*, is that with which a body paſſes always over equal ſpaces in equal times. And it is *variable*, or *unequal*, when the ſpaces paſſed over in equal times are unequal; in which caſe it is either *accelerated* or *retarded* Velocity; and this acceleration, or retardation, may alſo be equal or unequal, i. e. uniform or variable, &c. See ACCELERATION, and MOTION.

Velocity is alſo either *abſolute* or *relative*. *Abſolute Velocity* is that we have hitherto been conſidering, in which the Velocity of a body is conſidered ſimply in itſelf, or as paſſing over a certain ſpace in a certain time. But *relative* or *reſpective Velocity*, is that with which bodies approach to, or recede from one another, whether they both move, or one of them be at reſt. Thus, if one body move with the abſolute Velocity of 2 feet per ſecond, and another with that of 6 feet per ſecond; then if they move directly towards each other, the relative velocity with which they approach is that of 8 feet per ſecond; but if they move both the ſame way, ſo that the latter overtake the former, then the relative Velocity with which that overtakes it, is only that of 4 feet per ſecond, or only half of the former; and conſequently it will take double the time of the former before they come in contact together.

VELOCITY *in a Right Line*.—When a body moves with a uniform Velocity, the ſpaces paſſed over by it, in different times, are proportional to the times; alſo the ſpaces deſcribed by two different uniform Velocities, in the ſame time, are proportional to the Velocities; and conſequently, when both times and Velocities are unequal, the ſpaces deſcribed are in the compound ratio of the times and Velocities. That is, $S \propto TV$, and $s \propto tv$; or $S : s :: TV : tv$. Hence alſo, $V : v :: \frac{S}{T} : \frac{s}{t}$, or the Velocity is as the ſpace directly and the time reciprocally.

But in uniformly accelerated motions; the laſt degree of Velocity uniformly gained by a body in beginning from reſt, is proportional to the time; and the ſpace deſcribed from the beginning of the motion, is as the product of the time and Velocity, or as the ſquare of the Velocity, or as the ſquare of the time. That is, in uniformly accelerated motions, $v \propto t$, and $s \propto tv$ or $\propto v^2$ or $\propto t^2$. And, in fluxions, $s = vt$.

VELOCITY *of Bodies moving in Curves*.—According to Galileo's ſyſtem of the fall of heavy bodies, which is now univerſally admitted among philoſophers, the Velocities of a body falling vertically are, at each moment of its fall, as the ſquare roots of the heights from whence it has fallen; reckoning from the beginning of the deſcent. And hence he inferred, that if a body deſcend along an inclined plane, the Velocities it has, at the different times, will be in the ſame ratio: for ſince its Velocity is all owing to its fall, and it only falls as much as there is perpendicular height in the inclined plane, the Velocity ſhould be ſtill meaſured by that height, the ſame as if the fall were vertical.

The ſame principle led him alſo to conclude, that if a body fall through ſeveral contiguous inclined planes, making any angles with each other, much like a ſtick when broken, the Velocity would ſtill be regulated after the ſame manner, by the vertical heights of the different planes taken together, conſidering the laſt Velocity as the ſame that the body would acquire by a fall through the ſame perpendicular height.

This concluſion it ſeems continued to be acquieſced in, till the year 1672, when it was demonſtrated to be falſe, by James Gregory, in a ſmall piece of his intitled *Tentamina quædam Geometrica de Motu Penduli & Projectorum*. This piece has been very little known, becauſe it was only added to the end of an obſcure and pſeudonymous piece of his, then publiſhed, to expoſe the errors and vanity of Mr. Sinclair, profeſſor of natural philoſophy at Glaſgow. This little jeu d'eſprit of Gregory is intitled, *The great and new Art of Weighing Vanity: or a diſcovery of the Ignorance and Arrogance of the great and new Artiſt, in his Pſeudo-Philoſophical writings: by M. Patrick Mathers, Arch-Bedal to the Univerſity of S. Andrews*. In the *Tentamina*, Gregory ſhews what the real Velocity is, which a body acquires by deſcending down two contiguous inclined planes, forming an obtuſe angle, and that it is different from the Velocity a body acquires by deſcending perpendicularly through the ſame height; alſo that the Velocity in quitting the firſt plane, is to that with which it enters the ſecond, and in this latter direction, as radius to the coſine of the angle of inclination between the two planes.

This concluſion however, Gregory obſerves, does not apply to the motions of deſcent down any curve lines, becauſe the contiguous parts of curve lines do not form any angle between them, and conſequently no part of the Velocity is loſt by paſſing from one part of the curve to the other; and hence he infers, that the Velocities acquired in deſcending down a continued curve line, are the ſame as by falling perpendicularly through the ſame height. This principle is then applied, by the author, to the motion of pendulums and projectiles.

Varignon too, in the year 1693, followed in the ſame track, ſhewing that the Velocity loſt in paſſing from one right lined direction to another, becomes indefinitely ſmall in the courſe of a curve line; and that therefore the doctrine of Galileo holds good for the deſcent of bodies down a curve line, viz, that the Velocity

acquired at any point of the curve, is equal to that which would be acquired by a fall through the ſame perpendicular altitude.

The nature of every curve is abundantly determined by the ratio of the ordinates to the correſponding abſciſſes; and the eſſence of curves in general may be conceived as conſiſting in this ratio, which may be varied in a thouſand different ways. But this ſame ratio will be alſo that of two ſimple Velocities, by whoſe joint effect a body may deſcribe the curve in queſtion; and conſequently the eſſence of all curves, in general, is the ſame thing as the concourſe or combination of all the forces which, taken two by two, may move the ſame body. Thus we have a moſt ſimple and general equation of all poſſible curves, and of all poſſible Velocities. By means of this equation, as ſoon as the two ſimple Velocities of a body are known, the curve reſulting from them is immediately determined.

It may be obſerved, in particular, according to this equation, that an uniform Velocity, combined with a Velocity that always varies as the ſquare roots of the heights, the two produce the particular curve of a parabola, independent of the angle made by the directions of the two forces that give the Velocities; and conſequently a cannon ball, ſhot either horizontally or obliquely to the horizon, muſt always deſcribe a parabola, were it not for the reſiſtance of the air.

Circular VELOCITY. See CIRCULAR.

Initial VELOCITY, in Gunnery, denotes the Velocity with which military projectiles iſſue from the mouth of the piece by which they are diſcharged. This, it is now known, is much more conſiderable than was formerly apprehended. For the method of eſtimating it, and the reſult of a variety of experiments, by Mr. Robins, and myſelf, &c, ſee the articles GUN, GUNNERY, PROJECTILE, and RESISTANCE.

Mr. Robins had hinted in his New Principles of of Gunnery, at another method of meaſuring the Initial Velocities of military projectiles, viz, from the arc of vibration of the gun itſelf, in the act of expulſion, when it is ſuſpended by an axis like a pendulum. And Mr. Thompſon, in his experiments (Philoſ. Tranſ. vol. 71, p. 229) has purſued the ſame idea at conſiderable length, in a number of experiments, from whence he deduces a rule for computing the Velocity, which is ſomewhat different from that of Mr. Robins, but which agrees very well with his own experiments.

This rule however being drawn only from the experiments with a muſket barrel, and with a ſmall charge of powder, and beſides being different from that in the theory as propoſed by Robins; it was ſuſpected that it would not hold good when applied to cannon, or other large pieces of ordnance, of different and various lengths, and to larger charges of powder. For this reaſon, a great multitude of experiments, as related in my Tracts, vol. 1, were inſtituted with cannon of various lengths and charged with many different quantities of powder; and the Initial Velocities of the ſhot were computed both from the vibration of a balliſtic pendulum, and from the vibration of the gun itſelf; but the conſequence was, that theſe two hardly ever agreed together, and in many caſes they differed by almoſt 400 feet per ſecond in the Velocity. A brief abſtract for a compariſon between theſe two methods, is contained in the following tablet, viz.

Compariſon of the Velocities by the Gun and Pendulum.

Gun No.	2 Ounces.			4 Ounces.			8 Ounces.			16 Ounces.		
	Velocity by		Diff.	Velocity by		Diff.	Velocity by		Diff.	Velocity by		Diff.
	Gun	Pend.		Gun	Pend.		Gun	Pend.		Gun	Pend.	
1	830	780	50	1135	1100	35	1445	1430	15	1345	1377	−32
2	863	835	28	1203	1180	23	1521	1580	−59	1485	1656	−171
3	919	920	−1	1294	1300	−6	1631	1790	−159	1680	1998	−318
4	929	970	−41	1317	1370	−53	1669	1940	−271	1730	2106	−376

In this table, the firſt column ſhews the number of the gun, as they were of different lengths; viz, the length of number 1 was 30⅓ inches, number 2 was 40⅓ inches, number 3 was 60 inches, and number 4 was 83 inches, nearly. After the firſt column, the reſt of the table is divided into four ſpaces, for the four charges, 2, 4, 8, 16 ounces of powder: and each of theſe is divided into three columns: in the firſt of the three is the Velocity of the ball as determined from the vibration of the gun; in the ſecond is the Velocity as determined from the vibration of the pendulum; and in the third is the difference between the two, being ſo many feet per ſecond, which is marked with the negative ſign, or −, when the former Velocity is too little, otherwiſe it is poſitive.

From the compariſon contained in this table, it appears, in general, that the Velocities, determined by the two different ways, do not agree together; and that therefore the method of determining the Velocity of the ball from the recoil of the gun, is not generally true, although Mr. Robins and Mr. Thompſon had ſuſpected it to be ſo: and conſequently that the effect of the inflamed powder on the recoil of the gun, is not exactly the ſame when it is fired without a ball, as when it is fired with one. It alſo appears, that this difference is no ways regular, neither in the different

guns

guns with the ſame charge of powder, nor in the ſame gun with different charges: That with very ſmall charges, the Velocity by the gun is greater than that by the pendulum; but that the latter always gains upon the former, as the charge is increaſed, and ſoon becomes equal to it; and afterwards goes on to exceed it more and more: That the particular charge, at which the two Velocities become equal, is different in the different guns; and that this charge is leſs, or the equality ſooner takes place, as the gun is longer. And all this, whether we uſe the actual Velocity with which the ball ſtrikes the pendulum, or the ſame increaſed by the Velocity loſt by the reſiſtance of the air, in its flight from the gun to the pendulum.

VENTILATOR, a machine by which the noxious air of any cloſe place, as an hoſpital, gaol, ſhip, chamber, &c, may be diſcharged and changed for freſh air.

The noxious qualities of bad air have been long known; and Dr. Hales and others have taken great pains to point out the miſchiefs ariſing from foul air, and to prevent or remedy them. That philoſopher propoſed an eaſy and effectual one, by the uſe of his Ventilators; the account of which was read before the Royal Society in May 1741; and a farther account of it may be ſeen in his Deſcription of Ventilators, printed at London in 8vo, 1743; and ſtill farther in part 2, p. 32, printed in 1758; where the uſes and applications of them are pointed out for ſhips, and priſons, &c. For what is ſaid of the foul air of ſhips may be applied to that of gaols, mines, workhouſes, hoſpitals, barracks, &c. In mines, Ventilators may guard againſt the ſuffocations, and other terrible accidents ariſing from damps. The air of gaols has often proved infectious; and we had a fatal proof of this, by the accident that happened ſome years ſince at the Old Bailey ſeſſions. After that, Ventilators were uſed in the priſon, which were worked by a ſmall windmill, placed on the top of Newgate; and the priſon became more healthy.

Dr. Hales farther ſuggeſts, that Ventilators might be of uſe in making ſalt; for which purpoſe there ſhould be a ſtream of water to work them; or they might be worked by a windmill, and the brine ſhould be in long narrow canals, covered with boards of canvas, about a foot above the ſurface of the brine, to confine the ſtream of air, ſo as to make it act upon the ſurface of the brine, and carry off the water in vapours. Thus it might be reduced to a dry ſalt, with a ſaving of fuel, in winter and ſummer, or in rainy weather, or any ſtate of the air whatever. Ventilators, he apprehends, might alſo ſerve for drying linen hung in low, long, narrow galleries, eſpecially in damp or rainy weather, and alſo in drying woollen cloths, after they are fulled or dyed; and in this caſe, the Ventilators might be worked by the fulling water-mill. Ventilators might alſo be an uſeful appendage to malt and hop kilns; and the ſame author is farther of opinion, that a ventilation of warm dry air from the adjoining ſtove, with a cautious hand, might be of ſervice to trees and plants in green-houſes; where it is well known that air full of the rancid vapours which perſpire from the plants, is very unkindly to them, as well as the vapours from human bodies are to men: for freſh air is as neceſſary to the healthy ſtate of vegetables, as of animals.—Ventilators are alſo of excellent uſe for drying corn, hops, and malt.—Gunpowder may be thoroughly dried, by blowing air up through it by means of Ventilators; which is of great advantage to the ſtrength of it. Theſe Ventilators, even the ſmaller ones, will alſo ſerve to purify moſt eaſily, and effectually, the bad air of a ſhip's well, before a perſon is ſent down into it, by blowing air through a trunk, reaching near the bottom of it. And in a ſimilar manner may ſtinking water, and ill-taſted milk, &c, be ſweetened, viz, by paſſing a current of air through them, from bottom to top, which will carry the offenſive particles along with it.

For theſe and other uſes to which they might be applied, as well as for a particular account of the conſtruction and diſpoſition of Ventilators in ſhips, hoſpitals, priſons, &c, and the benefits attending them, ſee Hales's Treatiſe on Ventilators, part 2 paſſim; and the Philoſ. Tranſ. vol. 49, p. 332.

The method of drawing off air from ſhips by means of fire-pipes, which ſome have preferred to Ventilators, was publiſhed by Sir Robert Moray in the Philoſ. Tranſ. for 1665. Theſe are metal pipes, about 2½ inches diameter, one of which reaches from the fire-place to the well of the ſhip, and other three branches go to other parts of the ſhip; the ſtove hole and aſh hole being cloſed up, the fire is ſupplied with air through theſe pipes. The defects of theſe, compared with Ventilators, are particularly examined by Dr. Hales, ubi ſupra, p. 113.

In the latter part of the year 1741, M. Triewald, military architect to the king of Sweden, informed the ſecretary to the Royal Society, that he had in the preceding ſpring invented a machine for the uſe of ſhips of war, to draw out the foul air from under their decks, which exhauſted 36172 cubic feet of air in an hour, or at the rate of 21732 tuns in 24 hours. In 1742 he ſent one of theſe to France, which was approved of by the Academy of Sciences at Paris, and the navy of France was ordered to be furniſhed with the like Ventilators.

Mr. Eraſmus King propoſed to have Ventilators worked by the fire engines, in mines. And Mr. Fitzgerald has ſuggeſted an improved method of doing this, which he has alſo illuſtrated by figures. See Philoſ. Tranſ. vol. 50, p, 727.

There are various ways of Ventilation, or changing the air of rooms. Mr. Tidd contrived to admit freſh air into a room, by taking out the middle upper ſaſh pane of glaſs, and fixing in its place a frame box, with a round hole in its middle, about 6 or 7 inches diameter; in which hole are fixed, behind each other, a ſet of ſails of very thin broad copper-plates, which ſpread over and cover the circular hole, ſo as to make the air which enters the room, and turning round theſe ſails, to ſpread round in thin ſheets ſideways; and ſo not to incommode perſons, by blowing directly upon them, as it would do if it were not hindered by the ſails.

This method however is very unſeemly and diſagreeable in good rooms: and therefore, inſtead of it, the late ingenious Mr. John Whitehurſt ſubſtituted another; which was, to open a ſmall ſquare or rectangular hole in the party wall of the room, in the upper part near the cieling, at a corner or part diſtant from the

fire; and before it he placed a thin piece of metal or paſteboard &c, attached to the wall in its lower part juſt below the hole, but declining from it upwards, ſo as to give the air, that enters by the hole, a direction upwards againſt the cieling, along which it ſweeps and diſperſes itſelf through the room, without blowing in a current againſt any perſon. This method is very uſeful to cure ſmoky chimneys, by thus admitting conveniently freſh air. A picture placed before the hole prevents the ſight of it from diſfiguring the room. This, and many other methods of Ventilating, he meant to have publiſhed, and was occupied upon, when death put an end to his uſeful labours. Theſe have ſince been publiſhed, viz in 1794, 4to, by Dr. Willan.

VENUS, in Aſtronomy, one of the inferior planets, but the brighteſt and to appearance the largeſt of all the planets; and is deſigned by the mark ♀, ſuppoſed to be a rude repreſentation of a female figure, with her trailing robe.

Venus is eaſily diſtinguiſhed from all the other planets, by her whiteneſs and brightneſs, in which ſhe exceeds all the reſt, even Jupiter himſelf, and which is ſo conſiderable, that in a duſky place ſhe cauſes an object to project a ſenſible ſhadow, and ſhe is often viſible in the day-time. Her place in the ſyſtem is the ſecond from the ſun, viz, between Mercury and the earth, and in magnitude is about equal to the earth, or rather a little larger according to Dr. Herſchel's obſervations.

As Venus moves round the ſun, in a circle beneath that of the earth, ſhe is never ſeen in oppoſition to him, nor indeed very far from him; but ſeems to move backward and forward, paſſing him from ſide to ſide, to the diſtance of about 47 or 48 degrees, both ways, which is her greateſt elongation.

When ſhe appears weſt of the ſun, which is from her inferior conjunction to her ſuperior, ſhe riſes before him, or is a morning ſtar, and is called *Phoſphorus*, or *Lucifer*, or the *Morning Star*; and when ſhe is eaſtwards from the ſun, which is from her ſuperior conjunction to her inferior, ſhe ſets after him, or is an evening ſtar, and is called *Heſperus*, or *Veſper*, or the *Evening ſtar:* being each of thoſe in its turn for 290 days.

The real diameter of Venus is nearly equal to that of the earth, being about 7900 miles; her apparent mean diameter ſeen from the earth 59″, ſeen from the ſun, or her horizontal parallax, 30″; but as ſeen from the earth 18″·79 according to Dr. Herſchel: her diſtance from the ſun 70 million of miles; her eccentricity $\frac{7}{100}$ths of the ſame, or 490,000 miles; the inclination of her orbit to the plane of the ecliptic 3° 23′; the points of their interſection or nodes are 14° of ♊ and ♐; the place of her aphelion ♒ 4° 20′; her axis inclined to her orbit 75° ♌; her periodical courſe round the ſun 224 days 17 hours; the diurnal rotation round her axis very uncertain, being according to Caſſini only 23 hours, but according to the obſervations of Bianchini it is in 24 days 8 hours; though Dr. Herſchel thinks it cannot be ſo much. See alſo PLANETS.

Venus, when viewed through a teleſcope, is rarely ſeen to ſhine with a full face, but has phaſes and changes juſt like thoſe of the moon, being increaſing, decreaſing, horned, gibbous, &c: her illuminated part being conſtantly turned toward the ſun, or directed toward the eaſt when ſhe is a morning ſtar, and toward the weſt when an evening ſtar.

Theſe different phaſes of Venus were firſt diſcovered by Galileo; who thus fulfilled the prediction of Copernicus: for when this excellent aſtronomer revived the ancient Pythagorean ſyſtem, aſſerting that the earth and planets move round the ſun, it was objected that in ſuch a caſe the phaſes of Venus ſhould reſemble thoſe of the moon; to which Copernicus replied, that ſome time or other that reſemblance would be found out. Galileo ſent an account of the firſt diſcovery of theſe phaſes in a letter, written from Florence in 1611, to William de Medici, the duke of Tuſcany's ambaſſador at Prague; deſiring him to communicate it to Kepler. The letter is extant in the preface to Kepler's Dioptrics, and a tranſlation of it in Smith's Optics, p. 416. Having recited the obſervations he had made, he adds, "We have hence the moſt certain, ſenſible deciſion and demonſtration of two grand queſtions, which to this day have been doubtful and diſputed among the greateſt maſters of reaſon in the world. One is, that the planets in their own nature are opake bodies, attributing to Mercury what we have ſeen in Venus: and the other is, that Venus neceſſarily moves round the ſun; as alſo Mercury and the other planets; a thing well believed indeed by Pythagoras, Copernicus, Kepler, and myſelf, but never yet proved, as now it is, by ocular inſpection upon Venus."

Caſſini and Campani, in the years 1665 and 1666, diſcovered ſpots in the face of Venus: from the appearances of which the former aſcertained her motion round her axis; concluding that this revolution was performed in leſs than a day; or at leaſt that the bright ſpot which he obſerved, finiſhed its period either by revolution or libration in about 23 hours. And de la Hire, in 1700, through a teleſcope of 16 feet, diſcovered ſpots in Venus; which he found to be larger than thoſe in the moon.

The next obſervations of the ſame kind that occur, are thoſe of ſignior Binanchini at Rome, in 1726, 1727, 1728, who, with Campani's glaſſes, diſcovered ſeveral dark ſpots in the diſc of Venus, of which he gave an account and a repreſentation in his book entitled Heſperi et Phoſphori Nova Phenomena, publiſhed at Rome in 1728. From ſeveral ſucceſſive obſervations Bianchini concludes, that a rotation of Venus about her axis was not completed in 23 hours, as Caſſini imagined, but in 24½ days; that the north pole of this rotation faced the 20th degree of Aquarius, and was elevated 15° above the plane of the ecliptic, and that the axis kept parallel to itſelf, during the planet's revolution about the ſun. Caſſini the ſon, though he admits the accuracy of Bianchini's obſervations, diſputes the concluſion drawn from them, and finally obſerves, that if we ſuppoſe the period of the rotation of Venus to be 23 h. 20 min. it agrees equally well with the obſervations both of his father and Bianchini; but if ſhe revolve in 24 d. 8 h. then his father's obſervations muſt be rejected as of no conſequence.

In the Philoſ. Tranſ. 1792, are publiſhed the reſults of a courſe of obſervations on the planet Venus, begun in the year 1780, by Mr. Schroeter, of Lilienthal, Bremen. From theſe obſervations, the author infers, that

that Venus has an atmoſphere in ſome reſpects ſimilar to that of our earth, but far exceeding that of the moon in denſity, or power to weaken the rays of the ſun: that the diurnal period of this planet is probably much longer than that of other planets: that the moon alſo has an atmoſphere, though leſs denſe and high than that of Venus: and that the mountains of this planet are 5 or 6 times as high as thoſe on the earth.

Dr. Herſchel too, between the years 1777 and 1793, has made a long ſeries of obſervations on this planet, accounts of which are given in the Philoſ. Tranſ. for 1793. The reſults of theſe obſervations are: that the planet revolves about its axis, but the time of it is uncertain: that the poſition of its axis is alſo very uncertain: that the planet's atmoſphere is very conſiderable: that the planet has probably hills and inequalities on its ſurface, but he has not been able to ſee much of them, owing perhaps to the great denſity of its atmoſphere; as to the mountains of Venus, no eye, he ſays, which is not conſiderably better than his, or aſſiſted by much better inſtruments, will ever get a ſight of them: and that the apparent diameter of Venus, at the mean diſtance from the earth, is 18″·79; from whence it may be inferred, that this planet is ſomewhat larger than the earth, inſtead of being leſs, as former aſtronomers have imagined.

Sometimes Venus is ſeen in the diſc of the ſun, in form of a dark round ſpot. Theſe appearances, called Tranſits, happen but ſeldom, viz, when the earth is about her nodes at the time of her inferior conjunction. One of theſe tranſits was ſeen in England in 1639 by Mr. Horrox and Mr. Crabtree; and two in the preſent century, viz, the one June 6, 1761, and the other in June 1769. There will not happen another of them till the year 1874. See PARALLAX.

Except ſuch tranſits as theſe, Venus exhibits the ſame appearances to us regularly every 8 years; her conjunctions, elongations, and times of riſing and ſetting, being very nearly the ſame, on the ſame days, as before.

In 1672 and 1686, Caſſini, with a teleſcope of 34 feet, thought he ſaw a ſatellite move round this planet, at the diſtance of about $\frac{3}{4}$ of Venus's diameter. It had the ſame phaſes as Venus, but without any well defined form; and its diameter ſcarce exceeded $\frac{1}{4}$ of the diameter of Venus. Dr. Gregory (Aſtron. lib. 6, prop. 3) thinks it more than probable that this was a ſatellite; and ſuppoſes that the reaſon why it is not more frequently ſeen, is the unfitneſs of its ſurface to reflect the rays of the ſun's light; as is the caſe of the ſpots in the moon; for if the whole diſc of the moon were compoſed of ſuch, he thinks ſhe could not be ſeen ſo far as to Venus.

Mr. Short, in 1740, with a reflecting teleſcope of $16\frac{1}{2}$ inches focus, perceived a ſmall ſtar near Venus: with another teleſcope of the ſame focus, magnifying 50 or 60 times, and fitted with a micrometer, he found its diſtance from Venus about 10′; and with a magnifying power of 240, he obſerved the ſtar aſſume the ſame phaſes with Venus; its diameter ſeemed to be about $\frac{1}{3}$, or ſomewhat leſs, of the diameter of Venus; its light not ſo bright and vivid, but exceeding ſharp and well defined. He viewed it for the ſpace of an hour; but never had the good fortune to ſee it after the firſt morning. Philoſ. Tranſ. number 459, p. 646, or Abr. vol. 8, p. 208.

M. Montaign, of Limoges in France, preparing for obſerving the tranſit of 1761, diſcovered in the preceding month of May a ſmall ſtar, about the diſtance of 20′ from Venus, the diameter of it being about $\frac{1}{4}$ of that of the planet. Others have alſo thought they ſaw a like appearance. And indeed it muſt be acknowledged, that Venus may have a ſatellite, though it is difficult for us to ſee it. Its enlightened ſide can never be fully turned towards us, but when Venus is beyond the ſun; in which caſe Venus herſelf appears little bigger than an ordinary ſtar, and therefore her ſatellite may be too ſmall to be perceived at ſuch a diſtance. When ſhe is between us and the ſun, her moon has its dark ſide turned towards us; and when Venus is at her greateſt elongation, there is but half the enlightened ſide of the moon turned toward us, and even then it may be too far diſtant to be ſeen by us. But it was preſumed, that the two tranſits of 1761, and 1769, would afford opportunity for determining this point; and yet we do not find, although many obſervers directed their attention to this object, that any ſatellite was then ſeen in the ſun's diſc; unleſs we except two perſons, viz, an anonymous writer in the London Chronicle of May 18, who ſays that he ſaw the ſatellite of Venus on the ſun the day of the tranſit, at St. Neot's in Huntingdonſhire; that it moved in a track parallel to that of Venus, but nearer the ecliptic; that Venus quitted the ſun's diſc at 31 minutes after 8, and the ſatellite at 6 minutes after 9; and M. Montaign at Limoges, whoſe account of his obſervations is in the Memoirs of the Academy of Paris, from whence the following certificate is extracted:—CERTIFICATE. "We having examined, by order of the Academy, the remarks of M. Baudouin on a new obſervation of the ſatellite of Venus, made at Limoges the 11th of May by M. Montaign. This fourth obſervation, of great importance for the theory of the ſatellite, has ſhewn that its revolution muſt be longer than appeared by the firſt three obſervations. M. Baudouin believes it may be fixed at 12 days; as to its diſtance, it appears to him to be 50 ſemi-diameters of Venus; whence he infers that the maſs of Venus is equal to that of the earth. This maſs of Venus is a very eſſential element to aſtronomy, as it enters into many computations, and produces different phenomena: &c.

Signed L'Abbé De La Caille,
De La Lande."

VERBERATION, in Phyſics, a term uſed to expreſs the cauſe of ſound, which ariſes from a Verberation of the air, when ſtruck, in divers manners, by the ſeveral parts of the ſonorous body firſt put into a vibratory motion.

VERNAL, ſomething belonging to the ſpring ſeaſon: as vernal ſigns, vernal equinox, &c.

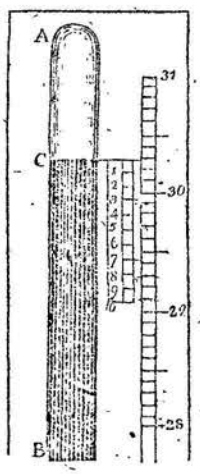
VERNIER, is a ſcale, or a diviſion, well adapted for the graduation of mathematical inſtruments, ſo called from its inventor Peter Vernier, a gentleman of Franche Comté, who communicated the diſcovery to the world in a ſmall tract, entitled La Conſtruction, l'Uſage, et les Proprietez du Quadrant Nouveau de Mathematique &c, printed at Bruſſels in 1631. This

was an improvement on the method of diviſion propoſed by Jacobus Curtius, printed by Tycho in Clavius's Aſtrolabe, in 1593. Vernier's method of diviſion, or dividing plate, has been very commonly, though erroneouſly, called by the name of Nonius; the method of Nonius being very different from that of Vernier, and much leſs convenient.

When the relative unit of any line is ſo divided into many ſmall equal parts, thoſe parts may be too numerous to be introduced, or if introduced, they may be too cloſe to one another to be readily counted or eſtimated; for which reaſon there have been various methods contrived for eſtimating the aliquot parts of the ſmall diviſions, into which the relative unit of a line may be commodiouſly divided; and among thoſe methods, Vernier's has been moſt juſtly preferred to all others. For the hiſtory of this, and other inventions of a ſimilar nature, ſee Robins's Math. Tracts, vol. 2, p. 265, &c.

Vernier's ſcale is a ſmall moveable arch, or ſcale, ſliding along the limb of a quadrant, or any other graduated ſcale, and divided into equal parts, that are one leſs in number than the diviſions of the portion of the limb correſponding to it. So, if we want to ſubdivide the graduations on any ſcale into for ex. 10 equal parts; we muſt make the Vernier equal in length to 11 of thoſe graduations of the ſcale, but dividing the ſame length of the Vernier itſelf only into 10 equal parts; for then it is evident that each diviſion on the Vernier will be $\frac{1}{10}$th part longer than the gradations on the inſtrument, or that the diviſion of the former is equal to $\frac{1}{10}$ of the degree on the latter, as that gains 1 in 10 upon this.

Thus let AB be a part of the upper end of a barometer tube, the quickſilver ſtanding at the point C; from 28 to 31 is a part of the ſcale of inches, viz. from 28 inches to 31 inches, divided into 10ths of inches; and the middle piece, from 1 to 10, is the Vernier, that ſlides up and down in a groove, and having 10 of its diviſions equal to 11 tenths of the inches, for the purpoſe of ſubdividing every 10th of the inch into 10 parts, or, the inches into centeſims or 100th parts. In practice, the method of counting is by obſerving (when the Vernier is ſet with its index at top pointing exactly againſt the upper ſurface of the mercury in the tube) which diviſion of the Vernier it is that exactly, or neareſt, coincides with a diviſion in the ſcale of 10ths of inches, for that will ſhew the number of 100ths, over the 10ths of inches next below the index at top. So, in the annexed figure, the top of the Vernier is between 2 and 3 tenths above the 30 inches of the barometer; and becauſe the 8th diviſion of the Vernier is ſeen to coincide with a diviſion of the ſcale, this ſhews that it is 8 centeſms more: ſo that the height of the quickſilver altogether, is 30·28, that is, 30 inches, and 28 hundredths, or 2 tenths and 8 hundredths.



If the ſcale were not inches and 10ths, but degrees of a quadrant, &c, then the 8 would be $\frac{8}{10}$ of a degree, or 48′; or if every diviſion on the ſcale be 10 minutes, then the Vernier will ſubdivide it into ſingle minutes, and the 8 will then be 8 minutes. And ſo for any other caſe.

By altering the number of diviſions, either in the degrees or in the Vernier, or in both, an angle can be obſerved to many different degrees of accuracy. Thus, if a degree on a quadrant be divided into 12 parts, each being 5 minutes, and the length of the Vernier be 21 ſuch parts, or $1°\frac{3}{4}$, and divided into 20 parts, then

$$\frac{1}{12} \times \frac{1}{20} = \frac{1°}{240} = \frac{1'}{4} = 15'',$$

is the ſmalleſt diviſion the Vernier will meaſure to: Or, if the length of the Vernier be $2°\frac{7}{12}$, and divided into 30 parts, then

$$\frac{1}{12} \times \frac{1}{30} = \frac{1°}{360} = \frac{1'}{6} = 10'',$$

is the ſmalleſt part in this caſe: Alſo

$$\frac{1}{12} \times \frac{1}{50} = \frac{1°}{600} = \frac{1'}{10} = 6'';$$

is the ſmalleſt part when the Vernier extends $4°\frac{1}{4}$. See Robertſon's Navigation, book 5, p. 279.

For the method of applying the Vernier to a quadrant, ſee *Hadley's* QUADRANT. And for the application of it to a teleſcope, and the principles of its conſtruction, ſee Smith's Optics, book 3, ſect. 861.

VERSED-*Sine*, of an arch, is the part of the diameter intercepted between the ſine and the commencement of the arc; and it is equal to the difference between the radius and the coſine. See *Verſed*-SINE. And for *coverſed ſine*, ſee COVERSED-*Sine*.

VERTEX *of an Angle*, is the angular point, or the point where the legs or ſides of the angle meet.

VERTEX *of a Figure*, is the uppermoſt point, or the vertex of the angle oppoſite to the baſe.

VERTEX *of a Curve*, is the extremity of the axis or diameter, or it is the point where the diameter meets the curve; which is alſo the vertex of the diameter.

VERTEX *of a Glaſs*, in Optics, the ſame as its pole.

VERTEX is alſo uſed, in Aſtronomy, for the point of the heavens vertically or perpendicularly over our heads, alſo called the zenith.

VERTEX, *Path of the*. See PATH.

VERTICAL, ſomething relating to the vertex or higheſt point. As,

VERTICAL *Point*, in Aſtronomy, is the ſame with vertex, or zenith.—Hence a ſtar is ſaid to be Vertical, when it happens to be in that point which is perpendicularly over any place.

VERTICAL *Circle*, is a great circle of the ſphere, paſſing through the zenith and nadir of a place.—The Vertical circles are alſo called *azimuths*. The meridian of any place is a Vertical circle, viz, that particular one which paſſes through the north or ſouth point of the horizon.—All the Vertical circles interſect one another in the zenith and nadir.

The uſe of the Vertical circles is to eſtimate or meaſure the height of the ſtars &c, and their diſtances from the zenith, which is reckoned on theſe circles; and to find their eaſtern and weſtern amplitude, by obſerving how many degrees the Vertical, in which the ſtar riſes or ſets, is diſtant from the meridian.

Prime VERTICAL, is that Vertical circle, or azimuth, which paſſes through the poles of the meridian; or which is perpendicular to the meridian, and paſſes through the equinoctial points.

Prime VERTICALS, in Dialling. See PRIME *Verticals*.

VERTICAL *of the Sun*, is the Vertical which paſſes through the centre of the ſun at any moment of time.—Its uſe is, in Dialling, to find the declination of the plane on which the dial is to be drawn, which is done by obſerving how many degrees that Vertical is diſtant from the meridian, after marking the point or line of the ſhadow upon the plane at any times.

VERTICAL *Dial*. See *Vertical* DIAL.

VERTICAL *Line*, in Dialling, is a line in any plane perpendicular to the horizon.——This is beſt found and drawn on an erect and reclining plane, by ſteadily holding up a ſtring and plummet, and then marking two points of the ſhadow of the thread on the plane, a good diſtance from one another: and drawing a line through theſe marks.

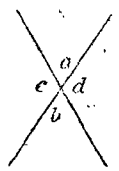
VERTICAL *Line*, in Conics, is a line drawn on the Vertical plane, and through the vertex of the cone.

VERTICAL *Line*, in Perſpective. See *Vertical* LINE.

VERTICAL *Plane*, in Conics, is a plane paſſing through the vertex of a cone, and parallel to any conic ſection.

VERTICAL *Plane*, in Perſpective. See PLANE and PERSPECTIVE.

VERTICAL *Angles*, or *Oppoſite Angles*, in Geometry, are ſuch as have their legs or ſides continuations of each other, and which conſequently have the ſame vertex or angular point. So the angles *a* and *b* are Vertical angles; as alſo the angles *c* and *d*.



VERTICITY, is that property of the magnet or loadſtone, or of a needle &c touched with it, by which it turns or directs itſelf to ſome peculiar point, as to its pole.—The attraction of the magnet was known long before its Verticity.

VERU, a comet, according to ſome writers, reſembling a ſpit, being nearly the ſame as the lonchites, only its head is rounder, and its train longer and ſharper pointed.

VESPER, in Aſtronomy, called alſo *Heſperus*, and the *Evening Star*, is the planet Venus, when ſhe is eaſtward of the ſun, and conſequently ſets after him, and ſhines as an evening ſtar.

VESPERTINE, in Aſtronomy, is when a planet is deſcending to the weſt after ſun-ſet, or ſhines as an evening ſtar.

VIA LACTEA, in Aſtronomy, the milky way, or Galaxy. See GALAXY.

VIA SOLIS, or *ſun's way*, is uſed among aſtronomers, for the ecliptic line, or path in which the ſun ſeems always to move.

VIBRATION, in Mechanics, a regular reciprocal motion of a body, as, for example, a pendulum, which being freely ſuſpended, ſwings or vibrates from ſide to ſide.

Mechanical authors, inſtead of Vibration, often uſe the term *oſcillation*, eſpecially when ſpeaking of a body that thus ſwings by means of its own gravity or weight.

The Vibrations of the ſame pendulum are all iſochronal; that is, they are performed in an equal time, at leaſt in the ſame latitude; for in lower latitudes they are found to be ſlower than in higher ones. See PENDULUM. In our latitude, a pendulum $39\frac{1}{8}$ inches long, vibrates ſeconds, making 60 Vibrations in a minute.

The Vibrations of a longer pendulum take up more time than thoſe of a ſhorter one, and that in the ſubduplicate ratio of the lengths, or the ratio of the ſquare roots of the lengths. Thus, if one pendulum be 40 inches long, and another only 10 inches long, the former will be double the time of the latter in performing a Vibration; for $\sqrt{40} : \sqrt{10} :: \sqrt{4} : \sqrt{1}$, that is as 2 to 1. And becauſe the number of Vibrations, made in any given time, is reciprocally as the duration of one Vibration, therefore the number of ſuch Vibrations is in the reciprocal ſubduplicate ratio of the lengths of the pendulums.

M. Mouton, a prieſt of Lyons, wrote a treatiſe, expreſsly to ſhew, that by means of the number of Vibrations of a given pendulum, in a certain time, may be eſtabliſhed an univerſal meaſure throughout the whole world; and may fix the ſeveral meaſures that are in uſe among us, in ſuch a manner, as that they might be recovered again, if at any time they ſhould chance to be loſt, as is the caſe of moſt of the ancient meaſures, which we now only know by conjecture.

The VIBRATIONS *of a Stretched Chord*, or *String*, ariſe from its elaſticity; which power being in this caſe ſimilar to gravity, as acting uniformly, the Vibrations of a chord follow the ſame laws as thoſe of pendulums. Conſequently the Vibrations of the ſame chord equally ſtretched, though they be of unequal lengths, are iſochronal, or are performed in equal times; and the ſquares of the times of Vibration are to one another inverſely as their tenſions, or powers by which they are ſtretched.

The Vibrations of a ſpring too are proportional to the powers by which it is bent. Theſe follow the ſame laws as thoſe of the chord and pendulum; and conſequently are iſochronal; which is the foundation of ſpring watches.

VIBRATIONS are alſo uſed in *Phyſics*, &c, and for ſeveral other regular alternate motions. Senſation, for inſtance, is ſuppoſed to be performed by means of the vibratory motion of the contents of the nerves, begun by external objects, and propagated to the brain.

This doctrine has been particularly illuſtrated by Dr. Hartley, who has extended it farther than any other writer, in eſtabliſhing a new theory of our mental operations.

The ſame ingenious author alſo applies the doctrine of Vibrations to the explanation of muſcular motion, which he thinks is performed in the ſame general manner as ſenſation and the perception of ideas. For a particular account of his theory, and the arguments by which it is ſupported, ſee his Obſervations on Man, vol. 1.

The ſeveral ſorts and rays of light, Newton conceives to make Vibrations of divers magnitudes; which, according to thoſe magnitudes, excite ſenſations of ſeveral colours; much after the ſame manner as Vibrations of air, according to their ſeveral magnitudes, excite ſenſations of ſeveral ſounds. See the article Colour.

Heat, according to the ſame author, is only an accident of light, occaſioned by the rays putting a fine, ſubtile, ethereal medium, which pervades all bodies, into a vibrative motion, which gives us that ſenſation. See Heat.

From the Vibrations or pulſes of the ſame medium, he accounts for the alternate fits of eaſy reflexion and eaſy tranſmiſſion of the rays.

In the Philoſophical Tranſactions it is obſerved, that the butterfly, into which the ſilk-worm is transformed, makes 130 Vibrations or motions of its wings, in one coition.

VIETA (Francis), a very celebrated French mathematician, was born in 1540 at Fontenai, or Fontenaile-Comté, in Lower Poitou, a province of France. He was Maſter of Requeſts at Paris, where he died in 1603, being the 63d year of his age. Among other branches of learning in which he excelled, he was one of the moſt reſpectable mathematicians of the 16th century, or indeed of any age. His writings abound with marks of great originality, and the fineſt genius, as well as intenſe application. His application was ſuch, that he has ſometimes remained in his ſtudy for three days together, without eating or ſleeping. His inventions and improvements in all parts of the mathematics were very conſiderable. He was in a manner the inventor and introducer of Specious Algebra, in which letters are uſed inſtead of numbers, as well as of many beautiful theorems in that ſcience, a full explanation of which may be ſeen under the article Algebra. He made alſo conſiderable improvements in geometry and trigonometry. His angular ſections are a very ingenious and maſterly performance: by theſe he was enabled to reſolve the problem of Adrian Roman, propoſed to all mathematicians, amounting to an equation of the 45th degree. Romanus was ſo ſtruck with his ſagacity, that he immediately quitted his reſidence of Wirtzbourg in Franconia, and came to France to viſit him, and ſolicit his friendſhip. His Apollonius Gallus, being a reſtoration of Apollonius's tract on Tangencies, and many other geometrical pieces to be found in his works, ſhew the fineſt taſte and genius for true geometrical ſpeculations.—He gave ſome maſterly tracts on Trigonometry, both plane and ſpherical, which may be found in the collection of his works, publiſhed at Leyden in 1646, by Schooten, beſides another large and ſeparate volume in folio, publiſhed in the author's life-time at Paris in 1579, containing extenſive trigonometrical tables, with the conſtruction and uſe of the ſame, which are particularly deſcribed in the introduction to my Logarithms, pa. 4 &c. To this complete treatiſe on Trigonometry, plane and ſpherical, are ſubjoined ſeveral miſcellaneous problems and obſervations, ſuch as, the quadrature of the circle, the duplication of the cube, &c. Computations are here given of the ratio of the diameter of a circle to the circumference, and of the length of the ſine of 1 minute, both to a great many places of figures; by which he found that the ſine of 1 minute is

between 2908881959
and 2908882056;

alſo the diameter of a circle being 1000 &c, that the perimeter of the inſcribed and circumſcribed polygon of 393216 ſides, will be as follows, viz, the

perim. of the inſcribed polygon 3141592653 5
perim. of the circumſcribed polygon 3141592653 7

and that therefore the circumference of the circle lies between thoſe two numbers.

Vieta having obſerved that there were many faults in the Gregorian Calendar, as it then exiſted, he compoſed a new form of it, to which he added perpetual canons, and an explication of it, with remarks and objections againſt Clavius, whom he accuſed of having deformed the true Lelian reformation, by not rightly underſtanding it.

Beſides thoſe, it ſeems a work greatly eſteemed, and the loſs of which cannot be ſufficiently deplored, was his *Harmonicon Cæleſte*, which, being communicated to father Merſenne, was, by ſome perfidious acquaintance of that honeſt-minded perſon, ſurreptitiouſly taken from him, and irrecoverably loſt, or ſuppreſſed, to the great detriment of the learned world. There were alſo, it is ſaid, other works of an aſtronomical kind, that have been buried in the ruins of time.

Vieta was alſo a profound decipherer, an accompliſhment that proved very uſeful to his country. As the different parts of the Spaniſh monarchy lay very diſtant from one another, when they had occaſion to communicate any ſecret deſigns, they wrote them in ciphers and unknown characters, during the diſorders of the league: the cipher was compoſed of more than 500 different characters, which yielded their hidden contents to the penetrating genius of Vieta alone. His ſkill ſo diſconcerted the Spaniſh councils for two years, that they publiſhed it at Rome, and other parts of Europe, that the French king had only diſcovered their ciphers by means of magic.

VINCULUM, in Algebra, a mark or character, either drawn over, or including, or ſome other way accompanying, a factor, diviſor, dividend, &c, when it is compounded of ſeveral letters, quantities, or terms, to connect them together as one quantity, and ſhew that they are to be multiplied, or divided, &c, together.

Vieta, I think, firſt uſed the bar or line over the quantities, for a Vinculum, thus $\overline{a+b}$; and Albert Girard the parentheſis thus $(a+b)$; the former way being now chiefly uſed by the Engliſh, and the latter by moſt other Europeans. Thus $\overline{a+b} \times c$, or $(a+b) \times c$, denotes the product of c and the ſum $a+b$ conſidered as one quantity. Alſo $\sqrt{a+b}$, or $\sqrt{(a+b)}$, denotes the ſquare root of the ſum $a+b$. Sometimes the mark : is ſet before a compound factor, as a Vinculum, eſpecially when it is very long, or an infinite ſeries; thus $3a \times : 1 - 2x + 3x^2 - 4x^3 + 5x^4$ &c.

VINDEMIATRIX, or Vindemiator, a fixed ſtar of the third magnitude, in the northern wing of the conſtellation Virgo.

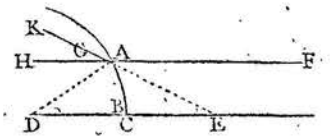
VIRGO,

VIRGO, in Aſtronomy, one of the ſigns or conſtellations of the zodiac, which the ſun enters about the 21ſt or 22d of Auguſt; being one of the 48 old conſtellations, and is mentioned by the aſtronomers of all ages and nations, whoſe works have reached us. Anciently the figure was that of a girl, almoſt naked, with an ear of corn in her hand, evidently to denote the time of harveſt among the people who invented this ſign, whoever they were. But the Greeks much altered the figure, with clothes, wings, &c, and variouſly explained the origin of it by their own fables: thus, they tell us that the virgin, now exalted into the ſkies, was, while on earth, that Juſtitia, the daughter of Aſtræus and Aurora, who lived in the golden age, and taught mankind their duty; but who, when their crimes increaſed, was obliged to leave the earth, and take her place in the heavens. Again, Heſiod gives the celeſtial maid another origin, and ſays ſhe was the daughter of Jupiter and Themis. There are alſo others who depart from both theſe accounts, and make her to have been Erigone, the daughter of Icarius: while others make her Parthene, the daughter of Apollo, who placed her there; and others, from the ear of corn, make it a repreſentation of Ceres; and others, from the obſcurity of her head, of Fortune.

The ancients, as they gave each of the 12 months of the year to the care of ſome one of the 12 principal deities, ſo they alſo threw into the protection of each of theſe one of the 12 ſigns of the zodiac. Hence Virgo, from the ear of corn in her hand, naturally fell to the lot of Ceres, and we accordingly find it called Signum Cereris.

The ſtars in the conſtellation Virgo, in Ptolomy's catalogue, are 32; in Tycho's 33; in Hevelius's 50; and in the Britannic 110.

VIRTUAL *Focus*, in Optics, is a point in the axis of a glaſs, where the continuation of a refracted ray meets it. Thus, let D be the centre, and DBE



the axis of the glaſs AB; upon which falls the ray FA. Now this ray will not proceed ſtraight forward, as AH, after paſſing the glaſs, but will take the courſe AK, being deflected from the perpendicular AD. If then the refracted ray KA be produced, by AE, to the axis at E, this point E Mr. Molineux calls the *Virtual focus*, or *point of divergence*.

VIS, a Latin word, ſignifying force or power; adopted by writers on phyſics, to expreſs divers kinds of natural powers or faculties.

The term Vis is either active or paſſive: the *Vis activa* is the power of producing motion; the *Vis paſſiva* is that of receiving or loſing it. The *Vis activa* is again ſubdivided into *Vis viva* and *Vis mortua*.

Vis *Abſoluta*, or *abſolute force*, is that kind of centripetal force which is meaſured by the motion that would be generated by it in a given body, at a given diſtance, and depends on the efficacy of the cauſe producing it.

Vis *Acceleratrix*, or *accelerating force*, is that centripetal force which produces an accelerated motion, and is proportional to the velocity which it generates in a given time; or it is as the motive or abſolute force directly, and as the quantity of matter moved inverſely.

Vis *Impreſſa* is defined by Newton to be the action exerciſed on any body to change its ſtate, either of reſt or moving uniformly in a right line.

This force conſiſts altogether in the action; and has no place in the body after the action is ceaſed: for the body perſeveres in every new ſtate by the *Vis inertiæ* alone.

This Vis impreſſa may ariſe from various cauſes; as from percuſſion, preſſion, and centripetal force.

Vis *Inertiæ*, or power of inactivity, is defined by Newton to be a power implanted in all matter, by which it reſiſts any change endeavoured to be made in its ſtate, that is, by which it becomes difficult to alter its ſtate, either of reſt or motion.

This power then agrees with the *Vis reſiſtendi*, or power of reſiſting, by which every body endeavours, as much as it can, to perſevere in its own ſtate, whether of reſt or uniform rectilinear motion; which power is ſtill proportional to the body, or to the quantity of matter in it, the ſame as the weight or gravity of the body; and yet it is quite different from, and even independent of the force of gravity, and would be and act juſt the ſame if the body were devoid of gravity. Thus, a body by this force reſiſts the ſame in all directions, upwards or downwards or obliquely; whereas gravity acts only downwards.

Bodies only exert this power in changes brought on their ſtate by ſome *Vis impreſſa*, force impreſſed on them. And the exerciſe of this power is, in different reſpects, both reſiſtance and impetus; reſiſtance, as the body oppoſes a force impreſſed on it to change its ſtate; and impetus, as the ſame body endeavours to change the ſtate of the reſiſting obſtacle. Phil. Nat. Princ. Math. lib. 1.

The *Vis inertiæ*, the ſame great author elſewhere obſerves, is a paſſive principle, by which bodies perſiſt in their motion or reſt, and receive motion, in proportion to the force impreſſing it, and reſiſt as much as they are reſiſted. See RESISTANCE.

Vis *Inſita*, or *innate force* of matter, is a power of reſiſting, by which every body, as much as in it lies, endeavours to perſevere in its preſent ſtate, whether of reſt or of moving uniformly forward in a right line. This force is always proportional to the quantity of matter in the body, and differs in nothing from the Vis inertiæ, but in our manner of conceiving it.

Vis *Centripeta*. See CENTRIPETAL *Force*.

Vis *Motrix*, or *moving force* of a centripetal body, is the tendency of the whole body towards the centre, reſulting from the tendency of all the parts, and is proportional to the motion which it generates in a given time; ſo that the Vis motrix is to the Vis acceleratrix, as the motion is to the celerity: and as the quantity of motion in a body is eſtimated by the product of the velocity into the quantity of matter, ſo the Vis motrix

ariſe

arifes from the Vis acceleratrix multiplied by the quantity of matter.

The followers of Leibnitz uſe the term *Vis motrix* for the force of a body in motion, in the ſame ſenſe as the Newtonians uſe the term *Vis inertiæ*; this latter they allow to be inherent in a body at reſt; but the former, or Vis motrix, a force inherent in the ſame body only whilſt in motion, which actually carries it from place to place, by acting upon it always with the ſame intenſity in every phyſical part of the line which it deſcribes.

Vis *Mortua*, and Vis *Viva*, in Mechanics, are terms uſed by Leibnitz and his followers for force, which they diſtinguiſh into two kinds, *Vis mortua*, and *Vis viva*; underſtanding by the former any kind of preſſure, or an endeavour to move, not ſufficient to produce actual motion, unleſs its action on a body be continued for ſome time; and by the latter, that force or power of acting which reſides in a body in motion.

VISIBLE, ſomething that is an object of viſion or ſight, or the property of a thing ſeen.

The Carteſians ſay that light alone is the proper object of viſion. But according to Newton, colour alone is the proper object of ſight; colour being that property of light by which the light itſelf is Viſible, and by which the images of opake bodies are painted on the retina.

As to the Situation and Place of Viſible Objects:

Philoſophers in general had formerly taken for granted, that the place to which the eye refers any Viſible object, ſeen by reflection or refraction, is that in which the viſual ray meets a perpendicular from the object upon the reflecting or the refracting plane. That this is the caſe with reſpect to plane mirrors is univerſally acknowledged; and ſome experiments with mirrors of other forms ſeem to favour the ſame concluſion, and thus afford reaſon for extending the analogy to all caſes of viſion. If a right line be held perpendicularly over a convex or concave mirror, its image ſeems to make one line with it. The ſame is the caſe with a right line held perpendicularly within water; for the part which is within the water ſeems to be a continuation of that which is without. But Dr. Barrow called in queſtion this method of judging of the place of an object, and ſo opened a new field of inquiry and debate in this branch of ſcience. This, with other optical inveſtigations, he publiſhed in his Optical Lectures, firſt printed in 1674. According to him, we refer every point of an object to the place from which the pencils of light iſſue, or from which they would have iſſued, if no reflecting or refracting ſubſtance intervened. Purſuing this principle, Dr. Barrow proceeded to inveſtigate the place in which the rays iſſuing from each of the points of an object, and that reach the eye after one reflection or refraction, meet; and he found that when the refracting ſurface was plane, and the refraction was made from a denſer medium into a rarer, thoſe rays would always meet in a place between the eye and a perpendicular to the point of incidence. If a convex mirror be uſed, the caſe will be the ſame; but if the mirror be plane, the rays will meet in the perpendicular, and beyond it if it be concave. He alſo determined, according to theſe principles, what form the image of a right line will take when it is preſented in different manners to a ſpherical mirror, or when it is ſeen through a refracting medium.

Dr. Barrow however notices an objection againſt the maxim above mentioned, concerning the ſuppoſed place of viſible objects, and candidly owns that he was not able to give a ſatisfactory ſolution of it. The objection is this: Let an object be placed beyond the focus of a convex lens, and if the eye be cloſe to the lens, it will appear confuſed, but very near to its true place. If the eye be a little withdrawn, the confuſion will increaſe, and the object will ſeem to come nearer; and when the eye is very near the focus, the confuſion will be very great, and the object will ſeem to be cloſe to the eye. But in this experiment the eye receives no rays but thoſe that are converging; and the point from which they iſſue is ſo far from being nearer than the object, that it is beyond it; notwithſtanding which the object is conceived to be much nearer than it is, though no very diſtinct idea can be formed of its preciſe diſtance.

The firſt perſon who took much notice of Dr. Barrow's hypotheſis, and the difficulty attending it, was Dr. Berkeley, who (in his Eſſay on a New Theory of Viſion, p. 30) obſerves, that the circle formed upon the retina, by the rays which do not come to a focus, produce the ſame confuſion in the eye, whether they croſs one another before they reach the retina, or tend to it afterwards; and therefore that the judgment concerning diſtance will be the ſame in both the caſes, without any regard to the place from which the rays originally iſſued; ſo that in this caſe, by receding from the lens, as the confuſion increaſes, which always accompanies the nearneſs of an object, the mind will judge that the object comes nearer. See *Apparent* DISTANCE.

M. Bouguer (in his Traité d'Optique, p. 104) adopts Barrow's general maxim, in ſuppoſing that we refer objects to the place from which the pencils of rays ſeemingly converge at their entrance into the pupil. But when rays iſſue from below the ſurface of a veſſel of water, or any other refracting medium, he finds that there are always two different places of this ſeeming convergence: one of them of the rays that iſſue from it in the ſame vertical circle, and therefore fall with different degrees of obliquity upon the ſurface of the refracting medium; and another of thoſe that fall upon the ſurface with the ſame degree of obliquity, entering the eye laterally with reſpect to one another. He ſays, ſometimes one of theſe images is attended to by the mind, and ſometimes the other; and different images may be obſerved by different perſons. And he adds, that an object plunged in water affords an example of this duplicity of images.

G. W. Krafft has ably ſupported Barrow's opinion, that the place of any point ſeen by reflection from the ſurface of any medium, is that in which rays iſſuing from it, infinitely near to one another, would meet; and conſidering the caſe of a diſtant object viewed in a concave mirror, by an eye very near it, when the image, according to Euclid and other writers, would be between the eye and the object, and Barrow's rule cannot be applied, he ſays that in this caſe the ſpeculum may

be conſidered as a plane, the effect being the ſame, only that the image is more obſcure. Com. Petrepol. vol. 12, p. 252, 256. See Prieſtley's Hiſt. of Light &c, p. 89, 688.

From the principle above illuſtrated ſeveral remarkable phenomena of viſion may be accounted for: as—That if the diſtance between two Viſible objects be an angle that is inſenſible, the diſtant bodies will appear as if contiguous: whence, a continuous body being the reſult of ſeveral contiguous ones, if the diſtances between ſeveral Viſibles ſubtend inſenſible angles, they will appear one continuous body; which gives a pretty illuſtration of the notion of a continuum.—Hence alſo parallel lines, and long viſtas, conſiſting of parallel rows of trees, ſeem to converge more and more the farther they are extended from the eye; and the roofs and floors of long extended alleys ſeen, the former to deſcend, and the latter to aſcend, and approach each other; becauſe the apparent magnitudes of their perpendicular intervals are perpetually diminiſhing, while at the ſame time we miſtake their diſtance.

As to the Different Diſtances of Viſible Objects:

The mind perceives the diſtance of Viſible objects, 1ſt, From the different configurations of the eye, and the manner in which the rays ſtrike the eye, and in which the image is impreſſed upon it. For the eye diſpoſes itſelf differently, according to the different diſtances it is to ſee; viz, for remote objects the pupil is dilated, and the cryſtalline brought nearer the retina, and the whole eye is made more globous; on the contrary, for near objects, the pupil is contracted, the cryſtalline thruſt forwards, and the eye lengthened. The mode of performing this however, has greatly divided the opinions of philoſophers. See Prieſtley's Hiſt. of Light &c, p. 638—652, where the ſeveral opinions of Deſcartes, Kepler, La Hire, are Le Roi, Porterfield, Jurin, Muſſchenbroek, &c, ſtated and examined.

Again, the diſtance of Viſible objects is judged of by the angle the object makes; from the diſtinct or confuſed repreſentation of the objects; and from the briſkneſs or feebleneſs, or the rarity or denſity of the rays.

To this it is owing, 1ſt, That objects which appear obſcure or confuſed, are judged to be more remote; a principle which the painters make uſe of to cauſe ſome of their figures to appear farther diſtant than others on the ſame plane. 2d, To this it is likewiſe owing, that rooms whoſe walls are whitened, appear the ſmaller; that fields covered with ſnow, or white flowers, ſhew leſs than when clothed with graſs; that mountains covered with ſnow, in the night time, appear the nearer, and that opake bodies appear the more remote in the twilight.

The Magnitude of Viſible Objects.

The quantity or magnitude of Viſible objects, is known chiefly by the angle contained between two rays drawn from the two extremes of the object to the centre of the eye. An object appears ſo large as is the angle it ſubtends; or bodies ſeen under a greater angle appear greater; and thoſe under a leſs angle leſs, &c. Hence the ſame thing appears greater or leſs as it is nearer the eye or farther off. And this is called the apparent magnitude.

But to judge of the real magnitude of an object, we muſt conſider the diſtance; for ſince a near and a remote object may appear under equal angles, though the magnitudes be different, the diſtance muſt neceſſarily be eſtimated, becauſe the magnitude is great or ſmall according as the diſtance is. So that the real magnitude is in the compound ratio of the diſtance and the apparent magnitude; at leaſt when the ſubtended angle, or apparent magnitude, is very ſmall; otherwiſe, the real magnitude will be in a ratio compounded of the diſtance and the ſine of the apparent magnitude, nearly, or nearer ſtill its tangent.

Hence, objects ſeen under the ſame angle, have their magnitudes in the ſame ratio as their diſtances. The chord of an arc of a circle appears of equal magnitude from every point in the circumference, though one point be vaſtly nearer than another. Or if the eye be fixed in any point in the circumference, and a right line be moved round ſo as its extremes be always in the periphery, it will appear of the ſame magnitude in every poſition. And the reaſon is, becauſe the angle it ſubtends is always of the ſame magnitude. And hence alſo, the eye being placed in any angle of a regular polygon, the ſides of it will all appear of equal magnitude; being all equal chords of a circle deſcribed about it.

If the magnitude of an object directly oppoſite to the eye be equal to its diſtance from the eye, the whole object will be diſtinctly ſeen, or taken in by the eye, but nothing more. And the nearer you approach an object; the leſs part you ſee of it.

The leaſt angle under which an ordinary object becomes viſible, is about one minute of a degree.

Of the Figure of Viſible Objects.

This is eſtimated chiefly from our opinion of the ſituation of the ſeveral parts of the object. This opinion of the ſituation, &c, enables the mind to apprehend an external object under this or that figure, more juſtly than any ſimilitude of the images in the retina, with the object can; the images being often elliptical, oblong, &c, when the objects they exhibit to the mind are circles, or ſquares, &c.

The laws of viſion, with regard to the figures of Viſible objects, are,

1. That if the centre of the eye be exactly in the direction of a right line, the line will appear only as a point.

2. If the eye be placed in the direction of a ſurface, it will appear only as a line.

3. If a body be oppoſed directly towards the eye, ſo as only one plane of the ſurface can radiate on it, the body will appear as a ſurface.

4. A remote arch, viewed by an eye in the ſame plane with it, will appear as a right line.

5. A ſphere, viewed at a diſtance, appears a circle.

6. Angular figures, at a diſtance, appear round.

7. If the eye look obliquely on the centre of a regular figure, or a circle, the true figure will not be ſeen; but the circle will appear oval, &c.

VISIBLE *Horizon, Place, &c.* See the ſubſtantives.

VISION, is the act of ſeeing, or of perceiving external objects by the organ of ſight.

When an object is ſo diſpoſed, that the rays of light, coming from all parts of it, enter the pupil of the eye, and preſent its image on the retina, that object is then ſeen. This is proved by experiment; for if the eye of any animal be taken out, and the ſkin and fat be carefully ſtripped off from the back part of it, till only the thin membrane, which is called the retina, remains to terminate it behind, and any object be placed before the front of the eye, the picture of that object will be ſeen figured as with a pencil on that membrane. There are thouſands of experiments which prove that this is the mechanical effect of Viſion, or ſeeing, but none of them all appear ſo conveniently as this, which is made with the very eye itſelf of an animal; an eye of an ox newly killed ſhews this happily, and with very little trouble. It will indeed appear ſingular in this, that the object is inverted, in the picture thus drawn of it, in the eye; and the caſe is the ſame in the eye of a living perſon.

Various other opinions however have been held concerning the means of Viſion among philoſophers.

The Platoniſts and Stoics held Viſion to be effected by the emiſſion of rays out of the eyes; conceiving that there was a ſort of light thus darted out; which, with the light of the external air, taking hold as it were of the objects, rendered them viſible; and thus returning back again to the eye, altered and new modified by the contact of the object, made an impreſſion on the pupil, which gave the ſenſation of the object.

Our own countryman, Roger Bacon, diſtinguiſhed as he was in many reſpects, alſo aſſents to the opinion that viſual rays proceed from the eye; giving this reaſon for it, that every thing in nature is qualified to diſcharge its proper functions by its own powers, in the ſame manner as the ſun, and other celeſtial bodies. Opus Majus, pa. 289.

The Epicureans held, that Viſion is performed by the emanation of corporeal ſpecies or images from objects; or a ſort of atomical effluvia continually flying off from the intimate parts of objects, to the eye.

The Peripatetics hold, with Epicurus, that Viſion is performed by the reception of ſpecies; but they differ from him in the circumſtances; for they will have the ſpecies (which they call *intentionales*) to be incorporeal. It is true, Ariſtotle's doctrine of Viſion, delivered in his chapter De Aſpectu, amounts to no more than this, that objects muſt have ſome intermediate body, that by this they may move the organ of ſight. To which he adds, in another place, that when we perceive bodies, it is their ſpecies, not their matter, that we receive; as a ſeal makes an impreſſion on wax, without the wax receiving any thing of the ſeal.

But this vague and obſcure account the Peripatetics have thought fit to improve. Accordingly, what their maſter calls ſpecies, the diſciples, underſtanding of real proper ſpecies, aſſert, that every viſible object expreſſes a perfect image of itſelf in the air contiguous to it; and this image another, ſomewhat leſs, in the next air; and the third another; and ſo on till the laſt image arrives at the cryſtalline, which they hold for the chief organ of ſight, or that which immediately moves the ſoul. Theſe images they call *intentional ſpecies*.

The modern philoſophers, as the Carteſians and Newtonians, give a better account of Viſion. They all agree, that it is performed by rays of light reflected from the ſeveral points of objects received in at the pupil, refracted and collected in their paſſage, through the coats and humours, to the retina; and this ſtriking, or making an impreſſion, on ſo many points of it; which impreſſion is conveyed, by the correſpondent capillaments of the optic nerve, to the brain, &c.

Baptiſta Porta's experiments with the camera obſcura, about the middle of the 16th century, convinced him that viſion is performed by the intermiſſion of ſomething into the eye, and not by viſual rays proceeding from the eye, as had been the general opinion before his time; and he was the firſt who fully ſatisfied himſelf and others upon this ſubject; though ſeveral philoſophers ſtill adhered to the old opinion.

As for the Peripatetic ſeries or chain of images, it is a mere chimera; and Ariſtotle's meaning is better underſtood without than with them. In fact, ſetting theſe aſide, the Ariſtotelian, Carteſian, and Newtonian doctrines of Viſion, are very conſiſtent with one another; for Newton imagines that Viſion is performed chiefly by the vibrations of a fine medium (which penetrates all bodies) excited in the bottom of the eye by the rays of light, and propagated through the capillaments of the optic nerves, to the ſenſorium. And Des Cartes maintains, that the ſun preſſing the materia ſubtilis, with which the whole univerſe is every where filled, the vibrations and pulſes of that matter reflected from objects, are communicated to the eye, and thence to the ſenſory; ſo that the action or vibration of a medium is equally ſuppoſed in all.

It is generally concluded then, that the images of objects are repreſented on the retina; which is only an expanſion of the fine capillaments of the optic nerve, and from whence the optic nerve is continued into the brain. Now any motion or vibration, impreſſed on one extremity of the nerve, will be propagated to the other: hence the impulſe of the ſeveral rays, ſent from the ſeveral points of the object, will be propagated as they are on the retina (that is, in their proper colours, &c, or in particular vibrations, or modes of preſſure, correſponding to them) to the place where thoſe capillaments are interwoven into the ſubſtance of the brain. And thus is Viſion brought to the common caſe of ſenſation.

Experience teaches us that the eye is capable of viewing objects at a certain diſtance, without any mental exertion. Beyond this diſtance, no mental exertion can be of any avail: but, within it, the eye poſſeſſes a power of adapting itſelf to the various occaſions that occur, the exerciſe of which depends on the volition of the mind. How this is effected, is a problem that has very much engaged the attention of optical writers: but it is doubted whether it has yet been ſatisfactorily explained. The firſt theory for the ſolution of this problem is that of Kepler. He ſuppoſes that the ciliary proceſſes contract the diameter of the eye, and lengthen its axis by a muſcular power. But Mr. Thomas Young (in ſome ingenious Obſervations on Viſion in the Philoſ. Tranſ. 1793) obſerves,

ſerves, that theſe proceſſes neither appear to contain any muſcular fibres, nor have any attachment by which they can be capable of performing this action.

Des Cartes aſcribed this contraction and elongation to a muſcularity of the cryſtalline, of which he ſuppoſed the ciliary proceſſes to be the tendons: but he neither demonſtrated this muſcularity, nor ſufficiently conſidered the connection with the ciliary proceſſes.

De la Hire allows of no change in the eye, except the contraction and dilatation of the pupil: this opinion he founds on an experiment which Dr. Smith has ſhewn to be fallacious. Haller adopted his hypotheſis, notwithſtanding its inconſiſtency with the principles of optics and conſtant experience.

Dr. Pemberton ſuppoſes that the cryſtalline contains muſcular fibres, by which one of its ſurfaces is flattened, while the other is made convex: but he has not demonſtrated the exiſtence of theſe fibres; and Dr. Jurin has proved that ſuch a change as this is inadequate to the effect.

Dr. Porterfield conceives that the ciliary proceſſes draw the cryſtalline forward, and make the cornea more convex. But the ciliary proceſſes are incapable of this action; and it appears from Dr. Jurin's calculations, that a ſufficient motion of this kind requires a very viſible increaſe in the length of the axis of the eye; an increaſe which has never yet been obſerved.

Dr. Jurin maintains that the uvea, at its attachment to the cornea, is muſcular; and that the contraction of this ring makes the cornea more convex. But this hypotheſis is not ſufficiently confirmed by obſervation.

Muſſchenbroek conjectures that the relaxation of this ciliary zone, which is nothing but the capſule of the vitreous humour where it receives the impreſſion of the ciliary proceſſes, permits the coats of the eye to puſh forward the cryſtalline and cornea. Such a voluntary relaxation however, Mr. Young obſerves, is wholly without example in the animal economy: beſides, if it actually occurred, the coats of the eye could not act as he conceives; nor could they act in this manner without being obſerved. He adds, that the contraction of the ciliary zone is equally inadequate and unneceſſary.

Mr. Young, having examined theſe theories, and ſome others of leſs moment, proceeds to inveſtigate a more probable ſolution of this optical difficulty.—Adverting to the obſervation of Dr. Porterfield, that thoſe who have been couched have not the power of accommodating the eye to different diſtances; and to the reflections of other writers on this ſubject; he was led to conclude that the rays of light, emitted by objects at a ſmall diſtance, could only be brought to foci on the retina by a nearer approach of the cryſtalline to a ſpherical form; and he imagined that no other power was capable of producing this change, beſide a muſcularity of part, or of the whole of its capſule:—but, on cloſely examining firſt with the naked eye and then with a magnifier, the cryſtalline of an ox's eye turned out of its capſule, he diſcovered a ſtructure which ſeemed to remove the difficulties that have long embarraſſed this branch of optics.

"The cryſtalline of the ox, ſays he, is compoſed of various ſimilar coats, each of which conſiſts of ſix muſcles, intermixed with a gelatinous ſubſtance, and attached to ſix membranous tendons. Three of the tendons are anterior, three poſterior; their length is about two-thirds of the ſemidiameter of the coat; their arrangement is that of three equal and equidiſtant rays, meeting in the axis of the cryſtalline; one of the anterior is directed towards the outer angle of the eye, and one of the poſterior towards the inner angle, ſo that the poſterior are placed oppoſite to the middle of the interſtices of the anterior: and planes paſſing through each of the ſix, and through the axis, would mark on either ſurface ſix regular equidiſtant rays. The muſcular fibres ariſe from both ſides of each tendon; they diverge till they reach the greateſt circumference of the coat; and, having paſſed it, they again converge, till they are attached reſpectively to the ſides of the neareſt tendons of the oppoſite ſurface. The anterior or poſterior portion of the ſix, viewed together, exhibits the appearance of three penniform-radiated muſcles. The anterior tendons of all the coats are ſituated in the ſame planes, and the poſterior ones in the continuations of theſe planes beyond the axis. Such an arrangement of fibres can be accounted for on no other ſuppoſition than that of muſcularity. This maſs is incloſed in a ſtrong membranous capſule, to which it is looſely connected by minute veſſels and nerves; and the connection is more obſervable near its greateſt circumference. Between the maſs and its capſule is found a conſiderable quantity of an aqueous fluid, the liquid of the cryſtalline.

"When the will is exerted to view an object at a ſmall diſtance, the influence of the mind is conveyed through the lenticular ganglion, formed from branches of the third and fifth pair of nerves by the filaments perforating the ſclerotica, to the orbiculus ciliaris, which may be conſidered as an annular plexus of nerves and veſſels; and thence by the ciliary proceſſes to the muſcle of the cryſtalline, which, by the contraction of its fibres, becomes more convex, and collects the diverging rays to a focus on the retina. The diſpoſition of fibres in each coat is admirably adapted to produce this change; for, ſince the leaſt ſurface that can contain a given bulk is that of a ſphere (Simpſon's Fluxions, pa. 486) the contraction of any ſurface muſt bring its contents nearer to a ſpherical form. The liquid of the cryſtalline ſeems to ſerve as a ſynovia in facilitating the motion, and to admit a ſufficient change of the muſcular part, with a ſmaller motion of the capſule.

Mr. Young proceeds to enquire whether theſe fibres can produce an alteration in the form of the lens ſufficiently great to account for the known effects; and he finds, by calculation, that, ſuppoſing the cryſtalline to aſſume a ſpherical form, its diameter will be 642 thouſandths of an inch, and its focal diſtance in the eye 926. Then, diſregarding the thickneſs of the cornea, we find (by Smith, art. 370) that ſuch an eye will collect thoſe rays on the retina, which diverge from a point at the diſtance of 12 inches and 8 tenths. This is a greater change than is neceſſary for an ox's eye; for if it be ſuppoſed capable of diſtinct Viſion at a diſtance ſomewhat leſs than 12 inches, yet it is probably far ſhort of being able to collect parallel rays. The human cryſtalline is ſuſceptible of a much greater change of form. The ciliary zone may admit of as much extenſion as this diminution of the diameter of the cryſtal-

line will require; and its elaſticity will aſſiſt the cellular texture of the vitreous humour, and perhaps the gelatinous part of the cryſtalline, in reſtoring the indolent form.—Mr. Young apprehends that the ſole office of the optic nerve is to convey ſenſation to the brain; and that the retina does not contribute to ſupply the lens with nerves.—As the human cryſtalline reſembles that of the ox, it may reaſonably be preſumed that the action of both organs depends on the ſame general principles.

This theory of Mr. Young's however is ſtrongly oppoſed by Dr. Hoſack, (Philoſ. Tranſ. 1794, part 2, pa. 196). He conteſts the exiſtence of the muſcles, which Mr. Young has deſcribed, for ſeveral reaſons. Firſt, from the tranſparency they muſt poſſeſs; otherwiſe there would be ſome irregularity in the refraction of thoſe rays which paſs through the ſeveral parts, differing both in ſhape and denſity. Another circumſtance is the number of theſe muſcles. Mr. Young deſcribes 6 in each lamina; and as Leuwenhoek makes 2000 laminæ in all, therefore the number of muſcles muſt amount to 12 thouſand, the action of which, Dr. Hoſack apprehends, muſt exceed comprehenſion. But the exiſtence of theſe muſcles is ſtill more doubtful, if the accuracy of Dr. Hoſack's obſervations be admitted. With the aſſiſtance of the beſt glaſſes, and with the greateſt attention, he could not diſcover the ſtructure of the cryſtalline deſcribed by Mr. Young, but found it to be perfectly tranſparent. He firſt obſerved the lens in its viſcid ſtate, and then expoſed different lenſes to a moderate degree of heat, ſo that they became opaque and dry; and it was eaſy to ſeparate the diſtinct layers deſcribed by Mr. Young. Theſe were ſo numerous as not to admit of having, each of them, 6 muſcles. Another conſideration, which ſeems to prove that theſe layers poſſeſs no diſtinct muſcles, is that, in this opaque ſtate, they are not viſible, but conſiſt of an almoſt infinite number of concentric fibres, not divided into particular bundles, but ſimilar to as many of the fineſt hairs of equal thickneſs, arranged in ſimilar order. This regular ſtructure of layers, compoſed of concentric fibres, Dr. Hoſack thinks is much better adapted to the tranſmiſſion of the rays of light than the irregular ſtructure of muſcles. Beſides, it ought to be conſidered that the cryſtalline lens is not the moſt eſſential organ in viewing objects at different diſtances; and if this be the caſe, the power of the eye cannot be owing to any changes in this lens. It is a fact, ſays Dr. Hoſack, that we can, in a great degree, do without it; as is the caſe after couching or extraction, by which operation all its parts muſt be deſtroyed. Dr. Porterfield, however, and Mr. Young, on his authority, maintain that patients, after the operation of couching, have not the power of accommodating the eye to different diſtances of objects. On the whole, Dr. Hoſack concludes that no ſuch muſcles, as Mr. Young has deſcribed, exiſt, and that he muſt have been deceived by ſome other appearances that reſembled muſcles: neither will he allow the effects aſcribed to the ciliary proceſſes in changing the ſhape or ſituation of the lens.

Dr. Hoſack then proceeds to illuſtrate the ſtructure and uſe of the external muſcles of the eye; which are 6 in number, 4 called recti or ſtraight, and 2 oblique, and by means of which he thinks the buſineſs is effected. The common purpoſes to which theſe muſcles are ſubſervient are well known: but beſide theſe, Dr. Hoſack ſuggeſts that it is not inconſiſtent with the general laws of nature, nor even with the animal œconomy, to imagine that, from their combination, they ſhould have a different action and an additional uſe. In deſcribing the preciſe action of theſe muſcles, he ſuppoſes an object to be ſeen diſtinctly firſt at the diſtance of 6 feet; in which caſe the picture of it falls exactly on the retina. He then directs his attention to another object at the diſtance of 6 inches, as nearly as poſſible in the ſame line. While he is viewing this, he loſes ſight of the firſt object, though the rays proceeding from it ſtill fall on the eye; and hence he infers that the eye muſt have undergone ſome change; ſo that the rays meet either before or behind the retina. But, as rays from a more diſtant object concur ſooner than thoſe from a nearer one, the picture of the more remote object muſt fall before the retina, while the others form a diſtinct image upon it. But yet the eye continued in the ſame place; and therefore the retina muſt, by ſome means, have been removed to a greater diſtance from the forepart of the eye, ſo as to receive the picture of the nearer object. This object, he contends, could not be ſeen diſtinctly, unleſs the retina were removed to a greater diſtance, or the refracting power of the media through which the rays paſſed were augmented:—but as the lens is the chief refracting medium, if we admit that this has no power of changing itſelf, we are under the neceſſity of adopting the firſt of theſe two ſuppoſitions.

The next object of inquiry is, how the external muſcles are capable of producing theſe changes. The recti are ſtrong, broad, and flat, and ariſe from the back part of the orbit of the eye; and, paſſing over the ball as over a pulley, they are inſerted by broad flat tendons at the anterior part of the eye. The oblique are inſerted towards the poſterior part by ſimilar tendons. When theſe different muſcles act jointly, the eye being in the horizontal poſition, and every muſcle in action contracting itſelf, the four recti by their combination muſt compreſs the various parts of the eye and lengthen its axis, while the oblique muſcles ſerve to keep the eye in its proper direction and ſituation. The convexity of the cornea, by means of its great elaſticity, is alſo increaſed in proportion to the degree of preſſure, and thus the rays of light paſſing through it are neceſſarily more converged. The elongation of the eye ſerves alſo to lengthen the media, in the aqueous, cryſtalline, and vitreous humours through which the rays paſs, ſo that their powers of refraction are proportionably increaſed. This is the general effect of the contraction of the external muſcles, according to Dr. Hoſack's ſtatement of it: to which it may be added, that we poſſeſs the ſame power of relaxing them in proportion to the greater diſtance of the object, till we arrive at the utmoſt extent of indolent Viſion. Dr. Hoſack alſo illuſtrates this hypotheſis by ſome experiments.

The miſrepreſentations of Viſion often depend upon the diſtance of the object. Thus, if an opake globe be placed at a moderate diſtance from the eye, the picture of it upon the retina will be a circle properly diverſified with light and ſhade, ſo that it will excite in the mind the ſenſation of a ſphere or globe; but, if the

the globe be placed at a great diſtance from the eye, the diſtance between thoſe lights and ſhades, which form the picture of a globe, will be imperceptible, and the globe will appear no otherwiſe than as a circular plane. In a luminous globe, diſtance is not neceſſary in order to take off the repreſentation of prominent and flat; an iron bullet, heated very red hot, and held but a few yards diſtance from the eye, appears a plane, not a prominent body; it has not the look of a globe, but of a circular plane. It is owing to this miſrepreſentation of Viſion that we ſee the ſun and moon flat by the naked eye, and the planets alſo, through teleſcopes, flat. It is in this light that aſtronomers, when they ſpeak of the ſun, moon, and planets, as they appear to our view, call them the diſcs of the ſun, moon, and planets, which we ſee.

The nearer a globe is to the eye, the ſmaller ſegment of it is viſible, the farther off the greater, and at a due diſtance the half; and, on the ſame principle, the nearer the globe is to the eye, the greater is its apparent diameter, that is, under the greater angle it will appear, the farther off the globe is placed, the leſs is its apparent diameter. This is a propoſition of importance, for, on this principle, we know that the ſame globe, when it appears larger, is nearer to our eye, and, when ſmaller, is farther off from it. Therefore, as we know that the globes of the ſun and moon continue always of the ſame ſize, yet appear ſometimes larger, and ſometimes ſmaller, to us, it is evident, that they are ſometimes nearer, and ſometimes farther off from the place whence we view them. Two globes, of different magnitude, may be made to appear of exactly the ſame diameter, if they be placed at different diſtances, and thoſe diſtances be exactly proportioned to their diameters. To this it is owing, that we ſee the ſun and moon nearly of the ſame diameter; they are, indeed, vaſtly different in real bulk, but, as the moon is placed greatly nearer to our eyes, the apparent magnitude of that little globe is nearly the ſame with that of the greater.

In this inſtance of the ſun and moon (for there cannot be a more ſtriking one) we ſee the miſrepreſentation of Viſion in two or three ſeveral ways. The apparent diameters of theſe globes are ſo nearly equal, that, in their ſeveral changes of place, they do, at times, appear to us abſolutely equal, or mutually greater than one another. This is often to be ſeen, but it is at no time ſo obvious, and ſo perfectly evinced, as in eclipſes of the ſun, which are total. In theſe we ſee the apparent magnitudes of the two globes vary ſo much according to their diſtances, that ſometimes the moon is large enough exactly to cover the diſc of the ſun, ſometimes it is larger, and a part of it every where extends beyond the diſc of the ſun; and, on the contrary, ſometimes it is ſmaller, and, though the eclipſe be abſolutely central, yet it is annular, or a part of the ſun's diſc is ſeen in the middle of the eclipſed part, enlightened, and ſurrounding the opake body of the moon in form of a lucid ring.

When an object, which is ſeen above, without other objects of compariſon, is of a known magnitude, we judge of its diſtance by its apparent magnitude; and cuſtom teaches us to do this with tolerable accuracy. This is a practical uſe of the miſrepreſentation of Viſion, and in the ſame manner, knowing that we ſee things, which are near us, diſtinctly, and thoſe which are diſtant, confuſedly, we judge of the diſtance of an object by the clearneſs, or confuſion, in which we ſee it. We alſo judge yet more eaſily and truly of the diſtance of an object by comparing it to another ſeen at the ſame time, the diſtance of which is better known, and yet more by comparing it with ſeveral others, the diſtances of which are more or leſs known, or more or leſs eaſily judged of. Theſe are the circumſtances which aſſiſt us, even by the miſrepreſentation of Viſion, to judge of diſtance; but, without one or more of theſe, the eye does not, in reality, enable us to judge concerning the diſtance of objects.

This miſrepreſentation, although it ſerves us on ſome occaſions, yet is very limited in its effects. Thus, though it helps us greatly in diſtinguiſhing the diſtance of objects that are about us, both with reſpect to ourſelves and them, and with reſpect to themſelves with one another, yet it can do nothing with the very remote. We ſee that immenſe concave circle, in which we ſuppoſe the fixed ſtars to be placed, at all this vaſt remove from us, and no change of place that we could make to get nearer to it, would be of any avail for determining the diſtance of the ſtars from one another. If we look at three or four churches from a diſtance of as many miles, we ſee them ſtand in a certain poſition with regard to one another. If we advance a great deal nearer to them, we ſee that poſition differ, but, if we move forward only eight or ten feet, the difference is not ſeen.

VISION, in Optics. The laws of Viſion, brought under mathematical demonſtrations, make the ſubject of Optics, taken in the greateſt latitude of that word; for, among mathematical writers, optics is generally taken, in a more reſtricted ſignification, for the doctrine of *direct Viſion*; catoptrics, for the doctrine of *reflected Viſion*; and dioptrics, for that of *refracted Viſion*.

Direct or *Simple* VISION, is that which is performed by means of direct rays; that is, of rays paſſing directly, or in right lines, from the radiant point to the eye. Such is that explained in the preceding article VISION.

Reflected VISION, is that which is performed by rays reflected from ſpeculums, or mirrors. The laws of which, ſee under REFLECTION, and MIRROR.

Refracted VISION, is that which is performed by means of rays refracted, or turned out of their way, by paſſing through mediums of different denſity; chiefly through glaſſes and lenſes. The laws of this, ſee under the article REFRACTION.

Arch of VISION. See ARCH.

Diſtinct VISION, is that by which an object is ſeen diſtinctly. An object is ſaid to be ſeen diſtinctly, when its outlines appear clear and well defined, and the ſeveral parts of it, if not too ſmall, are plainly diſtinguiſhable, ſo that they can eaſily be compared one with another, in reſpect to their figure, ſize, and colour.

In order to ſuch Diſtinct Viſion, it had commonly been thought that all the rays of a pencil, flowing from a phyſical point of an object, muſt be exactly united in a phyſical, or at leaſt in a ſenſible point of the retina. But Dr. Jurin has made it appear from experiments, that ſuch an exact union of rays is not always neceſſary

to Diſtinct Viſion. He ſhews that objects may be ſeen with ſufficient diſtinctneſs, though the pencils of rays iſſuing from the points of them do not unite preciſely in the ſame point on the retina; but that ſince, in this caſe, pencils from every point either meet before they reach the retina, or tend to meet beyond it, the light that comes from them muſt cover a circular ſpot upon it, and will therefore paint the image larger than perfect Viſion would repreſent it. Whence it follows, that every object placed either too near or too remote for perfect Viſion, will appear larger than it is by a penumbra of light, cauſed by the circular ſpaces, which are illuminated by pencils of rays proceeding from the extremities of the object.

The ſmalleſt diſtance of perfect Viſion, or that in which the rays of a ſingle pencil are collected into a phyſical point on the retina in the generality of eyes, Dr. Jurin, from a number of obſervations, ſtates at 5, 6, or 7 inches. The greateſt diſtance of diſtinct and perfect Viſion he found was more difficult to determine; but by conſidering the proportion of all the parts of the eye, and the refractive power of each, with the interval that may be diſcerned between two ſtars, the diſtance of which is known, he fixes it, in ſome caſes, at 14 feet 5 inches; though Dr. Porterfield had reſtricted it to 27 inches only, with reſpect to his own eye.

For other obſervations on this ſubject, ſee Jurin's Eſſay on Diſtinct and Indiſtinct Viſion, at the end of Smith's Optics; and Robins's Remarks on the ſame, in his Math. Tracts, vol. 2, pa. 278 &c. See alſo an ingenious paper on Viſion in the Philoſ. Tranſ. 1793, pa. 169, by Mr. Thomas Young.

Field of VISION. See FIELD.

VISUAL, relating to ſight, or ſeeing.

VISUAL *Angle*, is the angle under which an object is ſeen, or which it ſubtends. See ANGLE.

VISUAL *Line*. See LINE.

VISUAL *Point*, in Perſpective, is a point in the horizontal line, where all the ocular rays unite. Thus, a perſon ſtanding in a ſtraight long gallery, and looking forward; the ſides, floor, and cieling ſeem to meet and touch one another in this point, or common centre.

VISUAL *Rays*, are lines of light, conceived to come from an object to the eye.

VITELLIO, or VITELLO, a Poliſh mathematician of the 13th century, as he flouriſhed about 1254. We have of his a large *Treatiſe on Optics*, the beſt edition of which is that of 1572. Vitello was the firſt optical writer of any conſequence among the modern Europeans. He collected all that was given by Euclid, Archimedes, Ptolomy, and Alhazen; though his work is of but little uſe now.

VITREOUS *Humour*, or *Vitreus Humor*, denotes the third or glaſſy humour of the eye; thus called from its reſemblance to melted glaſs. It lies under the cryſtalline; by the impreſſion of which, its forepart is rendered concave. It greatly exceeds in quantity both the aqueous and cryſtalline humours taken together, and conſequently occupies much the greateſt part of the cavity of the globe of the eye. Scheiner ſays, that the refractive power of this humour is a medium between thoſe of the aqueous, which does not differ much from water, and of the cryſtalline, which is nearly the ſame with glaſs. Hawkſbee makes its refractive power the ſame with that of water; and, according to Robertſon, its ſpecific gravity agrees nearly with that of water.

VITRUVIUS (MARCUS VITRUVIUS POLLIO), a celebrated Roman architect, of whom however nothing is known, but what is to be collected from his ten books *De Architectura*, ſtill extant. In the preface to the ſixth book he writes, that he was carefully educated by his parents, and inſtructed in the whole circle of arts and ſciences; a circumſtance which he ſpeaks of with much gratitude, laying it down as certain, that no man can be a complete architect, without ſome knowledge and ſkill in every one of them. And in the preface to the firſt book he informs us, that he was known to Julius Cæſar; that he was afterwards recommended by Octavia to her brother Auguſtus Cæſar; and that he was ſo favoured and provided for by this emperor, as to be out of all fear of poverty as long as he might live.

It is ſuppoſed that Vitruvius was born either at Rome or Verona; but it is not known which. His books of architecture are addreſſed to Auguſtus Cæſar, and not only ſhew conſummate ſkill in that particular ſcience, but alſo very uncommon genius and natural abilities. Cardan, in his 16th book *De Subtilitate*, ranks Vitruvius as one of the 12 perſons, whom he ſuppoſes to have excelled all men in the force of genius and invention; and would not have ſcrupled to have given him the firſt place, if it could be imagined that he had delivered nothing but his own diſcoveries. Thoſe 12 perſons were, Euclid, Archimedes, Apollonius Pergæus, Ariſtotle, Archytas of Tarentum, Vitruvius, Achindus, Mahomet Ibn Moſes the inventor or improver of Algebra, Duns Scotus, John Suiſſet furnamed the Calculator, Galen, and Heber of Spain.

The architecture of Vitruvius has been often printed; but the beſt edition is that of Amſterdam in 1649. Perrault alſo, the noted French architect, gave an excellent French tranſlation of the ſame, and added notes and figures: the firſt edition of which was publiſhed at Paris in 1673, and the ſecond much improved, in 1684.—Mr. William Newton too, an ingenious architect, and late Surveyor to the works at Greenwich Hoſpital, publiſhed in 1780 &c. curious commentaries on Vitruvius, illuſtrated with figures; to which is added a deſcription, with figures, of the Military Machines uſed by the Ancients.

VIVIANI (VINCENTIO), a celebrated Italian mathematician, was born at Florence in 1621, ſome ſay 1622. He was a diſciple of the illuſtrious Galileo, and lived with him from the 17th to the 20th year of his age. After the death of his great maſter, he paſſed two or three years more in proſecuting geometrical ſtudies without interruption, and in this time it was that he formed the deſign of his Reſtoration of Ariſtæus. This ancient geometrician, who was contemporary with Euclid, had compoſed five books of problems *De Locis Solidis*, the bare propoſitions of which were collected by Pappus, but the books are entirely loſt; which Viviani undertook to reſtore by the force of his genius.

He broke this work off before it was finiſhed, in order to apply himſelf to another of the ſame kind, and that

that was, to reſtore the 5th book of Apollonius's Conic Sections. While he was engaged in this, the famous Borelli found, in the library of the Grand Duke of Tuſcany, an Arabic manuſcript, with a Latin inſcription, which imported, that it contained the eight books of Apollonius's Conic Sections: of which the 8th however was not found to be there. He carried this manuſcript to Rome, in order to tranſlate it, with the aſſiſtance of a profeſſor of the Oriental languages. Viviani, very unwilling to loſe the fruits of his labours, procured a certificate that he did not underſtand the Arabic language, and knew nothing of that manuſcript: he was ſo jealous on this head, that he would not even ſuffer Borelli to ſend him an account of any thing relating to it. At length he finiſhed his book, and publiſhed it, 1659, in folio, with this title, *De Maximis & Minimis Geometrica Divinatio in quintum Conicorum Apollonii Pergæi.* It was found that he had more than divined; as he ſeemed ſuperior to Apollonius himſelf.

After this he was obliged to interrupt his ſtudies for the ſervice of his prince, in an affair of great importance, which was, to prevent the inundations of the Tiber, in which Caſſini and he were employed for ſome time, though nothing was entirely executed.

In 1664 he had the honour of a penſion from Louis the 14th, a prince to whom he was not ſubject, nor could be uſeful. In conſequence he reſolved to finiſh his Divination upon Ariſteus, with a view to dedicate it to that prince; but he was interrupted in this taſk again by public works, and ſome negotiations which his maſter entruſted to him.—In 1666 he was honoured by the Grand Duke with the title of his firſt mathematician.—He reſolved three problems, which had been propoſed to all the mathematicians of Europe, and dedicated the work to the memory of Mr. Chapelain, under the title of *Enodatio Problematum* &c.—He propoſed the problem of the quadrable arc, of which Leibnitz and l'Hoſpital gave ſolutions by the Calculus Differentialis.—In 1669, he was choſen to fill, in the Royal Academy of Sciences, a place among the eight foreign aſſociates. This new favour reanimated his zeal; and he publiſhed three books of his Divination upon Ariſteus, at Florence in 1701, which he dedicated to the King of France. It is a thin folio, intitled, *De Locis Solidis ſecunda Divinatio Geometrica*, &c. This was a ſecond edition enlarged; the firſt having been printed at Florence in 1673.—Viviani laid out the fortune, which he had raiſed by the bounties of his prince, in building a magnificent houſe at Florence; in which he placed a buſt of Galileo, with ſeveral inſcriptions in honour of that great man; and died in 1703, at 81 years of age.

Viviani had, ſays Fontenelle, that innocence and ſimplicity of manners which perſons commonly preſerve, who have leſs commerce with men than with books; without that roughneſs and a certain ſavage fierceneſs which thoſe often acquire who have only to deal with books, not with men. He was affable, modeſt, a faſt and faithful friend, and, what includes many virtues in one, he was grateful in the higheſt degree for favours.

ULLAGE, *of a Caſk*, in Gauging, is ſo much as it wants of being full.

ULTERIOR, in Geography, is applied to ſome part of a country or province, which, with regard to the reſt of that country, is ſituate on the farther ſide of a river, or mountain, or other boundary, which divides the country into two parts.

ULTRAMUNDANE, beyond the world, is that part of the univerſe ſuppoſed to be without or beyond the limits of our world or ſyſtem.

UMBILICUS, and UMBILICAL *Point*, in Geometry, the ſame with focus.

UMBRA, a Shadow. See LIGHT, SHADOW, PENUMBRA, &c.

UNCIA, a term generally uſed for the 12th part of a thing. In which ſenſe it occurs in Latin writers, both for a weight, called by us an *ounce*, and a meaſure called an *inch*.

UNCIÆ, in Algebra, firſt uſed by Vieta, are the numbers prefixed to the letters in the terms of any power of a binomial; now more uſually, and generally, called *coefficients*. Thus, in the 4th power of $a + b$, viz,

$$a^4 + 4a^3b + 6a^2b^2 + 4ab^3 + b^4,$$

the Unciæ are 1, 4, 6, 4, 1.

Briggs firſt ſhewed how to find theſe Unciæ, one from another, in any power, independent of the foregoing powers. They are now uſually found by what is called Newton's binomial theorem, which is the ſame rule as Briggs's in another form. See BINOMIAL.

UNDECAGON, is a polygon of eleven ſides.

If the ſide of a regular Undecagon be 1, its area will be $9{\cdot}3656399 = \frac{11}{4} \times$ tang. of $73\frac{7}{11}$ degrees; and therefore if this number be multiplied by the ſquare of the ſide of any other regular Undecagon, the product will be the area of that Undecagon. See my Menſuration, pa. 114 &c, 2d edit.

UNDETERMINED, is ſometimes uſed for INDETERMINATE.

UNDULATORY *Motion*, is applied to a motion in the air, by which its parts are agitated like the waves of the ſea; as is ſuppoſed to be the caſe when the ſtring of a muſical inſtrument is ſtruck. This Undulatory motion of the air is ſuppoſed the matter or cauſe of ſound.—Inſtead of the Undulatory, ſome authors chooſe to call this a *vibratory* motion.

UNEVEN *Number*, the ſame as odd number, or ſuch as cannot be divided by 2 without leaving 1 remaining. The ſeries of Uneven Numbers are 1, 3, 5, 7, 9, &c. See NUMBER, and ODD *Number*.

UNGULA, in Geometry, is a part cut off a cylinder, cone, &c, by a plane paſſing obliquely through the baſe, and part of the curve ſurface; ſo called from its reſemblance to the (ungula) hoof of a horſe &c. For the contents &c of ſuch Ungulas, ſee my Menſuration, pa. 218—246, 2d edition.

UNICORN, in Aſtronomy. See MONOCEROS.

UNIFORM, or *Equable Motion*, is that by which a body paſſes always with the ſame celerity, or over equal ſpaces in equal times. See MOTION.

In Uniform motions, the ſpaces deſcribed or paſſed over, are in the compound ratio of the times and velocities; but the ſpaces are ſimply as the times, when the velocity is given; and as the velocities, when the time is given.

UNIFORM *Matter*, in Natural Philoſophy, is that which is all of the ſame kind and texture.

UNISON, in Muſic, is when two ſounds are exactly alike, or the ſame note, or tone.

What conſtitutes a Uniſon, is the equality of the number of vibrations, made in the ſame time, by the two ſonorous bodies.

It is a noted phenomenon in muſic, that an intenſe ſound being raiſed, either with the voice, or a ſonorous body, another ſonorous body near it, whoſe tone is either Uniſon, or octave to that tone, will ſound its proper note Uniſon, or octave, to the given note. The experiment is eaſily tried with the ſtrings of two inſtruments; or with a voice and harpſichord; or a bell, or even a drinking glaſs.

This phenomenon is thus accounted for: one ſtring being ſtruck, and the air put into a vibratory motion by it; every other ſtring, within the reach of that motion, will receive ſome impreſſion from it: but each ſtring can only move with a determinate velocity of recourſes or vibrations; and all Uniſons proceed from equal vibrations; and other concords from other proportions of vibration. The Uniſon ſtring then, keeping equal pace with the ſounding ſtring, as having the ſame meaſure of vibrations, muſt have its motion continued, and ſtill improved, till at length its motion become ſenſible, and it give a diſtinct ſound. Other concording ſtrings have their motions propagated in different degrees, according to the frequency of the coincidence of their vibrations with thoſe of the founded ſtring: the octave therefore moſt ſenſibly; then the 5th; after which, the croſſing of the motions prevents any effect.

This is illuſtrated, as Galileo firſt ſuggeſted, by the pendulum, which being ſet a-moving, the motion may be continued and augmented, by making frequent, light, coincident impulſes; as blowing on it when the vibration is juſt finiſhed: but if it be touched by any croſs or oppoſite motion, and that frequently too, the motion will be interrupted, and ceaſe altogether. So, of two Uniſon ſtrings, if the one be forcibly ſtruck, it communicates motion, by the air, to the other; and both performing their vibrations together, the motion of that other will be improved and heightened by the frequent impulſes received from the vibrations of the firſt, becauſe given preciſely when the other has finiſhed its vibration, and is ready to return: but if the vibrations of the chords be unequal in duration, there will be a croſſing of motions, more or leſs, according to the proportion of the inequality; by which the motion of the untouched ſtring will be ſo checked, as never to be ſenſible. And this we find to be the caſe in all conſonances, except Uniſon, octave, and the fifth.

UNIT, UNITE, or UNITY, in Arithmetic, the number one, or one ſingle individual part of diſcrete quantity. See NUMBER.—The place of units, is the firſt place on the right hand in integer numbers.

According to Euclid, Unity is not a number, for he defines number to be a multitude of Units.

UNITY, the abſtract or quality which conſtitutes or denominates a thing *one*.

UNIVERSE, a collective name, ſignifying the aſſemblage of heaven and earth, with all things in them.

The Ancients, and after them the Carteſians, imagine the Univerſe to be infinite; and the reaſon they give is, that it implies a contradiction to ſuppoſe it finite or bounded; ſince it is impoſſible not to conceive ſpace beyond any limits that can be aſſigned it; which ſpace, according to the Carteſians, is body, and conſequently part of the Univerſe.

UNLIKE *Quantities*, in Algebra, are ſuch as are expreſſed by different letters, or by different powers of the ſame letter. Thus, a, and b, and a^2, and ab are all Unlike quantities.

UNLIKE *Signs*, are the different ſigns + and −.

UNLIMITED or *Indeterminate Problem*, is ſuch a one as admits of many, or even of infinite anſwers. As, to divide a given triangle into two equal parts, or to deſcribe a circle through two given points. See DIOPHANTINE, and INDETERMINATE.

VOID *Space*, in Phyſics. See VACUUM.

VOLUTE, in Architecture, a kind of ſpiral ſcroll, and uſed in the Ionic and Compoſite capitals; of which it makes the principal characteriſtic and ornament.

VORTEX, or *Whirlwind*, in Meteorology, a ſudden, rapid, violent motion of the air, in circular whirling directions.

VORTEX is alſo uſed for an eddy or whirlpool, or a body of water, in certain ſeas and rivers, which runs rapidly round, forming a ſort of cavity in the middle.

VORTEX, in the Carteſian Philoſophy, is a ſyſtem or collection of particles of matter moving the ſame way, and round the ſame axis.

Such Vortices are the grand machines by which theſe philoſophers ſolve moſt of the motions and other phenomena of the heavenly bodies. And accordingly, the doctrine of theſe Vortices makes a great part of the Carteſian philoſophy.

The matter of the world they hold to have been divided at the beginning into innumerable little equal particles, each endowed with an equal degree of motion, both about its own centre, and ſeparately, ſo as to conſtitute a fluid.

Several ſyſtems, or collections of this matter, they farther hold to have been endowed with a common motion about certain points, as common centres, placed at equal diſtances, and that the matters, moving round theſe, compoſed ſo many Vortices.

Then, the primitive particles of the matter they ſuppoſe, by theſe inteſtine motions, to become, as it were, ground into ſpherical figures, and ſo to compoſe globules of divers magnitudes; which they call the matter of the ſecond element: and the particles rubbed, or ground off them, to bring them to that form, they call the matter of the firſt element.

And ſince there would be more of the firſt element than would ſuffice to fill all the vacuities between the globules of the ſecond, they ſuppoſe the remaining part to be driven towards the centre of the Vortex, by the circular motion of the globules; and that being there amaſſed into a ſphere, it would produce a body like the ſun.

This ſun being thus formed, and moving about its own axis with the common matter of the Vortex, would neceſſarily throw out ſome parts of its matter, through the vacuities of the globules of the ſecond element conſtituting the Vortex; and this eſpecially at ſuch places as are fartheſt from its poles; receiving, at the ſame time,

in,

in, by theſe poles, as much as it loſes in its equatorial parts. And, by this means, it would be able to carry round with it thoſe globules that are neareſt, with the greater velocity; and the remoter, with leſs. And by this means, thoſe globules, which are neareſt the centre of the ſun, muſt be ſmalleſt; becauſe, were they greater, or equal, they would, by reaſon of their velocity, have a greater centrifugal force, and recede from the centre. If it ſhould happen, that any of theſe ſun-like bodies, in the centres of the ſeveral Vortices, ſhould be ſo incruſtated, and weakened, as to be carried about in the Vortex of the true ſun; if it were of leſs ſolidity, or had leſs motion, than the globules towards the extremity of the ſolar Vortex, it would deſcend towards the ſun, till it met with globules of the ſame ſolidity, and ſuſceptible of the ſame degree of motion with itſelf; and thus, being fixed there, it would be for ever after carried about by the motion of the Vortex, without either approaching any nearer to the ſun, or receding from it; and ſo would become a planet.

Suppoſing then all this; we are next to imagine, that our ſyſtem was at firſt divided into ſeveral Vortices, in the centre of each of which was a lucid ſpherical body; and that ſome of theſe, being gradually incruſtated, were ſwallowed up by others which were larger, and more powerful, till at length they were all deſtroyed, and ſwallowed up by the largeſt ſolar Vortex; except ſome few which were thrown off in right lines from one Vortex to another, and ſo become comets.

But this doctrine of Vortices is, at beſt, merely hypothetical. It does not pretend to ſhew by what laws and means the celeſtial motions are effected, ſo much as by what means they poſſibly might, in caſe it ſhould have ſo pleaſed the Creator. But we have another principle which accounts for the ſame phenomena as well, nay, better than that of Vortices; and which we plainly find has an actual exiſtence in the nature of things: and this is gravity, or the weight of bodies.

The Vortices, then, ſhould be thrown out of philoſophy, were it only that two different adequate cauſes of the ſame phenomena are inconſiſtent.

But there are other objections againſt them. For, 1°, if the bodies of the planets and comets be carried round the ſun in Vortices, the bodies with the parts of the Vortex immediately inveſting them, muſt move with the ſame velocity, and in the ſame direction; and beſides, they muſt have the ſame denſity, or the ſame vis inertiæ. But it is evident, that the planets and comets move in the very ſame parts of the heavens with different velocity, and in different directions. It follows, therefore, that thoſe parts of the Vortex muſt revolve at the ſame time, in different directions, and with different velocities; ſince one velocity, and direction, will be required for the paſſage of the planets, and another for that of the comets.

2°, If it were granted, that ſeveral Vortices are contained in the ſame ſpace, and do penetrate each other, and revolve with divers motions; ſince theſe motions muſt be conformable to thoſe of the bodies, which are perfectly regular, and performed in conic ſections; it may be aſked, How they ſhould have been preſerved entire ſo many ages, and not diſturbed and confounded by the adverſe actions and ſhocks of ſo much matter as they muſt meet withal?

3°, The number of comets is very great, and their motions are perfectly regular, obſerving the ſame laws with the planets, and moving in orbits, that are exceedingly eccentric. Accordingly, they move every way, and towards all parts of the heavens, freely pervading the planetary regions, and going frequently contrary to the order of the ſigns; which would be impoſſible unleſs theſe Vortices were away.

4°, If the planets move round the ſun in Vortices, thoſe parts of the Vortices next the planets, we have already obſerved, would be equally denſe with the planets themſelves: conſequently the vortical matter contiguous to the perimeter of the earth's orbit, would be as denſe as the earth itſelf: and that between the orbits of the earth and Saturn, muſt be as denſe, or denſer. For a Vortex cannot maintain itſelf, unleſs the more denſe parts be in the centre, and the leſs denſe towards the circumference: and ſince the periodical times of the planets are in ſeſquialterate ratio of their diſtances from the ſun, the parts of the Vortex muſt be in the ſame ratio. Whence it follows, that the centrifugal forces of the parts will be reciprocally as the ſquares of the diſtances. Such, therefore, as are at a greater diſtance from the centre, will endeavour to recede from it with the leſs force. Accordingly, if they be leſs denſe, they muſt give way to the greater force, by which the parts nearer the centre endeavour to riſe. Thus, the more denſe will riſe, and the leſs denſe deſcend; and thus there will be a change of places, till the whole fluid matter of the Vortex be ſo adjuſted as that it may reſt in equilibrio.

Thus will the greateſt part of the Vortex without the earth's orbit, have a degree of denſity and inactivity, not leſs than that of the earth itſelf. Whence the comets muſt meet with a very great reſiſtance, which is contrary to all appearances. Cotes, Præf. ad Newt. Princip. The doctrine of Vortices, Newton obſerves, labours under many difficulties: for a planet to deſcribe areas proportional to the times, the periodical times of a Vortex ſhould be in a duplicate ratio of their diſtances from the ſun; and for the periodical time of the planets, to be in a ſeſquiplicate proportion of their diſtances from the ſun, the periodical times of the parts of the Vortex ſhould be in the ſame proportion of their diſtances: and, laſtly, for the leſs Vortices about Jupiter, Saturn, and the other planets, to be preſerved, and ſwim ſecurely in the ſun's Vortex, the periodical times of the ſun's Vortex ſhould be equal. None of which proportions are found to obtain in the revolutions of the ſun and planets round their axes. Phil. Nat. Princ. Math. apud Schol. Gen. in Calce.

Beſides, the planets, according to this hypotheſis, being carried about the ſun in ellipſes, and having the ſun in the focus of each figure, by lines drawn from themſelves to the ſun, they always deſcribe areas proportionable to the times of their revolutions; which that author ſhews the parts of no Vortex can do. Schol. prop. ult. lib. ii. Princip.

Again, Dr. Keill proves, in his Examination of Burnet's Theory, that if the earth were carried in a Vortex, it would move faſter in the proportion of three to two,

two, when it is in Virgo than when it is in Piſces; which all experience proves to be falſe.

There is, in the Philoſophical Tranſactions, a Phyſico-mathematical demonſtration of the impoſſibility and inſufficiency of Vortices to account for the Celeſtial Phenomena; by Monſ. de Sigorne. See Num. 457. Sect. vi. pa. 409 et ſeq.

This author endeavours to ſhew, that the mechanical generation of a Vortex is impoſſible; and that it has only an axiſugal force, and not a centrifugal and centripetal one; that it is not ſufficient for explaining gravity and its properties; that it deſtroys Kepler's aſtronomical laws; and therefore he concludes, with Newton, that the hypotheſis of Vortices is fitter to diſturb than explain the celeſtial motions. We muſt refer to the diſſertation itſelf for the proof of theſe aſſertions. See CARTESIAN PHILOSOPHY.

VOSSIUS (GERARD JOHN), one of the moſt learned and laborious writers of the 17th century, was of a conſiderable family in the Netherlands: and was born in 1577, in the Palatinate near Heidelberg, at a place where his father, John Voſſius, was miniſter. He firſt learned Latin, Greek, and Philoſophy at Dort, where his father had ſettled, and died. In 1595 he went to Leyden, where he farther purſued theſe ſtudies, joining mathematics to them, in which ſcience he made a conſiderable progreſs. He became Maſter of Arts and Doctor in Philoſophy in 1598; and ſoon after, Director of the College at Dort; then, in 1614, Director of the Theological College juſt founded at Leyden; and, in 1618, Profeſſor of Eloquence and Chronology in the Academy there, the ſame year in which appeared his Hiſtory of the Pelagian Controverſy. This hiſtory procured him much odium and diſgrace on the continent, but an ample reward in England, where archbiſhop Laud obtained leave of king Charles the 1ſt for Voſſius to hold a prebendary in the church of Canterbury, while he reſided at Leyden: this was in 1629, when he came over to be inſtalled, took a Doctor of Laws degree at Oxford, and then returned.—In 1633 he was called to Amſterdam to fill the chair of a Profeſſor of Hiſtory; where he died in 1649, at 72 years of age; after having written and publiſhed as many works as, when they came to be collected and printed at Amſterdam in 1695 &c, made 6 volumes folio, works which will long continue to be read with pleaſure and profit. The principal of theſe are,—1. *Etymologicon Linguæ Latinæ.*—2. *De Origine & Progreſſu Idololatriæ.*—3. *De Hiſtoricis Græcis.*—4. *De Hiſtoricis Latinis.*—5. *De Arte Grammatica.*—6. *De Vitiis Sermonis & Gloſſematis Latino-Barbaris.*—7. *Inſtitutiones Oratoriæ.*—8. *Inſtitutiones Poeticæ.*—9. *Ars Hiſtorica.*—10. *De quatuor Artibus popularibus, Grammatice, Gymnaſtice, Muſice, & Graphice.*—11. *De Philologia.*—12. *De Univerſa Matheſeos Natura & Conſtitutione.*—13. *De Philoſophia.*—14. *De Philoſophorum Sectis.*—15. *De Veterum Poetarum Temporibus.*

VOSSIUS (*Denis*), ſon of the foregoing Gerard John, died at 22 years of age, a prodigy of learning, whoſe inceſſant ſtudies brought on him ſo immature a death. There are of his, among other ſmaller pieces, Notes upon Cæſar's Commentaries, and upon Maimonides on Idolatry.

VOSSIUS (*Francis*), brother of Denis and ſon of Gerard John, died in 1645, after having publiſhed a Latin poem in 1640, on a naval victory gained by the celebrated Van Tromp.

VOSSIUS (*Gerard*), brother of Denis and Francis, and ſon of Gerard John, wrote Notes upon Paterculus, which were printed in 1639. He was one of the moſt learned critics of the 17th century; but died in 1640, like his two brothers, at a very early age, and before their father.

VOSSIUS (*Iſaac*), was the youngeſt ſon of Gerard John, and the only one that ſurvived him. He was born at Leyden in 1618, and was a man of great talents and learning. His father was his only preceptor, and his whole time was ſpent in ſtudying. His merit recommended him to a correſpondence with queen Chriſtina of Sweden, who employed him in ſome literary commiſſions. At her requeſt, he made ſeveral journeys into Sweden, where he had the honour to teach her the Greek language; though ſhe afterwards diſcarded him on hearing that he intended to write againſt Salmaſius, for whom ſhe had a particular regard. In 1663 he received a handſome preſent of money from Louis the 14th of France, accompanied with a complimentary letter from the miniſter Colbert.—In 1670 he came over to England, when he was created Doctor of Laws at Oxford, and king Charles the 2d made him Canon of Windſor; though he knew his character well enough to ſay, there was nothing that Voſſius refuſed to believe, excepting the Bible. He appears indeed, by his publications, which are neither ſo numerous nor ſo uſeful as his father's, to have been a moſt credulous man, while he afforded many circumſtances to bring his religious faith in queſtion. He died at his lodgings in Windſor Caſtle, in 1688; leaving behind him the beſt private library, as it was then ſuppoſed, in the world; which, to the ſhame and reproach of England, was ſuffered to be purchaſed and carried away by the univerſity of Leyden. His publications chiefly were:—1. *Periplus Scylacis Caryandenſis, &c*, 1639.—2. Juſtin, with Notes, 1640.—3. *Ignatii Epiſtolæ, & Barnabæ Epiſtola*, 1646.—4. *Pomponius Mela de Situ Orbis*, 1648.—5. *Diſſertatio de vera Ætate Mundi, &c*, 1659.—6. *De Septuaginta Interpretibus, &c*, 1661.—7. *De Luce*, 1662.—8. *De Motu Marium & Ventorum.*—9. *De Nili & aliorum Fluminum Origine.*—10. *De Poematum Cantu & Viribus Rythmi*, 1673.—11. *De Sybillinis aliiſque, quæ Chriſti natalem præceſſere*, 1679.—12. *Catullus, & in eum Iſaaci Voſſii Obſervationes*, 1684.—13. *Variarum Obſervationum liber*, 1685, in which are contained the following pieces: viz, *De Antiquæ Romæ & aliarum quarundam Urbium Magnitudine; De Artibus & Scientiis Sinarum; De Origine & Progreſſu Pulveris Bellici apud Europæos; De Triremium & Liburnicarum Conſtructione; De Emendatione Longitudinum; De patefacienda per Septentrionem ad Japonenſes & Indos Navigatione; De apparentibus in Luna circulis; Diurna Telluris converſione omnia gravia ad medium tendere.*

VOUSSOIRS, vault-ſtones, are the ſtones which immediately form the arch of a bridge, &c, being cut ſomewhat in the manner of a truncated pyramid, their under ſides conſtituting the intrados, to which their joints

joints or ends ſhould be every where in a perpendicular direction.

The length of the middle Vouſſoir, or key-ſtone, and which is the leaſt of all, ſhould be about $\frac{1}{7}\frac{1}{7}$th or $\frac{1}{8}\frac{1}{8}$th of the ſpan of the arch; from hence theſe ſtones ſhould be made larger and larger, all the way down to the impoſt; that they may the better ſuſtain the great weight which reſts upon them, without being cruſhed or broken, and that they may alſo bind the firmer together.

To find the juſt length of the Vouſſoirs, or the figure of the extrados, when that of the intrados is given; ſee my Principles of Bridges, or Emerſon's Conſtruction of Arches, in his volume of Miſcellanies.

URANIBURGH, or celeſtial town, the name of a celebrated obſervatory, in a caſtle in the little iſland Weenen, in the Sound; built by the celebrated Daniſh aſtronomer, Tycho Brahe, who furniſhed it with inſtruments for obſerving the courſe and motions of the heavenly bodies.

This obſervatory, which was finiſhed about the year 1580, had not ſubſiſted above 17 years when Tycho, who little thought to have erected an edifice of ſo ſhort a duration, and who had even publiſhed the figure and poſition of the heavens, which he had choſen for the moment to lay the firſt ſtone in, was obliged to abandon his country.

Soon after this, the perſons to whom the property of the iſland was given, demoliſhed the building: part of the ruins was diſperſed into divers places: the reſt ſerved to build Tycho a handſome ſeat upon his ancient eſtate, which to this day bears the name of Uraniburgh; and it was here that Tycho compoſed his catalogue of the ſtars. Its latitude is 55° 54′ north, and longitude 12° 47′ eaſt of Greenwich.

M. Picart, making a voyage to Uraniburgh, found that Tycho's meridian line, there drawn, deviated from the meridian of the world; which ſeems to confirm the conjecture of ſome perſons, that the poſition of the meridian line may vary.

URSA, in Aſtronomy, the Bear, a name common to two conſtellations of the northern hemiſphere, near the pole, diſtinguiſhed by *Major* and *Minor*.

Ursa *Major*, or the *Great Bear*, one of the 48 old conſtellations, and perhaps more ancient than many of the others; being familiarly known and alluded to by the oldeſt writers, and is mentioned by Homer as obſerved by navigators. It is ſuppoſed that this conſtellation is that mentioned in the book of Job, under the name of *Cheſil*, which our tranſlation has rendered Orion, where it is ſaid, "Canſt thou looſe the bands of Cheſil (Orion)?" It is farther ſaid that the Ancients repreſented each of theſe two conſtellations under the form of a waggon drawn by a team of horſes, and the Greeks originally called them waggons and two bears; they are to this day popularly called the wains, or waggons, and the greater of them Charles's Wain. Hence is remarked the propriety of the expreſſion, "looſe the bands &c," the binding and looſing being terms very applicable to a harneſs, &c.

Perhaps the Egyptians, or whoever elſe were the people that invented the conſtellations, placed thoſe ſtars, which are near the pole, in the figure of a bear, as being an animal inhabiting towards the north pole, and making neither long journeys, nor ſwift motions. But the Greeks, in their uſual way, have adapted ſome of their fables to it. They ſay this bear was Calliſto, daughter of Lycaon, king of Arcadia; that being debauched by Jupiter, he afterwards placed her in the heavens, as well as her ſon Arcturus.

The Greeks called this conſtellation Arctos and Helice, from its turning round the pole. The Latins from the name of the nymph, as variouſly written, Calliſto, Megiſto, and Flemiſto, and from the Arabians, ſometimes Feretrum Majus, the Great Bier. And the Urſa Minor, they called Feretrum Minus, the Little Bier. The Italians have followed the ſame cuſtom, and call them Cataletto. They ſpoke alſo of the Phenicians being guided by the Leſſer Bear, but the Greeks by the Greater.

There are two remarkable ſtars in this conſtellation, viz, thoſe in the middle of his body, conſidered as the two hindermoſt of the wain, and called the pointers, becauſe they always point nearly in a direction towards the north pole ſtar, and ſo are uſeful in finding this ſtar out.

The ſtars in Urſa Major, are, according to Ptolomy's catalogue, 35; in Tycho's 56; in Hevelius's 73; but in the Britannic catalogue 87.

Ursa *Minor*, the *Little Bear*, called alſo *Arctos Minor*, *Phœnice*, and *Cynoſura*, one of the 48 old conſtellations, and near the north pole, the large ſtar in the tip of its tale being very near to it, and thence called the pole-ſtar.

The Phenicians guided their navigations by this conſtellation, for which reaſon it was called Phenice, or the Phenician conſtellation. It was alſo called Cynoſura by the Greeks, becauſe, according to ſome, that was one of the dogs of the huntreſs Calliſto, or the Great Bear; but according to others Cynoſura was one of the Idæan nymphs that nurſed the infant Jupiter; and ſome ſay that Calliſto was another of them, and that, for their care, they were taken up together to the ſkies.

Ptolomy places in this conſtellation 8 ſtars, Tycho 7, Hevelius 12, and Flamſteed 24.

URSUS (Nicholas Raimarus), a very extraordinary perſon, and diſtinguiſhed in the ſcience of aſtronomy, was born at Henſtedt in Dithmarſen, in the duchy of Holſtein, about the year 1550. He was a ſwineherd in his youth, and did not begin to read till he was 18 years of age; but then he employed all the hours he could ſpare from his daily labour, in learning to read and write. He afterwards applied himſelf to learn the languages; and, having a ſtrong genius, made a rapid progreſs in Greek and Latin. He quickly learned alſo the French language, the mathematics, aſtronomy, and philoſophy; and moſt of them without the aſſiſtance of a maſter.

Having left his native country, he gained a maintenance by teaching; which he did in Denmark in 1584, and on the frontiers of Pomerania and Poland in 1585. It was in this place that he invented a new ſyſtem of aſtronomy, very little different from that of Tycho Brahe. This he communicated, in 1586, to the landgrave of Heſſe, which gave riſe to a terrible diſpute between him and Tycho. This celebrated aſtronomer charged him with being a plagiary: who, as he related, happening to come with his maſter into his ſtudy, ſaw there, drawn on a piece of paper, the figure of

his ſyſtem; and afterwards inſolently boaſted that he himſelf was the inventor of it. Urſus, upon this accuſation, wrote furiouſly againſt Tycho, called the honour of his invention in queſtion, aſcribing the ſyſtem to Apollonius Pergæus; and in ſhort abuſed him in ſo brutal a manner, that he was going to be proſecuted for it.

Urſus was afterwards invited by the emperor to teach the mathematics in Prague; from which city, to avoid the preſence of Tycho, he withdrew ſilently in 1589, and died ſoon after.

He made ſome improvements in trigonometry, and wrote ſeveral books, which diſcover the marks of his haſty ſtudies; his erudition being indigeſted, and his ſtyle incorrect, as is almoſt always to be obſerved of perſons that are late-learned.

VULPECULA *et* ANSER, the *Fox and Goose*, in Aſtronomy, one of the new conſtellations of the northern hemiſphere, made out of the unformed ſtars by Hevelius, in which he reckons 27 ſtars; but Flamſteed counts 35.

W.

WAL

WAD, or WADDING, in Gunnery, a ſtopple of paper, hay, ſtraw, old rope-yarn, or tow, rolled firmly up like a ball, or a ſhort cylinder, and forced into a gun upon the powder, to keep it cloſe in the chamber; or put up cloſe to the ſhot, to keep it from rolling out, as well as, according to ſome, to prevent the inflamed powder from dilating round the ſides of the ball, by its windage, as it paſſes along the chace, which it was thought would much diminiſh the effort of the powder. But, from the accurate experiments lately made at Woolwich, it has not been found to have any ſuch effect.

WADHOOK, or WORM, a long pole with a ſcrew at the end, to draw out the wad, or the charge, or paper &c from a gun.

WAGGONER, in Aſtronomy, is the conſtellation Urſa Major, or the Great Bear, called alſo vulgarly Charles's Wain.

WAGGONER is alſo uſed for a routier, or book of charts, deſcribing the ſeas, their coaſts, &c.

WALLIS (Dr. JOHN), an eminent Engliſh mathematician, was the ſon of a clergyman, and born at Aſhford in Kent, Nov. 23. 1616. After being inſtructed, at different ſchools, in grammar learning, in Latin, Greek, and Hebrew, with the rudiments of logic, muſic, and the French language, he was placed in Emanuel college, Cambridge. About 1640 he entered into orders, and was choſen fellow of Queen's college. He kept his fellowſhip till it was vacated by his marriage, but quitted his college to be chaplain to Sir Richard Darley; after a year ſpent in this ſituation, he ſpent two more as chaplain to lady Vere. While he lived in this family, he cultivated the art of deciphering, which proved very uſeful to him on ſeveral occaſions: he met with rewards and preferment from the government at home for deciphering letters for them; and it is ſaid, that the elector of Brandenburg ſent him a gold chain and medal, for explaining for him ſome letters written in ciphers.

WAL

In 1643 he publiſhed *Truth Tryed*, or Animadverſions on lord Brooke's treatiſe, called The Nature of Truth &c; ſtyling himſelf "a miniſter in London," probably of St. Gabriel Fenchurch, the ſequeſtration of which had been granted to him.—In 1644 he was choſen one of the ſcribes or ſecretaries to the aſſembly of divines at Weſtminſter.

Academical ſtudies being much interrupted by the civil wars in both the univerſities, many learned men from them reſorted to London, and formed aſſemblies there. Wallis belonged to one of theſe, the members of which met once a week, to diſcourſe on philoſophical matters; and this ſociety was the riſe and beginning of that which was afterwards incorporated by the name of the Royal Society, of which Wallis was one of the moſt early members.

The Savilian profeſſor of geometry at Oxford being ejected by the parliamentary viſitors, in 1649, Wallis was appointed to ſucceed him, and he opened his lectures there the ſame year. In 1650 he publiſhed ſome Animadverſions on a book of Mr. Baxter's, intitled, "Aphoriſms of Juſtification and the Covenant." And in 1653, in Latin, a Grammar of the Engliſh tongue, for the uſe of foreigners; to which was added, a tract *De Loquela ſeu Sonorum formatione*, &c, in which he conſiders philoſophically the formation of all ſounds uſed in articulate ſpeech, and ſhews how the organs being put into certain poſitions, and the breath puſhed out from the lungs, the perſon will thus be made to ſpeak, whether he hear himſelf or not. Purſuing theſe reflections, he was led to think it poſſible, that a deaf perſon might be taught to ſpeak, by being directed ſo to apply the organs of ſpeech, as the ſound of each letter required, which children learn by imitation and frequent attempts, rather than by art. He made a trial or two with ſucceſs; and particularly upon one Popham, which involved him in a diſpute with Dr. Holder, of which ſome account has already been given in the life of that gentleman.

In 1654 he took the degree of Doctor in Divinity; and the year after became engaged in a long controverſy with Mr. Hobbes. This philoſopher having, in 1655, printed his treatiſe *De Corpore Philoſophico*, Dr. Wallis the ſame year wrote a confutation of it in Latin, under the title of *Elenchus Geometriæ Hobbianæ*; which ſo provoked Hobbes, that in 1656 he publiſhed it in Engliſh, with the addition of what he called, "Six Leſſons to the Profeſſors of Mathematics in Oxford." Upon this Dr. Wallis wrote an anſwer in Engliſh, intitled, "Due Correction for Mr. Hobbes; or School-diſcipline for not ſaying his Leſſons right," 1656: to which Mr. Hobbes replied in a pamphlet called ΣΤΙΓΜΑΙ, &c, or Marks of the abſurd Geometry, Rural Language, Scottiſh Church-politics, and Barbariſms, of John Wallis, 1657." This was immediately rejoined to by Dr. Wallis, in *Hobbiani Puncti Diſpunctio*, 1657. And here this controverſy ſeems to have ended, at this time: but in 1661 Mr. Hobbes printed *Examinatio & Emendatio Mathematicorum Hodiernorum in ſex Dialogis*; which occaſioned Dr. Wallis to publiſh the next year, *Hobbius Heautontimorumenos*, addreſſed to Mr. Boyle.

In 1657 he collected and publiſhed his mathematical works, in two parts, entitled, *Mathеſis Univerſalis*, in 4to; and in 1658, *Commercium Epiſtolicum de Quæſtionibus quibuſdam Mathematicis nuper habitum*, in 4to; which was a collection of letters written by many learned men, as Lord Brounker, Sir Kenelm Digby, Fermat, Schooten, Wallis, and others.

He was this year choſen *Cuſtos Archivorum* of the univerſity. Upon this occaſion Mr. Stubbe, who, on account of his friend Mr. Hobbes, had before waged war againſt Wallis, publiſhed a pamphlet, intitled, "The Savilian Profeſſor's Caſe Stated," 1658. Dr. Wallis replied to this; and Mr. Stubbe republiſhed his caſe, with enlargements, and a vindication againſt the exceptions of Dr. Wallis.

Upon the Reſtoration he met with great reſpect; the king thinking favourably of him on account of ſome ſervices he had done both to himſelf and his father Charles the firſt. He was therefore confirmed in his places, alſo admitted one of the king's chaplains in ordinary, and appointed one of the divines empowered to reviſe the book of Common Prayer. He complied with the terms of the act of uniformity, and continued a ſteady conformiſt till his death. He was a very uſeful member of the Royal Society; and kept up a literary correſpondence with many learned men. In 1670 he publiſhed his *Mechanica; ſive de Motu*, 4to. In 1676 he gave an edition of *Archimedis Syracuſani Arenarius & Dimenſio Circuli*; and in 1682 he publiſhed from the manuſcripts, *Claudii Ptolomæi Opus Harmonicum*, in Greek, with a Latin verſion and notes; to which he afterwards added, *Appendix de veterum Harmonica ad hodiernam comparata*, &c. In 1685 he publiſhed ſome theological pieces; and, about 1690, was engaged in a diſpute with the Unitarians; alſo, in 1692, in another diſpute about the Sabbath. Indeed his books upon ſubjects of divinity are very numerous, but nothing near ſo important as his mathematical works.

In 1685 he publiſhed his Hiſtory and Practice of Algebra, in folio; a work that is full of learned and uſeful matter. Beſides the works above mentioned, he publiſhed many others, particularly his *Arithmetic of Infinites*, a book of genius and good invention, and perhaps almoſt his only work that is ſo, for he was much more diſtinguiſhed for his induſtry and judgment, than for his genius. Alſo a multitude of papers in the Philoſ. Tranſ. in almoſt every volume, from the 1ſt to the 25th volume. In 1697, the curators of the Univerſity preſs at Oxford thought it for the honour of the univerſity to collect the doctor's mathematical works, which had been printed ſeparately, ſome in Latin, ſome in Engliſh, and publiſhed them all together in the Latin tongue, in 3 vols folio, 1699.

Dr. Wallis died at Oxford the 28th of October 1703, in the 88th year of his age, leaving behind him one ſon and two daughters. We are told that he was of a vigorous conſtitution, and of a mind which was ſtrong, calm, ſerene, and not eaſily ruffled or diſcompoſed. He ſpeaks of himſelf, in his letter to Mr. Smith, in a ſtrain which ſhews him to have been a very cautious and prudent man, whatever his ſecret opinions and attachments might be: he concludes, "It hath been my endeavour all along to act by moderate principles, being willing, whatever ſide was uppermoſt, to promote any good deſign, for the true intereſt of religion, of learning, and of the public good."

WARD (Dr. Seth), an Engliſh prelate, chiefly famous for his knowledge in mathematics and aſtronomy, was the ſon of an attorney, and born at Buntingford, Hertfordſhire, in 1617 or 1618. From hence he was removed and placed a ſtudent in Sidney college, Cambridge, in 1632. Here he applied with great vigour to his ſtudies, particularly to the mathematics, and was choſen fellow of his college. In 1640 he was pitched upon by the Vice-chancellor to be Prævaricator, which at Oxford is called Terræ-filius; whoſe office it was to make a witty ſpeech, and to laugh at any thing or any body: a privilege which he exerciſed ſo freely, that the Vice-chancellor actually ſuſpended him from his degree; though he reverſed the cenſure the day following.

The civil war breaking out, Ward was involved not a little in the conſequences of it. He was ejected from his fellowſhip for refuſing the Covenant; againſt which he ſoon after joined with ſeveral others, in drawing up that noted treatiſe, which was afterwards printed. Being now obliged to leave Cambridge, he reſided for ſome time with certain friends about London, and at other times at Aldbury in Surry, with the noted mathematician Oughtred, where he proſecuted his mathematical ſtudies. He afterwards lived for the moſt part, till 1649, with Mr. Ralph Freeman at Aſpenden in Hertfordſhire, whoſe ſons he inſtructed, as their preceptor; after which he reſided ſome months with lord Wenman, of Thame Park, in Oxfordſhire.

He had not been long in this family before the viſitation of the univerſity of Oxford began; the effect of which was, that many learned and eminent perſons were turned out, and among them Mr. Greaves, the Savilian profeſſor of Aſtronomy: this gentleman laboured to procure Ward for his ſucceſſor, whoſe abilities in his way were univerſally known and acknowledged; and effected it; Dr. Wallis ſucceeding to the Geometry profeſſorſhip at the ſame time. Mr. Ward then entered himſelf of Wadham college, for the ſake of

Dr. Wilkins, who was the warden; and he presently applied himself to bring the astronomy lectures, which had long been neglected and disused, into repute again; and for this purpose he read them very constantly, never missing one reading day, all the while he held the lecture.

In 1654, both the Savilian professors did their exercises, in order to proceed doctors in divinity; and when they were to be presented, Wallis claimed precedency. This occasioned a dispute; which being decided in favour of Ward, who was really the senior, Wallis went out grand compounder, and so obtained the precedency. In 1659, Ward was chosen president of Trinity college; but was obliged at the Restoration to resign that place. He had amends made him, however, by being presented in 1660 to the rectory of St. Laurence Jewry. The same year he was also installed precentor of the church of Exeter. In 1661 he became fellow of the Royal Society, and dean of Exeter; and the year following he was advanced to the bishopric of the same church. In 1667 he was translated to the see of Salisbury; and in 1671 was made chancellor of the order of the garter; an honour which he procured to be permanently annexed to the see of Salisbury, after it had been held by laymen for above 150 years.

Dr. Ward was one of those unhappy persons who have the misfortune to survive their senses, which happened in consequence of a fever ill cured: he lived till the Revolution, but without knowing any thing of the matter; and died in January 1689, about 71 years of age. He was the author of several Latin works in astronomy and different parts of the mathematics, which were thought excellent in their day; but their use has been superseded by later improvements and the Newtonian philosophy. Some of these were,

1. A Philosophical Essay towards an Eviction of the Being and Attributes of God, &c. 1652.

2. De Cometis, &c; 4to, 1653.

3. In Ismaelis Bullialdi Astronomia Inquisitio; 4to, 1653.

4. Idea Trigonometriæ demonstratæ; 4to, 1654.

5. Astronomia Geometrica; 8vo, 1656. In this work, a method is proposed, by which the astronomy of the planets is geometrically resolved, either upon the Elliptical or Circular motion; it being in the third or last part of this work that he proposes and explains what is called Ward's Circular Hypothesis.

6. Exercitatio epistolica in Thomæ Hobbii Philosophiam, ad D. Joannem Wilkins; 1656, 8vo.

But that by which he hath chiefly signalized himself, as to astronomical invention, is his celebrated approximation to the true place of a planet, from a given mean anomaly, founded upon an hypothesis, that the motion of a planet, though it be really performed in an elliptic orbit, may yet be considered as equable as to angular velocity, or with an uniform circular motion round the upper focus of the ellipse, or that next the aphelion, as a centre. By this means he rendered the praxis of calculation much easier than any that could be used in resolving what has been commonly called Kepler's problem, in which the coequate anomaly was to be immediately investigated from the mean elliptic one. His hypothesis agrees very well with those orbits which are elliptical but in a very small degree, as that of the Earth and Venus: but in others, that are more elliptical, as those of Mercury, Mars, &c, this approximation stood in need of a correction, which was made by Bulliald. Both the method, and the correction, are very well explained and demonstrated, by Keill, in his Astronomy, lecture 24.

WARGENTIN (Peter), an ingenious Swedish mathematician and astronomer, was born Sept. 22, 1717, and died Dec. 13, 1783. He became secretary to the Academy at Stockholm in 1749, when he was only 32 years of age; and he became successively a member of most of the literary academies in Europe, as London, Paris, Petersburg, Gottingen, Upsal, Copenhagen, Drontheim, &c. In this country he is probably most known on account of his tables for computing the eclipses of Jupiter's satellites, which are annexed to the Nautical Almanac of 1779. I know not that he has published any separate work; but his communications were very numerous to several of those Academies of which he was a member; as the Academy of Stockholm, in which are 52 of his memoirs; in the Philosophical Transactions, the Upsal Acts, the Paris Memoirs, &c.

WATCH, a small portable machine, or movement, for measuring time; having its motion commonly regulated by a spiral spring. Perhaps, strictly speaking, watches are all such movements as *shew* the parts of time; as clocks are such as *publish* them, by striking on a bell, &c. But commonly, the term Watch is appropriated to such as are carried in the pocket; and clock to the large movements, whether they strike the hour or not.

Spring or *Pendulum* Watches stand pretty much on the same principle with pendulum clocks. For if a pendulum, describing small circular arcs, make vibrations of unequal lengths, in equal times, it is because it describes the greater arc with a greater velocity; so a spring put in motion, and making greater and less vibrations, as it is more or less stiff, and as it has a greater or less degree of motion given it, performs them nearly in equal times. Hence, as the vibrations of the pendulum had been applied to large clocks, to rectify the inequality of their motions; so, to correct the unequal motions of the balance in Watches, a spring is added, by the isochronism of whose vibrations the correction is to be affected. The spring is usually wound into a spiral; that, in the little compass allotted it, it may be as long as possible; and may have strength enough not to be mastered, and dragged about, by the inequalities of the balance it is to regulate. The vibrations of the two parts, viz, the spring and the balance, should be of the same length; but so adjusted, as that the spring, being more regular in the length of its vibrations than the balance, may occasionally communicate its regularity to the latter.

The Invention of Spring or Pocket Watches, is due to the last age. It is true, it is said, in the history of Charles the 5th, that a Watch was presented to that prince: but this was probably no more than a kind of clock to be set on a table: some resemblance of which we have still remaining in the ancient pieces made before the year 1670. Some accounts also say, the first Watches were made at Nuremberg in 1500, by Peter Hell,

Hell, and were called Nuremberg eggs, on account of their oval form. And farther, that the ſame year George Purbach, a mathematician of Vienna, employed a watch that pointed to ſeconds, for aſtronomical obſervations, which was probably a kind of clock. In effect, it is between Hook and Huygens that the glory of this excellent invention lies: but to which of them it properly belongs, has been greatly diſputed; the Engliſh aſcribing it to the former, and the French, Dutch, &c, to the latter. Derham, in his Artificial Clockmaker, ſays roundly, that Dr. Hook was the inventor; and adds, that he contrived various ways of regulation: one way was with a loadſtone: another with a tender ſtraight ſpring, one end of which played backward and forward with the balance; ſo that the balance was to the ſpring as the ball of a pendulum, and the ſpring as the rod of the ſame: a third method was with two balances, of which there were divers ſorts; ſome having a ſpiral ſpring to the balance for a regulator, and others without. But the way that prevailed, and which ſtill continues in mode, was with one balance, and one ſpring running round the upper part of the verge of it: though this has a diſadvantage, which thoſe with two ſprings &c were free from; in that, a ſudden jerk, or confuſed ſhake will alter its vibrations, and flurry it very much.

The time of theſe inventions was about the year 1658; as appears, among other evidences, from an inſcription on one of the double-balance Watches preſented to king Charles the ſecond, viz, Rob. Hook inven. 1658. T. Tompion fecit, 1675. The invention ſoon came into repute both at home and abroad; and two of the machines were ſent for by the Dauphin of France. Soon after this, M. Huygens's Watch with a ſpiral ſpring got abroad, and made a great noiſe in England, as if the longitude could be found by it. It is certain however, that this invention was later than the year 1673, when his book De Horol. Oſcillat. was publiſhed; in which there is no mention of this, though he ſpeaks of ſeveral other contrivances in the ſame way.

One of theſe the lord Brounker ſent for out of France, where M. Huygens had got a patent for them. This Watch agreed with Dr. Hook's, in the application of the ſpring to the balance; only that of Huygens had a longer ſpiral ſpring, and its pulſes and beats were much ſlower; alſo the balance, inſtead of turning quite round, as Dr. Hook's, turned ſeveral times every vibration. Huygens alſo invented divers other kinds of Watches, ſome of them without any ſtring or chain at all, which he called pendulum Watches.

Mr. Derham ſuggeſts that he ſuſpects Huygens's fancy was firſt ſet to work by ſome intelligence he might have of Hook's invention from Mr. Oldenburg, or ſome other of his correſpondents in England; though Mr. Oldenburg vindicates himſelf againſt that charge, in the Philoſ. Tranſ. numbers 118 and 129.

Watches, ſince their firſt invention, have gone on in a continued courſe of improvement, and they have lately been brought to great perfection, both in England and in France, but more eſpecially the former, particularly owing to the great encouragement that has been given to them by the Board of Longitude. Some of the chief writers and improvers of Watches, are, Le Roy, Cummins, Harriſon, Mudge, Emery, and Arnold, whoſe Watches are now in very high repute, and in frequent uſe in the navy and India ſhips, for keeping the longitude. See Derham's Artificial Clockmaker; Cummins's Principles of Clock and Watch work; Mudge's Thoughts on the Means of improving Watches, &c.

Striking WATCHES, are ſuch as, beſides the proper Watch part, for meaſuring time, have a clock part, for ſtriking the hours, &c. Theſe are real clocks; only moved by a ſpring inſtead of a weight; and are properly called pocket-clocks.

Repeating WATCHES, are ſuch as, by pulling a ſtring, &c, repeat the hour, quarter, or minute, at any time of the day or night.—This repetition was the invention of Mr. Barlow, being firſt put in practice by him in larger movements or clocks, about the year 1676. The contrivance immediately ſet the other artiſts to work, who ſoon contrived divers ways of effecting the ſame. But its application to pocket Watches was not known before K. James the ſecond's reign; when the ingenious inventor above mentioned was ſoliciting a patent for it. The talk of a patent engaged Mr. Quare to reſume the thoughts of a like contrivance, which he had in view ſome years before: he now effected it; and being preſſed to endeavour to prevent Mr. Barlow's patent, a Watch of each kind was produced before the king and council; upon trial of which, the preference was given to Mr. Quare's. The difference between them was, that Barlow's was made to repeat by puſhing in two pieces on each ſide the Watch-box; one of which repeated the hour, and the other the quarter: whereas Quare's was made to repeat by a pin that ſtuck out near the pendant, which being thruſt in (as now is done by thruſting in the pendant itſelf) repeated both the hour and quarter with the ſame thruſt.

Of the Mechaniſm of a WATCH.

Watches, as well as clocks, are compoſed of wheels and pinions, with a regulator to direct the quickneſs or ſlowneſs of the wheels, and of a ſpring which communicates motion to the whole machine. But the regulator and ſpring of a Watch are vaſtly inferior to the weight and pendulum of a clock, neither of which can be employed in Watches. Inſtead of a pendulum, therefore, they are obliged to uſe a balance (Pl. 34, fig. 4) to regulate the motion of a Watch; and of a ſpring (fig. 6), which ſerves inſtead of a weight, to give motion to the wheels and balance.

The wheels of a Watch, like thoſe of a clock, are placed in a frame, formed of two plates and four pillars. Fig. 3 repreſents the inſide of a Watch, after the plate (Fig. 5) is taken off. A is the barrel which contains the ſpring (fig. 6); the chain is rolled about the barrel, with one end of it fixed to the barrel A, and the other to the fuſee B.

When a Watch is wound up, the chain which was upon the barrel winds about the fuſee, and by this means the ſpring is ſtretched; for the interior end of the ſpring is fixed by a ſpring to the immoveable axis, about which the barrel revolves; the exterior end of the ſpring is fixed to the inſide of the barrel, which turns upon an axis. It is there eaſy to perceive how the ſpring extends itſelf, and how its elaſticity forces the

the barrel to turn round, and conſequently obliges the chain which is upon the fuſee to unfold and turn the fuſee; the motion of the fuſee is communicated to the wheel CC; then by means of the teeth, to the pinion *c*, which carries the wheel D; then to the pinion *d*, which carries the wheel E; then to the pinion *e*, which carries the wheel F; then to the pinion *f*, upon which is the balance-wheel G, whoſe pivot runs in the piece A, called the potance, and B called a follower, which are fixed on the plate fig. 5. This plate, of which only a part is repreſented, is applied to that of fig. 3, in ſuch a manner, that the pivots of the wheels enter into holes made in the plate fig. 3. Thus the impreſſed force of the ſpring is communicated to the wheels: and the pinion *f* being then connected to the wheel F, obliges it to turn (fig. 7). This wheel acts upon the pallats of the verge 1, 2, (fig. 4) the axis of which carries the balance HH (fig. 4). The pivot I, in the end of the verge, enters into the hole G in the potance A (fig. 5). In this figure the pallats are repreſented; but the balance is on the other ſide of the plate, as may be ſeen in fig. 11. The pivot 3 of the balance enters into a hole of the cock BC (fig. 10), a perſpective view of which is repreſented in fig. 12. Thus the balance, turns between the cock and the potance *c* (fig. 5), as in a kind of cage. The action of the balance-wheel upon the pallats 1, 2, (fig. 4) is the ſame with that of the ſame wheel in the clock; i. e. in a Watch the balance-wheel obliges the balance to vibrate backwards and forwards like a pendulum.

At each vibration of the balance a pallat allows a tooth of the balance-wheel to eſcape; ſo that the quickneſs of the motion of the wheels is entirely determined by the quickneſs of the vibrations of the balance, and theſe vibrations of the balance and motion of the wheels are produced by the action of the ſpring.

But the quickneſs or ſlowneſs of the vibrations of the balance depends not ſolely upon the action of the great ſpring, but chiefly upon the action of the ſpring *abc*, called the ſpiral ſpring (fig. 13) ſituated under the balance H, and repreſented in perſpective (fig. 11); the exterior end of the ſpiral is fixed to the pin *a* (fig. 13). This pin is applied near the plate in *a* (fig. 11); the interior end of the ſpiral is fixed by a peg to the centre of the balance. Hence if the balance be turned upon itſelf, the plates remaining immoveable, the ſpring will extend itſelf, and make the balance perform one revolution. Now, after the ſpiral is thus extended, if the balance be left to itſelf, the elaſticity of the ſpiral will bring back the balance, and in this manner the alternate vibrations of the balance are produced.

In fig. 7 all the wheels above deſcribed are repreſented in ſuch a manner, that we may eaſily perceive at firſt ſight how the motion is communicated from the barrel to the balance.

In fig. 8 are repreſented the wheels under the dial-plate, by which the hands are moved. The pinion *a* is adjuſted to the force of the prolonged pivot of the wheel D (fig. 7), and is called a cannon pinion. This wheel revolves in an hour. The end of the axis of the pinion *a*, upon which the minute hand is fixed, is ſquare; the pinion (fig. 8) is indented into the wheel *b*, which is carried by the pinion *a*. Fig. 9 is a wheel fixed upon a barrel, into the cavity of which the pinion *a* enters, and upon which it turns freely. This wheel *d* revolves in 12 hours, and carries along with it the hour-hand.

WATER, in Phyſiology, a clear, inſipid, and colourleſs fluid, coagulable into a tranſparent ſolid ſubſtance, called ice, when placed in a temperature of 32 of Fahrenheit's thermometer, or lower, but volatile and fluid in every degree of heat above that; and when pure, or freed from heterogeneous particles, is reckoned one of the four elements.

By ſome late experiments of Meſſrs. Lavoiſier, Watt, Cavendiſh, Prieſtley, Kirwan, &c, it appears, that Water conſiſts of dephlogiſticated air, and inflammable air or phlogiſton intimately united; or, as Mr. Watt conceives, of thoſe two principles deprived of part of their latent heat. And in ſome inſtances it appears that air and Water are mutually convertible into each other. Thus, Mr. Cavendiſh (Philoſ. Tranſ. vol. 74, p. 128) recites ſeveral experiments, in which he changed common air into pure Water, by decompoſing it in conjunction with inflammable air. Dr. Prieſtley likewiſe, having decompoſed dephlogiſticated and inflammable air, by firing them together by the electric exploſion, found a manifeſt decompoſition of Water, which, as nearly as he could judge, was equal in weight to that of the decompoſed air. He alſo made a number of other curious experiments, which ſeemed to favour the idea of a converſion of Water into air, without abſolutely proving it. The difficulty which M. De Luc and others have found in expelling all air from Water, is beſt accounted for on the ſuppoſition of the generation of air from Water; and admitting that the converſion of Water into air is effected by the intimate union of what is called the principle of heat with the Water, it appears ſufficiently analogous to other changes, or rather combinations, of ſubſtances. Is not, ſays Dr. Prieſtley, the acid of nitre, and alſo that of vitriol, a thing as unlike to air as Water is, their properties being as remarkably different? And yet it is demonſtrable that the acid of nitre is convertible into the pureſt reſpirable air, and probably by the union of the ſame principle of heat. Philoſ. Tranſ. vol. 73, p. 414 &c.

Indeed there ſeems to be Water in all bodies, and particles of almoſt all kinds of matter in Water; ſo that it is hardly ever ſufficiently pure to be conſidered as an element. Water, if it could be had alone, and pure, Boerhaave argues, would have all the requiſites of an element, and be as ſimple as fire; but there is no expedient hitherto diſcovered for procuring it ſo pure. Rain Water, which ſeems the pureſt of all thoſe we know of, is replete with infinite exhalations of all kinds, which it imbibes from the air: ſo that if filtered and diſtilled a thouſand times, there ſtill remain fæces. Beſides this, and the numberleſs impurities it acquires after it is raiſed, by mixing with all ſorts of effluvia in the atmoſphere, and by falling upon and running over the earth, houſes, and other places. There is alſo fire contained in all Water; as appears from its fluidity, which is owing to fire alone. Nor can any kinds of filtering through ſand, ſtone, &c, free it entirely from ſalts &c. Nor have all the experiments that have been invented by the philoſophers, ever been able to derive Water perfectly pure. Hence Boerhaave ſays, that he is convinced nobody ever ſaw a drop of pure Water; that

that the utmoſt of its purity known, only amounts to its being free from this or that ſort of matter; and that it can never, for inſtance, be quite deprived of ſalt; ſince air will always accompany Water, and air always contains ſalt.

Water ſeems to be diffuſed everywhere, and to be preſent in all ſpace wherever there is matter. There are hardly any bodies in nature but what will yield Water: it is even aſſerted that fire itſelf is not without it. A ſingle grain of the fiery ſalt, which in a moment's time will penetrate through a man's hand, readily imbibes half its weight of Water, and melts even in the drieſt air imaginable. Among innumerable inſtances, hartſhorn, kept 40 years, and turned as hard and dry as any metal, ſo that it will yield ſparks of fire when ſtruck againſt a flint, yet being put into a glaſs veſſel, and diſtilled, will afford $\frac{1}{3}$th part of its quantity of Water. Bones dead and dried 25 years, and thus become almoſt as hard as iron, yet by diſtillation have yielded half their weight of Water. And the hardeſt ſtones, ground and diſtilled, always diſcover a portion of it. But hitherto no experiment ſhews, that Water enters as a principle into the combination of metallic matters, or even into that of vitreſcible ſtones.

From ſuch conſiderations, philoſophers have been led to hold the opinion, that all things were made of Water. Baſil Valentine, Paracelſus, Van Helmont, and others have maintained, that Water is the elemental matter or ſtamen of all things, and ſuffices alone for the production of all the viſible creation. Thus too Newton: "All birds, beaſts, and fiſhes, inſects, trees, and vegetables, with their ſeveral parts, do grow out of Water, and watery tinctures, and ſalts; and by putrefaction they all return again to watery ſubſtances." And the ſame doctrine is held, and confirmed by experiments, by Van Helmont, Boyle, and others.

But Dr. Woodward endeavours to ſhew that the whole is a miſtake.—Water containing extraneous corpuſcles, ſome of which, according to him, are the proper matter of nutrition; the Water being ſtill found to afford ſo much the leſs nouriſhment, the more it is purified by diſtillation. So that Water, as ſuch, does not ſeem to be the proper nutriment of vegetables; but only the vehicle which contains the nutritious particles, and carries them along with it, through all the parts of the plant.

Helmont however carries his ſyſtem ſtill farther, and imagines that all bodies may be reconverted into Water. His alkaheſt, he affirms, adequately reſolves plants, animals, and minerals, into one liquor, or more, according to their ſeveral internal differences of parts; and the alkaheſt, being abſtracted again from theſe liquors, in the ſame weight, and with the ſame virtues, as when it diſſolved them, the liquors may, by frequent cohobations from chalk, or ſome other proper matter, be totally deprived of their ſeminal endowments, and at laſt return to their firſt matter; which is inſipid Water.

Spirit of wine, of all other ſpirits, ſeems freeſt from Water: yet Helmont affirms, it may be ſo united with Water, as to become Water itſelf. He adds, that it is material Water, only under a ſulphureous diſguiſe. And the ſame thing he obſerves of all ſalts, and of oils, which may be almoſt wholly changed into Water.

No ſtandard for the Weight and Purity of WATER.—Water ſcarce ever continues two moments exactly of the ſame weight; by reaſon of the air and fire contained in it. The expanſion of Water in boiling ſhews what effect the different degrees of fire have on the gravity of Water. This makes it difficult to fix the ſpecific gravity of Water, in order to ſettle its degree of purity. However, the pureſt Water we can obtain, according to the experiments of Mr. Hawkſbee, is 850 times heavier than air: or according to the experiments of Mr. Cavendiſh, the thermometer being at 50° and the barometer at 29$\frac{1}{4}$, about 800 times as heavy as air: and according to the experiments of Sir Geo. Shuckburgh, when the barometer is at 29·27 and the thermometer at 53°, Water is 836 times heavier than air; whence alſo may be deduced this general proportion, which may be accounted a ſtandard, viz. that, when the barometer is at 30° and the thermometer at 55°, then Water is 820 times heavier than air; alſo that in ſuch a ſtate the cubic foot of Water weighs 1000 ounces avoirdupois, and that of air 1·222, or 1$\frac{2}{9}$ nearly, alſo that of mercury 13600 ounces; and for other ſtates of the thermometer and barometer, the allowance is after this rate, viz. that the column of mercury in the barometer varies its length by the 10 thouſandth part of itſelf for a change of each ſingle degree of temperature, and Water changes by $\frac{1}{2000}$ part of its height or magnitude by each degree of the ſame. However, we have not any very exact ſtandard in air; for Water being ſo much heavier than air, the more Water there is contained in the air, the heavier of courſe muſt the air be; as indeed a conſiderable part of the weight of the atmoſphere ſeems to ariſe from the Water that is in it.

Properties and Effects of WATER.——Water is a very volatile body. It is entirely reduced into vapours and diſſipated, when expoſed to the fire and unconfined.

Water heated in an open veſſel, acquires no more than a certain determinate degree of heat, whatever be the intenſity of the fire to which it is expoſed; which greateſt degree of heat is when it boils violently.

It has been found that the degree of heat neceſſary to make Water boil, is variable, according to the purity of the Water and the weight of the atmoſphere. The following table ſhews the degree of heat at which Water boils, at various heights of the barometer, being a medium between thoſe reſulting from the experiments of Sir Geo. Shuckburgh and M. De Luc:

Height of the Barometer.	Heat of Boiling Water.
Inches.	°
26	205
26$\frac{1}{2}$	206
27	206·9
27$\frac{1}{2}$	207·7
28	208·5
28$\frac{1}{2}$	209·4
29	210·3
29$\frac{1}{2}$	211·2

30$\frac{1}{2}$	212·8
31	213·6

Water is found the moſt penetrative of all bodies, after fire, and the moſt difficult to confine; paſſing through leather, bladders, &c, which will confine air; making its way gradually through woods; and is only retainable in glaſs and metals; nay it was found by experiment at Florence, that when ſhut up in a ſpherical veſſel of gold, which was preſſed with a great force, it made its way through the pores even of the gold itſelf.

Water, by this penetrative quality alone, may be inferred to enter the compoſition of all bodies, both vegetable, animal, foſſil, and even mineral; with this particular circumſtance, that it is eaſily, and with a gentle heat, ſeparable again from bodies it had united with.

And yet the ſame Water, as little coheſive as it is, and as eaſily ſeparated from moſt bodies, will cohere firmly with ſome others, and bind them together in the moſt ſolid maſſes; as in the tempering of earth, or aſhes, clay, or powdered bones, &c, with Water, and then dried and burnt, when the maſſes become hard as ſtones, though without the Water they would be mere duſt or powder. Indeed it appears wonderful that Water, which is otherwiſe an almoſt univerſal diſſolvent, ſhould nevertheleſs be a great coagulator.

Some have imagined that Water is incompreſſible, and therefore nonelaſtic; founding their opinion on the celebrated Florentine experiment above mentioned, with the globe of gold; when the Water being, as they ſay, incapable of condenſation, rather than yield, tranſuded through the pores of the metal, ſo that the ball was found wet all over the outſide; till at length making a cleft in the gold, it ſpun out with great vehemence. But the truth of the concluſions drawn from this Florentine experiment has been very juſtly queſtioned; Mr. Canton having proved by accurate experiments, that Water is actually compreſſed even by the weight of the atmoſphere. See COMPRESSION.

Beſides, the diminution of ſize which Water ſuffers when it paſſes to a leſs degree of heat, ſufficiently ſhews that the particles of this fluid are, like thoſe of all other known ſubſtances, capable of approaching nearer together.

Ditch WATER, is often uſed as an object for the microſcope, and ſeldom fails to afford a great variety of animalcules; often appearing of a greeniſh, reddiſh, or yellowiſh colour, from the great multitudes of them. And to the ſame cauſe is to be aſcribed the green ſkim on the ſurface of ſuch Water. Dunghill Water is alſo full of an immenſe crowd of animalcules.

Freſh WATER, is ſaid of that which is inſipid, or without ſalt, and inodorous; being the natural and pure ſtate of the element.

Hard WATER, or *Crude* WATER, is that in which ſoap does not diſſolve completely or uniformly, but is curdled. The diſſolving power of hard Water is leſs than that of ſoft; and hence its unfitneſs for waſhing, bleaching, dyeing, boiling kitchen vegetables, &c.

The hardneſs of Water may ariſe either from ſalts, or from gas. That which ariſes from ſalts, may be diſcovered and remedied by adding ſome drops of a ſolution of fixed alkali; but the latter by boiling, or expoſure to the open air.

Spring Waters are often hard; but river Water ſoft. Hard Waters are remarkably indiſpoſed to corrupt; they even preſerve putreſcible ſubſtances for a conſiderable length of time: hence they ſeem to be beſt fitted for keeping at ſea, eſpecially as they are ſo eaſily ſoftened by a little alkaline ſalt.

Putrid WATER, is that which has acquired an offenſive ſmell and taſte by the putreſcence of animal or vegetable ſubſtances contained in it. This kind of Water is in the higheſt degree pernicious to the human frame, and capable of bringing on mortal diſeaſes even by its ſmell. Quicklime put into water is uſeful to preſerve it longer ſweet; or even expoſure to the air in broad ſhallow veſſels. And putrid Water may be in a great meaſure ſweetened, by paſſing a current of freſh air through it, from bottom to top.

Rain WATER may be conſidered as the pureſt diſtilled Water, but impregnated during its paſſage through the air with a conſiderable quantity of phlogiſtic and putreſcent matter; whence it is ſuperior to any other in fertilizing the earth. Hence alſo it is inferior for domeſtic purpoſes to ſpring or river Water, even if it could be readily procured: but ſuch as is gotten from ſpouts placed below the roofs of houſes, the common way of procuring it in this country, is evidently very impure, and becomes putrid in a ſhort time.

River or *Running* WATER, is next in purity to ſnow or diſtilled water; and for domeſtic purpoſes ſuperior to both, in having leſs putreſcent matter, and more fixed air. That however is much the pureſt that runs over a clean rocky or ſtony bottom.

River Waters generally putrefy ſooner than thoſe of ſprings. During the putrefaction, they throw off a part of their heterogeneous matter, and at length become ſweet again, and purer than at firſt; after which they commonly preſerve a long time: this is remarkably the caſe with the Thames Water, taken up about London; which is commonly uſed by ſeamen, in their voyages.

Salt WATER, ſuch as has much ſalt in it, ſo as to be ſenſible to the taſte.

Sea WATER, or Water of the ſea, is an aſſemblage of bodies, in which Water can ſcarce be ſaid to have the principal part: it is an univerſal colluvies of all the bodies in nature, ſuſtained and kept ſwimming in Water as a vehicle: being a ſolution of common ſalt, ſal catharticus amarus, a ſelenitic ſubſtance, and a compound of muriatic acid with magneſia, mixed together in various proportions. It may be freſhened by ſimple diſtillation without any addition, and thus it has ſometimes been uſeful in long voyages at ſea. Sea Water by itſelf has a purgative quality, owing to the ſalts it contains; and has been greatly recommended in ſcrophulous diſorders.

Sea Water is about 3 parts in 100 heavier than common Water; and its temperature at great depths is from 34 to 40 degrees; but near the ſurface it follows more nearly the temperature of the air.

Snow WATER, is the pureſt of all the common Waters, when the ſnow has been collected pure. Kept in a warm place, in clean glaſs veſſels, not cloſely ſtopped, but covered from duſt, &c, ſnow-water becomes in time putrid; though in well-ſtopped bottles it remains unaltered for ſeveral years. But diſtilled Water ſuffers no alteration in either circumſtance.

Spring WATER is commonly impregnated with a ſmall

ſmall portion of imperfect neutral ſalt, extracted from the different ſtrata through which it percolates. Some contain a vaſt quantity of ſtony matter, which they depoſit as they run along, and thus form maſſes of ſtone; ſometimes incruſtating various animal and vegetable matters, which they are therefore ſaid to petrify. Spring-Water is much uſed for domeſtic purpoſes, and on account of its coolneſs is an agreeable drink; but on account of its being uſually ſomewhat hard, is inferior to that which has run for a conſiderable way in a channel.

Spring-water ariſes from the rain, and from the miſts and moiſture in the atmoſphere. Theſe falling upon hills and other parts of the earth, ſoak into the ground, and paſs along till they find a vent out again, in the form of a ſpring.

WATER-*Bellows*, in Mechanics, are bellows, for blowing air into furnaces, that are worked by the force of water.

WATER-*Clock*. See CLEPSYDRA.

WATER-*Engine*, an engine for extinguiſhing fires; or any engine to raiſe water; or any engine moved by the force of Water. See ENGINE, and STEAM *Engine*.

WATER-*Gage*, an inſtrument for meaſuring the depth or quantity of any water. See GAGE.

WATER-*Level*, is the true level which the ſurface of ſtill Water takes, and is the trueſt of any.

WATER-*Logged*, in Sea-Language, denotes the ſtate of a ſhip when, by receiving a great quantity of Water into her hold, by leaking, &c, ſhe has become heavy and inactive upon the ſea, ſo as to yield without reſiſtance to the effort of every wave ruſhing over her deck.

WATER-*Machine*. See MACHINE.

WATER-*Meaſure*. Salt, ſea-coal, &c, while on board veſſels in the pool, or river, are meaſured with the corn-buſhel heaped up; or elſe 5 ſtriked pecks are allowed to the buſhel. This is called Water-meaſure; and it exceeds Wincheſter-meaſure by about 3 gallons in the buſhel.

WATER-*Microſcope*. See MICROSCOPE.

WATER-*Mill*. See MILL.

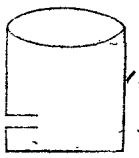
Motion of WATER, in Hydraulics. The theory of the motion of running Water is one of the principal objects of hydraulics, and to which many eminent mathematicians have paid their attention. But it were to be wiſhed that their theories were more conſiſtent with each other, and with experience. The inquiſitive reader may conſult Newton's Principia, lib. 2, pr. 36, with the comment. Dan. Bernoulli's Hydrodynamica. J. Bernoulli, Hydraulica, Oper. tom. 4, pa. 389. Dr. Jurin, in the Philoſ. Tranſ. num. 452, or Abridg. vol. 8, pa. 282. Graveſande, Phyſic. Elem. Mathem. lib. 3, par. 2. Maclaurin's Flux. art. 537. Poleni de Caſtellis, Ximenes, D'Alembert, Boſſu, Buat, and many others.

But notwithſtanding the labours of all theſe eminent authors, this intricate ſubject ſtill remains in a great meaſure obſcure and uncertain. Even the ſimple caſe of the motion of running water, when it iſſues from a hole in the bottom of a veſſel, has never yet been determined, ſo as to give univerſal ſatisfaction to the learned. On this head, it is now pretty generally allowed, that the velocity of the iſſuing ſtream, is equal to that which a heavy body acquires by falling through the height of the fluid above the hole, as may be demonſtrated by theory: but in practice, the quantity of the effluent Water is much leſs than what is given by this theory; owing to the obſtruction to the motion in the hole, partly from the ſides of it, and partly from the different directions of the parts of the Water in entering it, which thence obſtruct each other's motion. And this obſtruction, and the diminution in the quantity of Water run out, is ſtill the more in proportion as the hole is the ſmaller; in ſuch ſort, that when the hole is very ſmall, the quantity is diminiſhed in the ratio of $\sqrt{2}$ to 1 very nearly, which is the ratio of the greateſt diminution; and for larger holes, the diminution is always leſs and leſs. This fact is aſcertained, or admitted by Newton, and all the other philoſophers abovementioned, with ſome ſmall variations.

That the velocity of the Water in the hole, or at leaſt ſome part of it, as that for example in the middle of the ſtream, is equal to that abovementioned, is even evinced by experiment, by directing the ſtream either ſideways, or upwards: for in the former caſe, it is found to range upon an horizontal plane, a diſtance that juſt anſwers to that velocity, by the nature of projectiles; and in the latter caſe, the jet riſes nearly to the height of the Water in the veſſel; which it could not do, if its velocity were not equal to that acquired by the free deſcent of a body through that height. Hence it is evident then, that the particles of the Water, which are in the hole at the ſame moment of time, do not all burſt out with the ſame velocity; and, in fact, the velocity is found to decreaſe all the way from the middle of the hole, where it is greateſt, towards the ſide or edge, where it is the leaſt.

At a ſmall diſtance from the hole, the diameter of the vein of Water is much leſs than that of the hole. Thus, if the diameter of the hole be 1, the diameter of the vein of Water juſt without it, will be $\frac{7}{25}$, or 0·84, according to Newton's meaſure, who firſt obſerved this phenomenon; and according to Poleni's meaſure 0·78 nearly.

By the experiments of Buat (Principes d'Hydraulique), the quantity by theory is to that by experiment, for a ſmall hole made in the thin ſide of a reſervoir, as 8 to 5. When a ſhort pipe is added to the hole outwards, of the length of two or three times its diameter, that ratio is as 16 to 13. And when the ſhort pipe is all within ſide the veſſel, as in the margin, the ſame ratio becomes that of 3 to 2. Poleni alſo found that the quantity of Water flowing through a pipe or tube, was much greater than that through a hole of the ſame diameter in the thin ſide or bottom of the veſſel, the height of the head of Water above each being the ſame. See alſo many other curious circumſtances in Buat's Principes above mentioned.



Some authors give this rule for finding the height due to the velocity in a flat orifice, or a medium among all the parts of it, ſuch that this medium velocity being drawn into the area of the hole, ſhall give the quantity per ſecond that runs through: viz, let *A* denote the area

area of the ſurface of the Water in the veſſel, *a* the area of the orifice by which the Water iſſues, and *H* the height of the Water above the orifice; then, as $2A - a : A :: H : h$, the height due to the medium velocity, or the height from which a body muſt freely deſcend, by the force of gravity, to acquire that mean velocity.

Authors are not yet agreed as to the force with which a vein of Water, ſpouting from a round hole in the ſide of a veſſel, preſſes upon a plane directly oppoſed to the motion of the vein. Moſt authors agree, that the preſſure of this vein, flowing uniformly, ought to be equal to the weight of a cylinder of Water, whoſe baſe is equal to the hole through which the Water flows, and its height equal to the height of the Water in the veſſel above the hole. The experiments made by Mariotte, and others, ſeem to countenance this opinion. But Dan. Bernoulli rejects it, and eſtimates this preſſure by the weight of a column of the fluid, whoſe diameter is equal to the contracted vein (according to Newton's obſervation abovementioned), and the height of which is equal to double the altitude due to the real velocity of the ſpouting Water; and this preſſure is alſo equal to the force of repulſion, ariſing from the reaction of the ſpouting Water upon the veſſel. The ingenious author remarks that he ſpeaks only of ſingle veins of Water, the whole of which are received by the planes upon which they preſs; for as to the preſſures exerted by fluids ſurrounding the bodies they preſs upon, as the wind, or a river, the caſe is different, though confounded with the former by writers on this ſubject. Hydrodynamica, pa. 289.

Another rule however had been adopted by the Academicians of Paris, who made a number of experiments to confirm or eſtabliſh it. Hiſt. Acad. Paris, ann. 1699, ſect. 3, cap. 5.

D. Bernoulli, on the other hand, thinks his own theory ſufficiently eſtabliſhed by the experiments he relates; for the particulars of which ſee the Acta Petropolitana, vol. 8, pa. 122.

This ingenious author is of opinion that his theory of the quantity of the force of repulſion, exerted by a vein of ſpouting Water, might be uſefully applied to move ſhips by pumping; and he thinks the motion produced by this repulſive force would fall little, if at all, ſhort of that produced by rowing. He has given his reaſons and computations at length in his Hydrodynamica, pa. 293 &c.

This ſcience of the preſſures exerted by Water or other fluids in motion, is what Bernoulli calls *Hydraulico-ſtatica*. This ſcience differs from hydroſtatics, which conſiders only the preſſure of Water and other fluids at reſt; whereas hydraulico-ſtatics conſiders the preſſure of Water in motion. Thus the preſſure exerted by Water moving through pipes, upon the ſides of thoſe pipes, is an hydraulico-ſtatical conſideration, and has been erroneouſly determined by many, who have given no other rules in theſe caſes, but ſuch as are applicable only to the preſſure of fluids at reſt. See Hydrodynam. pa. 256 &c.

WATER-*Poiſe*. See HYDROMETER, and AREOMETER.

Dr. Hook contrived a Water-poiſe, which may be of good ſervice in examining the purity &c of Water. It conſiſts of a round glaſs ball, like a bolt head, about 3 inches diameter, with a narrow ſtem or neck, the 24th of an inch in diameter; which being poiſed with red lead, ſo as to make it but little heavier than pure ſweet Water, and thus fitted to one end of a fine balance, with a counterpoiſe at the other end; upon the leaſt addition of even the 2000th part of ſalt to a quantity of Water, half an inch of the neck will emerge above the water. Philoſ. Tranſ. num. 197.

Raiſing of WATER, in Hydraulics. The great uſe of raiſing Water by engines for the various purpoſes of life, is well known. Machines have in all ages been contrived with this view; a detail of the beſt of which, with the theory of their conſtruction, would be very curious and inſtructive. M. Belidor has executed this in part in his Architecture Hydraulique. Dr. Deſaguliers has alſo given a deſcription of ſeveral engines to raiſe Water, in his Courſe of Experimental Philoſophy, vol. 2; and there are ſeveral other ſmaller works of the ſame kind.

Engines for raiſing Water are either ſuch as throw it up with a great velocity, as in jets; or ſuch as raiſe it from one place to another by a gentle motion. For the general theory of theſe engines, ſee Bernoulli's Hydrodynamica.

Deſaguliers has ſettled the maximum of engines for raiſing water, thus: a man with the beſt Water engine cannot raiſe above one hogſhead of Water in a minute, 10 feet high, to hold it all day; but he can do almoſt twice as much for a minute or two.

WATER-*Spout*. See SPOUT.

WATER-*Wheel*, an engine for raiſing Water in great quantity out of a deep well, &c. See PERSIAN-*Wheel*.

WATER-*Works*. See *Raiſing of* WATER.

WAVE, in Phyſics, a volume of water elevated by the action of the wind &c, upon its ſurface, into a ſtate of fluctuation, and accompanied by a cavity. The extent from the bottom or loweſt point of one cavity, and acroſs the elevation, to the bottom of the next cavity, is the breadth of the Wave.

Waves are conſidered as of two kinds, which may be diſtinguiſhed from one another by the names of natural and accidental Waves. The natural Waves are thoſe which are regularly proportioned in ſize to the ſtrength of the wind which produces them. The accidental Waves are thoſe occaſioned by the wind's reacting upon itſelf by repercuſſion from hills or high ſhores, and by the daſhing of the Waves themſelves, otherwiſe of the natural kind, againſt rocks and ſhoals; by which means theſe Waves acquire an elevation much above what they can have in their natural ſtate.

Mr. Boyle proved, by numerous experiments, that the moſt violent wind never penetrates deeper than 6 feet into the water; and it ſeems a natural conſequence of this, that the water moved by it can only be elevated to the ſame height of 6 feet from the level of the ſurface in a calm; and theſe 6 feet of elevation being added to the 6 of excavation, in the part from whence that water ſo elevated was raiſed, ſhould give 12 feet for the utmoſt elevation of a Wave. This is a calculation that does great honour to its author; as many experiments and obſervations

obſervations have proved that it is very nearly true in deep ſeas, where the Waves are purely natural, and have no accidental cauſes to render them larger than their juſt proportion.

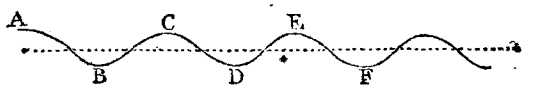
It is not to be underſtood however, that no Wave of the ſea can riſe more than 6 feet above its natural level in open and deep water; for Waves vaſtly higher than theſe are formed in violent tempeſts in the great ſeas. Theſe however are not to be accounted Waves in their natural ſtate, but as compound Waves formed by the union of many others; for in theſe wide plains of water, when one Wave is raiſed by the wind, and would elevate itſelf up to the exact height of 6 feet, and no more, the motion of the water is ſo great, and the ſucceſſion of Waves ſo quick, that while this is riſing, it receives into it ſeveral other Waves, each of which would have been at the ſame height with itſelf; theſe run into the firſt Wave one after another, as it is riſing; by which means its riſe is continued much longer than it naturally would have been, and it becomes accumulated to an enormous ſize. A number of theſe complicated Waves riſing together, and being continued in a long ſucceſſion by the continuation of the ſtorm, make the Waves ſo dangerous to ſhips, which the ſailors in their phraſe call mountains high.

Different Waves do not diſturb one another when they move in different directions. The reaſon is, that whatever figure the ſurface of the water has acquired by the motion of the Waves, there may in that be an elevation and depreſſion; as alſo ſuch a motion as is required in the motion of a Wave.

Waves are often produced by the motion of a tremulous body, which alſo expand themſelves circularly, though the body goes and returns in a right line; for the water which is raiſed by the agitation, deſcending, forms a cavity, which is every where ſurrounded with a riſing.

The Motion of the WAVES, makes an article in the Newtonian philoſophy; that author having explained their motions, and calculated their velocity from mathematical principles, ſimilar to the motion of a pendulum, and to the reciprocation of water in the two legs of a bent and inverted ſyphon or tube.

His propoſition concerning ſuch canal or tube is the 44th of the 2d book of his Principia, and is this: "If water aſcend and deſcend alternately in the erected legs of a canal or pipe; and a pendulum be conſtructed, whoſe length between the point of ſuſpenſion and the centre of oſcillation, is equal to half the length of the water in the canal; then the water will aſcend and deſcend in the ſame times in which the pendulum oſcillates." The author hence infers, in prop. 45, that the velocity of Waves is in the ſubduplicate ratio of their breadths; and in prop. 46, he proceeds "To find the velocity of Waves," as follows: "Let a pendulum be conſtructed, whoſe length between the point of ſuſpenſion and the centre of oſcillation is equal to the breadth of the Waves; and in the time that the pendulum will perform one ſingle oſcillation, the Waves will advance forward nearly a ſpace equal to their breadth. That which I call the breadth of the Waves, is the tranſverſe meaſure lying between the deepeſt part of the hollows, or between the tops of the ridges. Let ABCDEF repreſent the ſurface of ſtagnant water aſcending and deſcending in ſucceſſive Waves; alſo let



A, C, E, &c, be the tops of the Waves; and B, D, F, &c, the intermediate hollows. Becauſe the motion of the Waves is carried on by the ſucceſſive aſcent and deſcent of the water, ſo that the parts of it, as A, C, E, &c, which are higheſt at one time, become loweſt immediately after; and becauſe the motive force, by which the higheſt parts deſcend and the loweſt aſcend, is the weight of the elevated water, that alternate aſcent and deſcent will be analogous to the reciprocal motion of the water in the canal, and obſerve the ſame laws as to the times of its aſcent and deſcent; and therefore (by prob. 44, above mentioned) if the diſtances between the higheſt places of the Waves A, C, E, and the loweſt B, D, F, be equal to twice the length of any pendulum, the higheſt parts A, C, E, will become the loweſt in the time of one oſcillation, and in the time of another oſcillation will aſcend again. Therefore between the paſſage of each Wave, the time of two oſcillations will intervene; that is, the Wave will deſcribe its breadth in the time that the pendulum will oſcillate twice; but a pendulum of 4 times that length, and which therefore is equal to the breadth of the Waves, will juſt oſcillate once in that time. *Q. E. I.*

"*Corol.* 1. Therefore Waves, whoſe breadth is equal to $39\frac{1}{8}$ inches, or $3\frac{3}{16}\frac{5}{6}$ feet, will advance through a ſpace equal to their breadth in one ſecond of time; and therefore in one minute they will go over a ſpace of $195\frac{5}{8}$ feet; and in an hour a ſpace of 11737 feet, nearly, or 2 miles and almoſt a quarter.

"*Corol.* 2. And the velocity of greater or leſs Waves, will be augmented or diminiſhed in the ſubduplicate ratio of their breadth.

"Theſe things (Newton adds) are true upon the ſuppoſition, that the parts of water aſcend or deſcend in a right line; but in fact, that aſcent and deſcent is rather performed in a circle; and therefore I propoſe the time defined by this propoſition as only near the truth."

Stilling WAVES *by means of Oil.* This wonderful property, though well known to the Ancients, as appears from the writings of Pliny, was for many ages either quite unnoticed, or treated as fabulous by ſucceeding philoſophers. Of late it has, by means of Dr. Franklin, again attracted the attention of the learned; though it appears, from ſome anecdotes, that ſeafaring people have always been acquainted with it. In Martin's deſcription of the Weſtern Iſlands of Scotland, we have the following paſſage: "The ſteward of Kilda, who lives in Pabbay, is accuſtomed, in time of a ſtorm, to tie a bundle of puddings, made of the fat of ſea-fowl, to the end of his cable, and lets it fall into the ſea behind his rudder. This, he ſays, hinders the Waves from breaking, and calms the ſea." Mr. Pennant, in his Britiſh Zoology, vol. iv, under the article

Seal, takes notice, that when theſe animals are devouring a very oily fiſh, which they always do under water, the Waves above are remarkably ſmooth; and by this mark the fiſhermen know where to find them. Sir Gilbert Lawſon, who ſerved long in the army at Gibraltar, aſſured Dr. Franklin, that the fiſhermen in that place are accuſtomed to pour a little oil on the ſea, in order to ſtill its motion, that they may be enabled to ſee the oyſters lying at its bottom, which are there very large, and which they take up with a proper inſtrument. A ſimilar practice obtains among fiſhermen in various other parts, and Dr. Franklin was informed by an old ſea-captain, that the fiſhermen of Liſbon, when about to return into the river, if they ſaw too great a ſurf upon the bar, would empty a bottle or two of oil into the ſea, which would ſuppreſs the breakers, and allow them to paſs freely.

The Doctor having revolved in his mind all theſe pieces of information, became impatient to try the experiment himſelf. At laſt having an opportunity of obſerving a large pond very rough with the wind, he dropped a ſmall quantity of oil upon it. But having at firſt applied it on the lee ſide, the oil was driven back again upon the ſhore. He then went to the windward ſide, and poured on about a tea-ſpoon full of oil; this produced an inſtant calm over a ſpace ſeveral yards ſquare, which ſpread amazingly, and extended itſelf gradually till it came to the lee-ſide; making all that quarter of the pond, perhaps half an acre, as ſmooth as glaſs. This experiment was often repeated in different places, and always with ſucceſs. Our author accounts for it in the following manner:

"There ſeems to be no natural repulſion between water and air, to keep them from coming into contact with each other. Hence we find a quantity of air in water; and if we extract it by means of the air pump, the ſame water again expoſed to the air will ſoon imbibe an equal quantity.—Therefore air in motion, which is wind, in paſſing over the ſmooth ſurface of water, may rub as it were upon that ſurface, and raiſe it into wrinkles; which, if the wind continues, are the elements of future Waves. The ſmalleſt Wave once raiſed does not immediately ſubſide and leave the neighbouring water quiet; but in ſubſiding raiſes nearly as much of the water next to it, the friction of the parts making little difference. Thus a ſtone dropped into a pool raiſes firſt a ſingle Wave round itſelf, and leaves it, by ſinking to the bottom; but that firſt Wave ſubſiding raiſes a ſecond, the ſecond a third, and ſo on in circles to a great extent.

"A ſmall power continually operating, will produce a great action. A finger applied to a weighty ſuſpended bell, can at firſt move it but little; if repeatedly applied, though with no greater ſtrength, the motion increaſes till the bell ſwings to its utmoſt height, and with a force that cannot be reſiſted by the whole ſtrength of the arm and body. Thus the ſmall firſt raiſed Waves being continually acted upon by the wind, are, though the wind does not increaſe in ſtrength, continually increaſed in magnitude, riſing higher and extending their baſes, ſo as to include a vaſt maſs of water in each Wave, which in its motion acts with great violence. But if there be a mutual repulſion between the particles of oil, and no attraction between oil and water, oil dropped on water will not be held together by adheſion to the ſpot whereon it falls; it will not be imbibed by the water; it will be at liberty to expand itſelf; and it will ſpread on a ſurface that, beſides being ſmooth to the moſt perfect degree of poliſh, prevents, perhaps by repelling the oil, all immediate contact, keeping it at a minute diſtance from itſelf; and the expanſion will continue, till the mutual repulſion between the particles of the oil is weakened and reduced to nothing by their diſtance.

"Now I imagine that the wind blowing over water thus covered with a film of oil cannot eaſily catch upon it, ſo as to raiſe the firſt wrinkles, but ſlides over it, and leaves it ſmooth as it finds it. It moves the oil a little indeed, which being between it and the water, ſerves it to ſlide with, and prevents friction, as oil does between thoſe parts of a machine that would otherwiſe rub hard together. Hence the oil dropped on the windward ſide of a pond proceeds gradually to leeward, as may be ſeen by the ſmoothneſs it carries with it quite to the oppoſite ſide. For the wind being thus prevented from raiſing the firſt wrinkles that I call the elements of Waves, cannot produce Waves, which are to be made by continually acting upon and enlarging thoſe elements; and thus the whole pond is calmed.

"Totally therefore we might ſuppreſs the Waves in any required place, if we could come at the windward place where they take their riſe. This in the ocean can ſeldom if ever be done. But perhaps ſomething may be done on particular occaſions to moderate the violence of the Waves when we are in the midſt of them, and prevent their breaking when that would be inconvenient. For when the wind blows freſh, there are continually riſing on the back of every great Wave a number of ſmall ones, which roughen its ſurface, and give the wind hold, as it were, to puſh it with greater force. This hold is diminiſhed by preventing the generation of thoſe ſmall ones. And poſſibly too, when a Wave's ſurface is oiled, the wind, in paſſing over it, may rather in ſome degree preſs it down, and contribute to prevent its riſing again, inſtead of promoting it.

"This, as mere conjecture, would have little weight, if the apparent effects of pouring oil into the midſt of Waves were not conſiderable, and as yet not otherwiſe accounted for.

"When the wind blows ſo freſh, as that the Waves are not ſufficiently quick in obeying its impulſe, their tops being thinner and lighter, are puſhed forward, broken, and turned over in a white foam. Common Waves lift a veſſel without entering it; but theſe, when large, ſometimes break above and pour over it, doing great damage.

"That this effect might in any degree be prevented, or the height and violence of Waves in the ſea moderated, we had no certain account; Pliny's authority for the practice of ſeamen in his time being ſlighted. But diſcourſing lately on this ſubject with his excellency Count Bentinck of Holland, his ſon the honourable Captain Bentinck, and the learned profeſſor Allemand (to all whom I ſhowed the experiment of ſmoothing in a windy day the large piece of water at the head of the

green

green park), a letter was mentioned which had been received by the Count from Batavia, relative to the ſaving of a Dutch ſhip in a ſtorm by pouring oil into the ſea."

WAY *of a Ship*, is ſometimes uſed for her wake or track. But more commonly the term is underſtood of the courſe or progreſs which ſhe makes on the water under ſail: thus, when ſhe begins her motion, ſhe is ſaid to be *under Way*; when that motion increaſes, ſhe is ſaid to have *freſh Way* through the water; when ſhe goes apace, they ſay *ſhe has a good Way*; and the account of her rate of ſailing by the log, they call, *keeping an account of her Way*. And becauſe moſt ſhips are apt to fall a little to the leeward of their true courſe; it is cuſtomary, in caſting up the log-board, to allow ſomething for her *leeward Way*, or *leeway*. Hence alſo a ſhip is ſaid to have *head-Way*, and *ſtern-Way*.

WAYWISER, an inſtrument for meaſuring the road, or diſtance travelled; called alſo PERAMBULATOR, and PEDOMETER. See theſe two articles.

Mr. Lovell Edgworth communicated to the Society of Arts, &c, an account of a Way-wiſer of his invention; for which he obtained a ſilver medal. This machine conſiſts of a nave, formed of two round flat pieces of wood, 1 inch thick and 8 inches in diameter. In each of the pieces there are cut eleven grooves, $\frac{5}{8}$ of an inch wide, and $\frac{3}{8}$ deep; and when the two pieces are ſcrewed together, they encloſe eleven ſpokes, forming a wheel of ſpokes, without a rim: the circumference of the wheel is exactly one pole; and the inſtrument may be eaſily taken to pieces, and put up in a ſmall compaſs. On each of the ſpokes there is driven a ferril, to prevent them from wearing out; and in the centre of the nave, there is a ſquare hole to receive an axle. Into this hole is inſerted an iron or braſs rod, which has the thread of a very fine ſcrew worked upon it from one end to the other; upon this ſcrew hangs a nut which, as the rod turns round with the wheel, advances towards the nave of the wheel or recedes from it. The nut does this, becauſe it is prevented from turning round with the axle, by having its centre of gravity placed at ſome diſtance below the rod, ſo as always to hang perpendicularly like a plummet. Two ſides of this ſcrew are filed away flat, and have figures engraved upon them, to ſhew by the progreſſive motion of the nut, how many circumvolutions of the wheel and its axle have been made: on one ſide the diviſions of miles, furlongs, and poles are in a direct order, and on the other ſide the ſame diviſions are placed in a retrograde order.

If the perſon who uſes this machine places it at his right hand ſide, holding the axle looſely in his hands, and walks forward, the wheel will revolve, and the nut advance from the extremity of the rod towards the nave of the wheel. When two miles have been meaſured, it will have come cloſe to the wheel. But to continue this meaſurement, nothing more is neceſſary than to place the wheel at the left hand of the operator; and the nut will, as he continues the courſe, recede from the axletree, till another ſpace of two miles is meaſured.

It appears from the conſtruction of this machine, that it operates like circular compaſſes; and does not, like the common wheel Way-wiſer, meaſure the ſurface of every ſtone and molehill, &c, but paſſes over moſt of the obſtacles it meets with, and meaſures the chords only, inſtead of the arcs of any curved ſurfaces upon which it rolls.

WEATHER, denotes the ſtate or diſpoſition of the atmoſphere, with regard to heat and cold, drought and moiſture, fair or foul, wind, rain, hail, froſt, ſnow, fog, &c. See ATMOSPHERE, HAIL, HEAT, FROST, RAIN, &c.

There does not ſeem in all philoſophy any thing of more immediate concernment to us, than the ſtate of the Weather; as it is in, and by means of the atmoſphere, that all plants are nouriſhed, and all animals live and breathe; and as any alterations in the denſity, heat, purity, &c, of that, muſt neceſſarily be attended with proportionable ones in the ſtate of theſe.

The great, but regular alterations, a little change of Weather makes in many parts of inanimate matter, every perſon knows, in the common inſtance of barometers, thermometers, hygrometers, &c; and it is owing partly to our inattention, and partly to our unequal and intemperate courſe of life, that we alſo, like many other animals, do not feel as great and as regular ones in the tubes, chords, and fibres of our own bodies.

To eſtabliſh a proper theory of the Weather, it would be neceſſary to have regiſters carefully kept in divers parts of the globe, for a long ſeries of years; from whence we might be enabled to determine the directions, breadth, and bounds of the winds, and of the weather they bring with them; with the correſpondence between the Weather of divers places, and the difference between one ſort and another at the ſame place. We might thus in time learn to foretell many great emergencies; as, extraordinary heats, rains, froſts, droughts, dearths, and even plagues, and other epidemical diſeaſes, &c.

It is however but very few, and partial regiſters or accounts of the Weather, that have been kept. The Royal Society, the French Academy, and a few particular philoſophers, have at times kept ſuch regiſters as their fancies have dictated, but at no time a regular and correſpondent ſeries in many different places, at the ſame time, followed with particular compariſons and deductions from the whole, &c. The moſt of what has been done in this way, is as follows: The volumes of the Philoſophical Tranſactions from year to year; the ſame, for inſtructions and examples pertaining to the ſubject, vol. 65, part 2, art. 16; Eraſ. Bartholin has obſervations of the Weather for every day in the year 1671: Mr. W. Merle made the like at Oxford, for 7 years: Dr. Plot did the ſame at the ſame place, for the year 1684: Mr. Hillier, at Cape Corſe, for the years 1686 and 1687: Mr. Hunt and others at Greſham College, for the years 1695 and 1696: Dr. Derham at Upminſter in Eſſex, for the years 1691, 1692, 1697, 1698, 1699, 1703, 1704, 1705: Mr. Townley, in Lancaſhire, in 1697, 1698: Mr. Cunningham, at Emin in China, for the years 1698, 1699, 1700, 1701: Mr. Locke, at Oats in Eſſex, 1692: Dr. Scheuchzer, at Zurich, 1708; and Dr. Tilly, at Piſa, the ſame year: Profeſſor Toaldo, at Padua, for many years: Mr. T. Barker, at Lyndon, in Rutland, for many years in the Philoſ. Tranſ.: Mr. Dalton for Kendal, and Mr. Croſthwaite for Keſwick, in the years 1788,

1788, 1789, 1790, 1791, 1792, &c; and ſeveral others. The regiſter now kept, for many years, in the Philoſ. Tranſ. contains an account, two times every day, of the thermometer, barometer, hygrometer, quantity of rain, direction and ſtrength of the wind, and appearance of the atmoſphere, as to fair, cloudy, foggy, rainy, &c. And if ſimilar regiſters were kept in many other parts of the globe, and printed in ſuch-like public Tranſactions, they might readily be conſulted, and a proper uſe made of them, for eſtabliſhing this ſcience on the true baſis of experiment.

From many experiments, ſome general obſervations have been made, as follow: That barometers generally riſe and fall together, even at very diſtant places, and a conſequent conformity and ſimilarity of Weather; but this is the more uniformly ſo, as the places are nearer together, as might be expected. That the variations of the barometer are greater, as the places are nearer the pole; thus, for inſtance, the mercury at London has a greater range by 2 or 3 lines than at Paris; and at Paris, a greater than at Zurich; and at ſome places near the equator, there is ſcarce any variation at all. That the rain in Switzerland and Italy is much greater in quantity, for the whole year, than in Eſſex; and yet the rains are more frequent, or there are more rainy days, in Eſſex, than at either of thoſe places. That cold contributes greatly to rain; and this apparently by condenſing the ſuſpended vapours, and ſo making them deſcend: thus, very cold months, or ſeaſons, are commonly followed immediately by very rainy ones; and cold ſummers are always wet ones. That high ridges of mountains, as the Alps, and the ſnows with which they are covered, not only affect the neighbouring places by the colds, rains, vapours, &c, which they produce; but even diſtant countries, as England, often partake of their effects. See a collection of ingenious and meteorological obſervations and conjectures, by Dr. Franklin, in his Experiments, &c, pa. 182, &c. Alſo a Meteorological Regiſter kept at Mansfield Woodhouſe, from 1784 to 1794, Nottingham 1795, 8vo; and Kirwin's ingenious papers on this ſubject in the Tranſactions of the Iriſh Academy, vol. 5. See alſo the articles EVAPORATION, RAIN, and WIND.

Other Prognoſtics and Obſervations, are as follow:

That a thick dark ſky, laſting for ſome time, without either ſun or rain, always becomes firſt fair, and then foul, i. e. it changes to a fair clear ſky, before it turns to rain. And the reaſon is obvious: the atmoſphere is replete with vapours which, though ſufficient to reflect and intercept the ſun's rays from us, yet want denſity to deſcend; and while the vapours continue in the ſame ſtate, the Weather will do ſo too: accordingly, ſuch Weather is commonly attended with moderate warmth, and with little or no wind to diſturb the vapours, and a heavy atmoſphere to ſuſtain them; the barometer being commonly high: but when the cold approaches, and by condenſing the vapours drives them into clouds or drops, then way is made for the ſun beams; till the ſame vapours, by farther condenſation, be formed into rain, and fall down in drops.

That a change in the warmth of the Weather is followed by a change in the wind. Thus, the northerly and ſoutherly winds, though commonly accounted the *cauſes* of cold and warm Weather, are really the *effects* of the cold or warmth of the atmoſphere; of which Dr. Derham aſſures us he had ſo many confirmations, that he makes no doubt of it. Thus, it is common to ſee a warm ſoutherly wind ſuddenly changed to the north, by the fall of ſnow or hail; or to ſee the wind, in a cold froſty morning, north, when the ſun has well warmed the air, wheel towards the ſouth; and again turn northerly or eaſterly in the cold evening.

That moſt vegetables expand their flowers and down in ſunſhiny Weather: and towards the evening, and againſt rain, cloſe them again; eſpecially at the beginning of their flowering, when their ſeeds are tender and ſenſible. This is viſible enough in the down of Dandelion, and other downs: and eminently ſo in the flowers of pimpernel; the opening and ſhutting of which make what is called the countryman's *Weather-wiſer*, by which he foretels the Weather of the following day. The rule is, when the flowers are cloſe ſhut up, it betokens rain, and foul Weather; but when they are ſpread abroad, fair Weather.

The ſtalk of trefoil, lord Bacon obſerves, ſwells againſt rain, and grows more upright: and the like may be obſerved, though leſs ſenſibly, in the ſtalks of moſt other plants. He adds, that in the ſtubble fields there is found a ſmall red flower, called by the country people pimpernel, which opening in a morning, is a ſure indication of a fine day.

It is very conceivable that vegetables ſhould be affected by the ſame cauſes as the Weather, as they may be conſidered as ſo many hygrometers and thermometers, conſiſting of an infinite number of tracheæ, or air-veſſels; by which they have an immediate communication with the air, and partake of its moiſture, heat, &c.

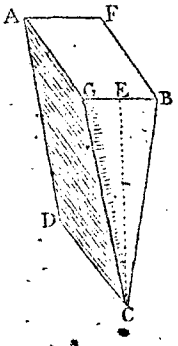
Hence it is, that all wood, even the hardeſt and moſt ſolid, ſwells in moiſt Weather; the vapours eaſily inſinuating into the pores, eſpecially of the lighter and drier kinds. And hence is derived a very extraordinary uſe of wood, viz, for breaking rocks or milſtones. The method at the quarries is this: Having cut a rock into the form of a cylinder, the workmen divide it into ſeveral thinner cylinders, of horizontal courſes, by making holes at proper diſtances round the great one; into theſe holes they drive pieces of ſallow wood, dried in an oven; theſe in moiſt Weather, imbibing the humidity from the air, ſwell, and acting like wedges they break or cleave the rock into ſeveral flat ſtones. And, in like manner, to ſeparate large blocks of ſtone in the quarry, they wedge ſuch pieces of wood into holes, forming the block into the intended ſhape, and then pour water upon the wedges, to produce the effect more immediately.

WEATHER-*Glaſſes*, are inſtruments contrived to ſhew the ſtate of the atmoſphere, as to heat, cold, moiſture, weight, &c; and ſo to meaſure the changes that take place in thoſe reſpects; by which means we are enabled to predict the alteration of Weather, as to rain, wind, froſt, &c.

Under the claſs of Weather-glaſſes, are comprehended barometers, thermometers, hygrometers, manometers, and anemometers.

WEDGE,

WEDGE, in Geometry, is a ſolid having a rectangular baſe, and two of its oppoſite ſides ending in an acies or edge. Thus, AB is the rectangular baſe; and DC the edge; a perpendicular CE, from the edge to the baſe, is the height of the Wedge. When the length of the edge DC is equal to the length of the baſe BF; which is the moſt common form of it, the Wedge is equal to half a rectangular priſm of the ſame baſe AB and height EC; or it is then a whole triangular priſm, having the triangle BCG for its baſe, and AG or DC for its height. If the edge be more or leſs than AG, its ſolid content will be more or leſs. But, in all caſes of the Wedge, the following is a general rule for finding the content of it, viz,



To twice the length of the baſe add the length of the edge, multiply the ſum by the breadth of the baſe, and the product by the height of the Wedge; then $\frac{1}{6}$ of the laſt product will be the ſolid content.

That is, $\overline{2AG + DC} \times AF \times \frac{1}{6} EC =$ the content. See this rule demonſtrated, and illuſtrated with examples, in my Menſuration, p. 191, 2d edition.

WEDGE, in Mechanics, one of the five mechanical powers, or ſimple engines; being a geometrical Wedge, or very acute triangular priſm, applied to the ſplitting of wood, or rocks, or raiſing great weights.

The Wedge is made of iron, or ſome other hard matter, and applied to the raiſing of vaſt weights, or ſeparating large or very firm blocks of wood or ſtone, by introducing the thin edge of the Wedge, and driving it in by blows ſtruck upon the back by hammers or mallets.

The Wedge is the moſt powerful of all the ſimple machines, having an almoſt unlimited and double advantage over all the other ſimple mechanical powers; both as it may be made vaſtly thin, in proportion to its height; in which conſiſts its own natural power; and as it is urged by the force of percuſſion, or of ſmart blows, which is a force incomparably greater than any mere dead weight or preſſure, ſuch as is employed upon other machines. And accordingly we find it produces effects vaſtly ſuperior to thoſe of any other power whatever; ſuch as the ſplitting and raiſing the largeſt and hardeſt rocks; or even the raiſing and lifting the largeſt ſhip, by driving a Wedge below it; which a man can do by the blow of a mallet: and thus the ſmall blow of a hammer, on the back of a Wedge, appears to be incomparably greater than any mere preſſure, and will overcome it.

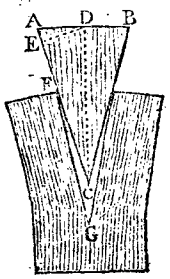
To the Wedge may be referred all edge-tools, and tools that have a ſharp point, in order to cut, cleave, ſlit, ſplit, chop, pierce, bore, or the like; as knives, hatchets, ſwords, bodkins, &c.

In the Wedge, the friction againſt the ſides is very great, at leaſt equal to the force to be overcome; becauſe the Wedge retains any poſition to which it is driven; and therefore the reſiſtance is at leaſt doubled by the friction.

Authors have been of various opinions concerning the principle from whence the Wedge derives its power. Ariſtotle conſiders it as two levers of the firſt kind, inclined towards each other, and acting oppoſite ways. Guido Ubaldi, Merſenne, &c, will have them to be levers of the ſecond kind. But De Lanis ſhews, that the Wedge cannot be reduced to any lever at all. Others refer the Wedge to the inclined plane. And others again, with De Stair, will hardly allow the Wedge to have any force at all in itſelf; aſcribing much the greateſt part to the mallet which drives it.

The doctrine of the force of the Wedge, according to ſome writers, is contained in this propoſition: "If a power directly applied to the head of a Wedge, be to the reſiſtance to be overcome, as the breadth of the back GB, is to the height EC; then the power will be equal to the reſiſtance; and if increaſed, it will overcome it."

But Deſaguliers has proved that, when the reſiſtance acts perpendicularly againſt the ſides of the Wedge, the power is to the whole reſiſtance, as the thickneſs of the back is to the length of both the ſides taken together. And the ſame proportion is adopted by Wallis (Op. Math. vol. 1, p. 1016), Keill (Intr. ad Ver. Phyſ.), Graveſande (Elem. Math. Lib. 1, cap. 14), and by almoſt all the modern mathematicians. Graveſande indeed diſtinguiſhes the mode in which the Wedge acts, into two caſes, one in which the parts of a block of wood, &c, are ſeparated farther than the edge has penetrated to, and the other in which they have not ſeparated farther: In his Scholium de Ligno findendo (ubi ſupra), he obſerves, that when the parts of the wood are ſeparated before the Wedge, the equilibrium will be when the force by which it is puſhed in, is to the reſiſtance of the wood, as the line DE drawn from the middle of the baſe to the ſide of the Wedge but perpendicular to the ſeparated ſide of the wood continued FG, is to the height of the Wedge DC; but when the parts of the wood are ſeparated no farther than the Wedge is driven in, the equilibrium will be, when the power is to the reſiſtance, as the half baſe AD, is to its ſide AC.



Mr. Ferguſon, in eſtimating the proportion of equilibrium in the two caſes laſt mentioned by Graveſande, agrees with this author, and other modern philoſophers, in the latter caſe; but in the former he contends, that when the wood cleaves to any diſtance before the Wedge, as it generally does, then the power impelling the Wedge, will be to the reſiſtance of the wood, as half its thickneſs, is to the length of either ſide of the cleft, eſtimated from the top or acting part of the Wedge: for, ſuppoſing the Wedge to be lengthened down to the bottom of the cleft, the power will be to the reſiſtance, as half the thickneſs of the Wedge is to the length of either of its ſides. See Ferguſon's Lect. p. 40, &c, 4to. See alſo Deſagu. Exp. Phil. vol. 1, p. 107; and Ludlam's Eſſay on the Power of the Wedge, printed in 1770; &c.

The generally acknowledged property of the Wedge, and the ſimpleſt way of demonſtrating it, ſeem to be the following: When a Wedge is kept in equilibrio, the power acting againſt the back, is to the force acting prepen-

perpendicularly againſt either ſide, as the breadth of the back AB, is to the length of the ſide AC or BC. —*Demonſtra.* For any three forces which ſuſtain one another in equilibrio, are as the correſponding ſides of a triangle that are drawn perpendicular to the directions in which the forces act. But AB is perpendicular to the force acting on the back, to drive the Wedge forward; and the ſides AC and BC are perpendicular to the forces acting upon them; therefore the three forces are as the ſaid lines AB, AC, BC.

Hence, the thinner a Wedge is, the greater is its effect, in ſplitting any body, or in overcoming any reſiſtance againſt the ſide of the Wedge.

WEDNESDAY, the 4th day of the week, formerly conſecrated by the inhabitants of the northern nations to Woden or Oden; who, being reputed the author of magic and inventor of all the arts, was thought to anſwer to the Mercury of the Greeks and Romans, in honour of whom the ſame day was by them called *dies Mercurii*; and hence it is denoted by aſtronomers by the character of Mercury ☿.

WEEK, a diviſion of time that compriſes ſeven days.

The origin of this diviſion of Weeks, or of computing time by ſevenths, is much controverted. It has often been thought to have taken its riſe from the four quarters or intervals of the moon, between her changes of phaſes, which, being about 7 days diſtant, gave occaſion to the diviſion: but others more probably, from the ſeven planets.

Be this however as it may, the diviſion is certainly very ancient. The Syrians, Egyptians, and moſt of the oriental nations, appear to have uſed it from the earlieſt ages: though it did not get footing in the weſt till brought in by chriſtianity. The Romans reckoned their days not by ſevenths, but by ninths; and the ancient Greeks by decads, or tenths; in imitation of which the new French calendar ſeems to have been framed.

The Jews divided their time by Weeks, of 7 days each, as preſcribed by the law of Moſes; in which they were appointed to work 6 days, and to reſt the 7th, in commemoration of the creation, which being effected in 6 days, God reſted on the 7th.

Some authors will even have the uſe of Weeks, among the other eaſtern nations, to have proceeded from the Jews; but with little appearance of probability. It is with better reaſon that others ſuppoſe the uſe of Weeks, among the eaſtern nations, to be a remnant of the tradition of the creation, which they had ſtill retained with divers others; or elſe from the number of the planets.

The Jews denominated the days of the Week, the firſt, ſecond, third, fourth, and fifth; and the ſixth day they named the preparation of the ſabbath, or 7th day, which anſwered to our Saturday. And the like method is ſtill kept up by the chriſtian Arabs, Perſians, Ethiopians, &c.

The ancient heathens denominated the days of the Week from the ſeven planets; which names are ſtill moſtly retained among the chriſtians of the weſt: thus, the firſt day was called *dies ſolis*, *ſun-day*; the 2d *dies lunæ*, *moon day*; &c; a practice the more natural on Dion's principle, that the Egyptians took the diviſion of the Week itſelf from the ſeven planets.

In fact, the true reaſon for theſe denominations ſeems to be founded in aſtrology. For the aſtrologers diſtributing the government and direction of all the hours in the Week among the ſeven planets, ♄ ♃ ♂ ☉ ♀ ☿ ☽, ſo as that the government of the firſt hour of the firſt day fell to Saturn, that of the ſecond day to Jupiter, &c, they gave each day the name of the planet which, according to their doctrine, preſided over the firſt hour of it, and that according to the order above ſtated. So that the order of the planets in the Week, bears little relation to that in which they follow in the heavens: the former being founded on an imaginary power each planet has, in its turn, on the firſt hour of each day.

Dion Caſſius gives another reaſon for the denomination, drawn from the celeſtial harmony. For it being obſerved, that the harmony of the diateſſaron, which conſiſts in the ratio of 4 to 3, is of great force and effect in muſic; it was judged meet to proceed directly from Saturn to the Sun; becauſe, according to the old ſyſtem, there are three planets between Saturn and the Sun, and 4 from the Sun to the Moon.

Our Saxon anceſtors, before their converſion to Chriſtianity, named the ſeven days of the Week from the Sun and Moon and ſome of their deified heroes, to whom they were peculiarly conſecrated, and repreſenting the ancient gods or planets; which names we received and ſtill retain: Thus, Sunday was devoted to the Sun; Monday to the Moon; Tueſday to Tuiſco; Wedneſday to Woden; Thurſday to Thor, the thunderer; Friday to Friga or Friya or Fræa, the wife of Thor; and Saturday to Seater. And nearly according to this order, the modern aſtronomers expreſs the days of the Week by the ſeven planets as below:

☉ Sunday
☾ Monday
♂ Tueſday
☿ Wedneſday
♃ Thurſday
♀ Friday
♄ Saturday.

In the ſame order and number alſo do theſe obtain in the Hindoo days of the Week. See Kinderſley's Specimens of Hindoo Literature, juſt publiſhed, 8vo.

WEIGH, WAY, or WEY, a weight of cheeſe, wool, &c, containing 256 pounds avoirdupois. Of corn, the Weigh contains 40 buſhels; of barley or malt, 6 quarters.

WEIGHT, or *Gravity*, in Phyſics, a quality in natural bodies, by which they tend downwards toward the centre of the earth. See GRAVITY.

Weight, like gravity, may be diſtinguiſhed into *abſolute*, *ſpecific*, and *relative*.

Newton demonſtrates, 1. That the Weights of all bodies, at equal diſtances from the centre of the earth, are directly proportional to the quantities of matter that each contains: Whence it follows, that the Weights of bodies have no dependence on their ſhapes or textures; and that all ſpaces are not equally full of matter.

2. On different parts of the earth's ſurface, the Weight of the ſame body is different; owing to the ſpheroidal figure of the earth, which cauſes the body on the ſurface to be nearer the centre in going from the equator toward the poles; and the increaſe in the Weight is

nearly

nearly in proportion to the verſed ſine of double the latitude; or, which is the ſame thing, to the ſquare of the right ſine of the latitude: the Weight at the equator to that at the pole, being as 229 to 230; or the whole increaſe of Weight from the equator to the pole, is the 229th part of the former.

3. That the Weights of the ſame body, at different diſtances above the earth, are inverſely as the ſquares of the diſtances from the centre. So that, a body at the diſtance of the moon, which is 60 ſemidiameters from the earth's centre, would weigh only the 3600th part of what it weighs at the earth's ſurface.

4. That at different diſtances within the earth, or below the ſurface, the weights of the ſame body are directly as the diſtances from the earth's centre: ſo that, at half way toward the centre, a body would weigh but half as much, and at the very centre it would be no Weight at all.

5. A body immerſed in a fluid, which is ſpecifically lighter than itſelf, loſes ſo much of its Weight, as is equal to the Weight of a quantity of the fluid of the ſame bulk with itſelf. Hence, a body loſes more of its weight in a heavier fluid than in a lighter one; and therefore it weighs more in a lighter fluid than in a heavier one.

The Weight of a cubic foot of pure water, is 1000 ounces, or 62½ pounds, avoirdupois. And the Weights of the cubic foot of other bodies, are as ſet down under the article *Specific* GRAVITY.

In the Philoſ. Tranſ. (number 458, p. 457 &c) is contained ſome account of the analogy between Engliſh Weights and meaſures, by Mr. Barlow. He ſtates, that anciently the cubic foot of water was aſſumed as a general ſtandard for liquids. This cubic foot, of 62½ lb, multiplied by 32, gives 2000, the weight of a ton: and hence 8 cubic feet of water made a hogſhead, and 4 hogſheads a tun, or ton, in capacity and denomination, as well as Weight.

Dry meaſures were raiſed on the ſame model. A buſhel of wheat, aſſumed as a general ſtandard for all ſorts of grain, alſo weighed 62½lb. Eight of theſe buſhels make a quarter, and 4 quarters, or 32 buſhels, a ton Weight. Coals were ſold by the chaldron, ſuppoſed to weigh a ton, or 2000 pounds; though in reality it weighs perhaps upwards of 3000 pounds.

Hence a ton in Weight is the common ſtandard for liquids, wheat, and coals. Had this analogy been adhered to, the confuſion now complained of would have been avoided.—It may reaſonably be ſuppoſed that corn and other commodities, both dry and liquid, were firſt ſold by Weight; and that meaſures, for convenience, were afterwards introduced, as bearing ſome analogy to the Weights before uſed.

WEIGHT, *Pondus*, in Mechanics, denotes any thing to be raiſed, ſuſtained, or moved by a machine; or any thing that in any manner reſiſts the motion to be produced.

In all machines, there is a natural and fixed ratio between the Weight and the moving power: and if they be ſuch as to balance each other in equilibrio, and then the machine be put in motion by any other force; the Weight and power will always be reciprocally as the velocities of them, or of their centres of gravity; or their momentums will be equal, that is, the product of the Weight multiplied by its velocity, will be equal to the product of the power multiplied by its velocity.

WEIGHT, in Commerce, denotes a body of a known Weight, appointed to be put into a balance againſt other bodies, whoſe Weight is required to be known. Theſe Weights are uſually of lead, iron, or braſs; though in ſeveral parts of the Eaſt Indies common flints are uſed; and in ſome places a ſort of little beans.

The diverſity of Weights, in all nations, and at all times, makes one of the moſt perplexing circumſtances in commerce, &c. And it would be a very great convenience if all nations could agree upon a univerſal ſtandard, and ſyſtem, both of Weights and meaſures.

Weights may be diſtinguiſhed into *ancient* and *modern*, *foreign* and *domeſtic*.

Modern WEIGHTS, *uſed in the ſeveral parts of Europe, and the Levant.*

Engliſh WEIGHTS. By the 27th chapter of Magna Charta, the Weights are to be the ſame all over England: but for different commodities there are two different ſorts, viz, *troy Weight*, and *averdupois Weight*.

The origin from which both of theſe are raiſed, is the grain of wheat, gathered in the middle of the ear:

32 of theſe, well dried, made one pennyweight,
20 pennyweights - - - - - one ounce, and
12 ounces - - - - - - - - one pound troy;

by Stat. 51 Hen. III; 31 Edw. I; 12 Henry VII.

A learned writer has ſhewn that, by the laws of aſſize, from William the Conqueror to the reign of Henry VII, the legal pound Weight contained a pound of 12 ounces, raiſed from 32 grains of wheat; and the legal gallon meaſure contained 8 of thoſe pounds of wheat, 8 gallons making the buſhel, and 8 buſhels the quarter.

Henry VII. altered the old Engliſh Weight, and introduced the troy pound in its ſtead, being 3 quarters of an ounce only heavier than the old Saxon pound, or 1-16th heavier. The firſt ſtatute that directs the uſe of the averdupois Weight, is that of 24 Henry VIII; and the particular uſe to which this Weight is thus directed, is ſimply for weighing butcher's meat in the market; though it is now uſed for weighing all ſorts of coarſe and large articles. This pound contains 7000 troy grains; while the troy pound itſelf contains only 5760 grains, and the old Saxon pound Weight but 5400 grains. Philoſ. Tranſ. vol. 65, art. 3.

Hence there are now in common uſe in England, two different Weights, viz, troy Weight, and averdupois Weight, the former being employed in weighing ſuch fine articles as jewels, gold, ſilver, ſilk, liquors, &c; and the latter for coarſe and heavy articles, as bread, corn, fleſh, butter, cheeſe, tallow, pitch, tar, iron, copper, tin, &c. and all grocery wares. And Mr. Ward ſuppoſes that it was brought into uſe from this circumſtance, viz, as it was cuſtomary to allow larger Weight, of ſuch coarſe articles, than the law had expreſsly enjoined, and this he obſerves happened to be a 6th part more. Apothecaries buy their drugs by averdupois Weight, but they compound them by troy Weight, though under ſome little variation of name and diviſions.

The troy or trone pound Weight in Scotland, which by ſtatute is to be the ſame as the French pound, is commonly ſuppoſed equal to $15\frac{3}{4}$ Engliſh troy ounces, or 7560 grains; but by a mean of the ſtandards kept by the dean of gild of Edinburgh, it weighs $7599\frac{1}{16}$ or 7600 grains nearly.

The following tables ſhew the diviſions of the troy and averdupois Weights.

Table of Troy Weight, as uſed,

1. By the Goldſmiths, &c.

Grains	Pennywt.	Ounce	Pound
24 =	1 dwt.		
480 =	20 =	1 oz.	
5760 =	240 =	12 =	1 lb.

2. By the Apothecaries.

Grains	Scruples	Drams	Ounces	Pound
20 =	1 ℈			
60 =	3 =	1 ʒ		
480 =	24 =	8 =	1 ℥	
5760 =	288 =	96 =	12 =	1 lb.

Table of Averdupois Weight.

Drams	Ounces	Pounds	Quarters	Hund. wt.	Ton
16 =	1				
256 =	16 =	1			
7168 =	448 =	28 =	1		
28672 =	1792 =	112 =	4 =	1	
573440 =	35840 =	2240 =	80 =	20 =	1

Mr. Ferguſon (Lect. on Mech. p. 100, 4to) gives the following compariſon between troy and averdupois Weight.

175 troy pounds are equal to 144 averdup. pounds.
175 troy ounces are equal to 192 averdup. ounces.
1 troy pound contains 5760 grains.
1 averdupois pound contains 7000 grains.
1 averdupois ounce contains $437\frac{1}{2}$ grains.
1 averdupois dram contains 27·34375 grains.
1 troy pound contains 13 oz. 2·651428576 drams averdupois
1 averdup. lb. contains 1 lb 2 oz 11 dwts 16 gr troy

The moneyers, jewellers, &c, have a particular claſs of Weights, for gold and precious ſtones, viz, *carat* and *grain*; and for ſilver, the *pennyweight* and *grain*. The moneyers have alſo a peculiar ſubdiviſion of the troy grain: thus, dividing

the grain into 20 mites
the mite into 24 droits
the droit into 20 periots
the periot into 24 blanks.

The dealers in wool have likewiſe a particular ſet of Weights; viz, the *ſack*, *weigh*, *tod*, *ſtone*, and *clove*, the proportions of which are as below: viz,

the ſack containing 2 weighs
the weigh - - - - $6\frac{1}{2}$ tods
the tod - - - - - - 2 ſtones
the ſtone - - - - - 2 cloves
the clove - - - - - 7 pounds.

Alſo 12 ſacks make a laſt or 4368 pounds.

Farther,
56 lb of old hay, or 60 lb new hay, make a truſs.
40 lb of ſtraw make a truſs.
36 truſſes make a load, of hay or ſtraw.
14 lb make a ſtone.
5 lb of glaſs a ſtone.

French WEIGHTS. The common or Paris pound Weight, is to the Engliſh troy pound, as 21 to 16, and to the averdupois pound as 27 to 25; it therefore contains 7560 troy grains; and it is divided into 16 ounces like the pound averdupois, but more particularly thus: the pound into 2 *marcs*; the marc into 8 *ounces*; the ounce into 8 *gros*, or *drams*; the groſs or dram into 3 deniers, Paris ſcruples or pennyweights; and the pennyweight into 24 *grains*; the grain being an equivalent to a grain of wheat. So that the Paris ounce contains $472\frac{1}{2}$ troy grains, and therefore it is to the Engliſh troy ounce as 63 to 64. But in ſeveral of the French provinces, the pound is of other different Weights. A *quintal* is equal to 100 pounds.

The Weights above enumerated under the two articles of Engliſh and French Weights, are the ſame as are uſed throughout the greateſt part of Europe; only under ſomewhat different names, diviſions, and proportions. And beſides, particular nations have alſo certain Weights peculiar to themſelves, of too little conſequence here to be enumerated. But to ſhew the proportion of theſe ſeveral Weights to one another, there may be here added a reduction of the divers pounds in uſe throughout Europe, by which the other Weights are eſtimated, to one ſtandard pound, viz, the pound of Amſterdam, Paris, and Bourdeaux; as they were accurately calculated by M. Ricard, and publiſhed in the new edition of his Traité de Commerce, in 1722.

Proportion of the WEIGHTS *of the chief Cities in Europe, to that of Amſterdam.*

100 pounds of Amſterdam are equal to

108 lbs	of Alicant	100 lbs	of Bilboa
105	Antwerp	105	Bois le Duc
120	Archangel, or 3 poedes	151	Bologna
		100	Bourdeaux
105	Arſchot	104	Bourg en Breſſe
120	Avignon	103	Bremen
98	Baſil	125	Breſlaw
100	Bayonne	105	Bruges
166	Bergamo	105	Bruſſels
97	Berg. op Zoom	105	Cadiz
$95\frac{1}{4}$	Bergen, Norw.	105	Cologne
111	Bern.	$107\frac{1}{2}$	Copenhagen
100	Beſançon	87	Conſtantinople

WEIGHTS *continued.*

100 pounds of Amſterdam are equal to

113½	lbs of Dantzic	154	lbs of Meſſina
100	Dort	168	Milan
97	Dublin	126	Montpelier
97	Edinburgh	125	Muſcovy
143	Florence	100	Nantes
98	Franckfort, fur Maine	100	Nancy
		169	Naples
105	Gaunt	98	Nuremberg
89	Geneva	100	Paris
163	Genoa	112½	Revel
102	Hamburgh	109	Riga
125	Koningſberg	100	Rochel
105	Leipſic	146	Rome
106	Leyden	100	Rotterdam
143	Leghorn	96	Rouen
105½	Liege	100	S. Malo
106	Liſbon	100	S. Sebaſtian
114	Liſle	158⅓	Saragoſa
109	London, averdupois	100	Seville
		114	Smyrna
105	Louvain	110	Stetin
105	Lubeck	81	Stockholm
141½	Lucca	118	Tholouſe
116	Lyons	151	Turin
114	Madrid	158½	Valencia
105	Malines	182	Venice.
123¼	Marſeilles		

Ancient WEIGHTS.

1. The Weights of the ancient Jews, reduced to the Engliſh troy Weights, will ſtand as below:

	lb	oz	dwt	gr
Shekel	0	0	9	2 4/7
Manch	2	3	6	10 4/7
Talent	113	10	1	10 2/7

2. Grecian and Roman Weights, reduced to Engliſh troy Weight, are as in the following table:

	lb	oz	dwt	gr
Lentes	0	0	0	0 35/144
Siliquæ	0	0	0	3 1/24
Obolus	0	0	0	9 2/24
Scriptulum	0	0	0	18 3/24
Drachma	0	0	2	6 12/24
Sextula	0	0	3	0 6/7
Sicilicus	0	0	4	13 2/7
Duella	0	0	6	1 5/7
Uncia	0	0	18	5 1/7
Libra	0	10	18	13 5/7

The Roman ounce is the Engliſh averdupois ounce, which they divide into 7 denarii, as well as 8 drachms: and as they reckoned their denarius equal to the Attic drachm, this will make the Attic Weights one-eighth heavier than the correſpondent Roman Weights. Arbuth.

Regulation of WEIGHTS *and Meaſures.* This is a branch of the king's prerogative. For the public convenience, theſe ought to be univerſally the ſame throughout the nation, the better to reduce the prices of articles to equivalent values. But as Weight and meaſure are things in their nature arbitrary and uncertain, it is neceſſary that they be reduced to ſome fixed rule or ſtandard. It is however impoſſible to fix ſuch a ſtandard by any written law or oral proclamation; as no perſon can, by words only, give to another an adequate idea of a pound Weight, or foot-rule. It is therefore expedient to have recourſe to ſome viſible, palpable, material ſtandard; by forming a compariſon with which, all Weights and meaſures may be reduced to one uniform ſize. Such a ſtandard was anciently kept at Wincheſter: and we find in the laws of king Edgar, near a century before the conqueſt, an injunction that that meaſure ſhould be obſerved throughout the realm.

Moſt nations have regulated the ſtandard of meaſures of length from ſome parts of the human body; as the palm, the hand, the ſpan, the foot, the cubit, the ell (*ulna* or arm), the pace, and the fathom. But as theſe are of different dimenſions in men of different proportions, ancient hiſtorians inform us, that a new ſtandard of length was fixed by our king Henry the firſt; who commanded that the *ulna* or ancient ell, which anſwers to the modern yard, ſhould be made of the exact length of his own arm.

A ſtandard of long meaſure being once gained, all others are eaſily derived from it; thoſe of greater length by multiplying that original ſtandard, thoſe of leſs by dividing it. Thus, by the ſtatute called *compoſitio ulnarum et perticarum*, 5½ yards make a perch; and the yard is ſubdivided into 3 feet, and each foot into 12 inches; which inches will be each of the length of 3 barley corns. But ſome, on the contrary, derive all meaſures, by compoſition, from the barley corn.

Superficial meaſures are derived by ſquaring thoſe of length; and meaſures of capacity by cubing them.

The ſtandard of Weights was originally taken from grains or corns of wheat, whence our loweſt denomination of Weights is ſtill called a *grain*; 32 of which are directed, by the ſtatute called *compoſitio menſurarum*, to compoſe a pennyweight. 20 of which make an ounce, and 12 ounces a pound, &c.

Under king Richard the firſt it was ordained, that there ſhould be only one Weight and one meaſure throughout the nation, and that the cuſtody of the aſſize or ſtandard of Weights and meaſures, ſhould be committed to certain perſons in every city and borough; from whence the ancient office of the king's ulnager ſeems to have been derived. Theſe original ſtandards were called *pondus regis*, and *menſura domini regis*, and are directed by a variety of ſubſequent ſtatutes to be kept in the exchequer chamber, by an officer called the *clerk of the market*, except the wine gallon, which is committed to the city of London, and kept in Guildhall.

The Scottiſh ſtandards are diſtributed among the oldeſt boroughs. The elwand is kept at Edinburgh, the pint at Stirling, the pound at Lanark, and the firlot at Linlithgow.

The two principal Weights eſtabliſhed in Great Britain, are troy Weight, and avoirdupois Weight,

as before mentioned. Under the head of the former it may farther be added, that

A carat is a Weight of 4 grains; but when the term is applied to gold, it denotes the degree of fineneſs. Any quantity of gold is ſuppoſed divided into 24 parts. If the whole maſs be pure gold, it is ſaid to be 24 carats fine; if there be 23 parts of pure gold, and one part of alloy or baſe metal, it is ſaid to be 23 carats fine, and ſo on.

Pure gold is too ſoft to be uſed for coin. The ſtandard coin of this kingdom is 22 carats fine. A pound of ſtandard gold is coined into $44\frac{1}{2}$ guineas, and therefore every guinea ſhould weigh 5 dwts $9\frac{3}{8}\frac{9}{9}$ grains.

A pound of ſilver for coin contains 11 oz 2 dwts pure ſilver, and 18 dwts alloy: and ſtandard ſilver-plate, 11 ounces pure ſilver, with 1 ounce alloy. A pound of ſtandard ſilver is coined into 62 ſhillings; and therefore the Weight of a ſhilling ſhould be 3 dwts $20\frac{8}{11}$ grains.

Univerſal Standard for WEIGHTS *and Meaſures.*

Philoſophers, from their habits of generalizing, have often made ſpeculations for forming a general ſtandard for Weights and meaſures through the whole world. Theſe have been deviſed chiefly of a philoſophical nature, as beſt adapted to univerſality. After the invention of pendulum clocks, it firſt occurred that the length of a pendulum which ſhould vibrate ſeconds, would be proper to be made a univerſal ſtandard for lengths; whether it ſhould be called a yard, or any thing elſe. But it was found, that it would be difficult in practice, to meaſure and determine the true length of ſuch a pendulum, that is the diſtance between the point of ſuſpenſion and the point of oſcillation. Another cauſe of inaccuracy was afterwards diſcovered, when it was found that the ſeconds pendulum was of different lengths in all the different latitudes, owing to the ſpheroidal figure of the earth, which cauſes that all places in different latitudes are at different diſtances from the centre, and conſequently the pendulums are acted upon by different forces of gravity, and therefore require to be of different lengths. In the latitude of London this is found to be $39\frac{1}{8}$ inches.

The Society of Arts in London, among their many laudable and patriotic endeavours, offered a handſome premium for the diſcovery of a proper ſtandard for Weights and meaſures. This brought them many frivolous expedients, as well as one which was an improvement on the method of the pendulum, by one Hatton. This conſiſted in meaſuring the difference of the lengths of two pendulums of different times of vibration; which could be performed more eaſily and accurately than that of the length of one ſingle pendulum. This method was put in practice, and fully explained and illuſtrated, by the late Mr. Whitehurſt, in his attempt to aſcertain an Univerſal Standard of Weights and Meaſures. But ſtill the ſame kind of inaccuracy of meaſurement &c, obtains in this way, as in the ſingle pendulum, though in a ſmaller degree.

Another method that has been propoſed for this purpoſe, is the ſpace that a heavy body falls freely through in 1 ſecond of time. But this is an experiment more difficult than the former to be made with accuracy; on which account, different perſons will all make the ſpace fallen to be of different quantities, which would give as many different ſtandards of length. Add to this, that the ſpheroidal form of the earth here again introduces a diverſity in the ſpace, owing to the different diſtances from the centre, and the conſequent diverſity in the force of gravity by which the body falls. This ſpace has been found to be 193 inches, or $16\frac{1}{12}$ feet, in the latitude of London; but it will be a different quantity in other latitudes.

Many other inferior expedients have alſo been propoſed for the purpoſe of univerſal meaſures, and Weights; but there is another which now has the beſt proſpect of ſucceſs, and is at preſent under particular experiments, by the philoſophers both of this and the French nation. This method is by the meaſure of the degrees of latitude; which would give a large quantity, and admit of more accurate meaſures, by ſubdiviſion, than what could be obtained by beginning from a ſmall quantity, or meaſure, and thence to proceed increaſing by multiples. This meaſure might be taken either from the extent of the whole compaſs of the earth, or of all the 360 degrees, or a medium degree among them all, or from the meaſure of a degree in the medium latitude of 45 degrees. It will alſo be moſt convenient to make the ſubdiviſions of this meaſure, when found, to proceed decimally, or continually by 10ths.

The univerſal ſtandard for lengths being once eſtabliſhed, thoſe of Weights, &c, would eaſily follow. For inſtance, a veſſel, of certain dimenſions, being filled with diſtilled water, or ſome other homogeneous matter, the Weight of that may be conſidered as a ſtandard for Weights.

WEIGHT of the Air, Water, &c. See thoſe articles ſeverally. See alſo SPECIFIC GRAVITY.

WERST, a Ruſſian meaſure of length, equal to 3500 Engliſh feet.

WEST, one of the cardinal points of the horizon, or of the compaſs, diametrically oppoſite to the eaſt, or lying on the left hand when we face the north. Or Weſt is ſtrictly the interſection of the prime vertical with the horizon, on that ſide where the ſun ſets.

WEST *Wind*, is alſo called *Zephyrus*, and *Favonius*.

WEST *Dial*. See DIAL.

WESTERN *Amplitude*, *Horizon*, *Ocean*. See the ſeveral articles.

WESTING, in Navigation, is the quantity of departure made good to the weſtward from the meridian.

WEY. See WEIGH.

WHALE, in Aſtronomy, one of the conſtellations. See CETUS.

WHEEL, in Mechanics, a ſimple machine, conſiſting of a circular piece of wood, metal, or other matter, that revolves on an axis. This is otherwiſe called *Wheel and Axle*, or AXIS *in Peritrochio*, as a mechanical power, being one of the moſt frequent and uſeful of any. In this capacity of it, the Wheel is a kind of perpetual lever, and the axis another leſſer one; or the radius of the Wheel and that of its axis may be conſidered as the longer and ſhorter arms of a lever, the centre of the Wheel being the fulcrum or point of

ſuſpen-

ſuſpenſion. Whence it is, that the power of this machine is eſtimated by this rule, as the radius of the axis is to the radius of the Wheel or of the circumference, ſo is any given power, to the weight it will ſuſtain.

Wheels, as well as their axes, are frequently dented, or cut into teeth, and are then of uſe upon innumerable occaſions; as in jacks, clocks, mill-work, &c; by which means they are capable of moving and acting on one another, and of being combined together to any extent; the teeth either of the axis or circumference working in thoſe of other Wheels or axles; and thus, by multiplying the power to any extent, an amazing great effect is produced.

To compute the power of a combination of Wheels; the teeth of the axis of every Wheel acting on thoſe in the circumference of the next following. Multiply continually together the radii of all the axes, as alſo the radii of all the Wheels; then it will be, as the former product is to the latter product, ſo is a given power applied to the circumference, to the weight it can ſuſtain. Thus, for example, in a combination of five Wheels and axles, to find the weight a man can ſuſtain, or raiſe, whoſe force is equal to 150 pounds, the radii of the Wheels being 30 inches, and thoſe of the axes 3 inches. Here $3\times 3\times 3\times 3\times 3 = 243$, and $30\times 30\times 30\times 30\times 30 = 24300000$, therefore as 243 : 24300000 :: 150 : 15000000 lb, the weight he can ſuſtain, which is more than 6696 tons weight. So prodigious is the increaſe of power in a combination of Wheels!

But it is to be obſerved, that in this, as well as every other mechanical engine, whatever is gained in power, is loſt in time; that is, the weight will move as much ſlower than the power, as the force is increaſed or multiplied, which in the example above is 100000 times ſlower.

Hence, having given any power, and the weight to be raiſed, with the proportion between the Wheels and axles neceſſary to that effect; to find the number of the Wheels and axles. Or, having the number of the Wheels and axles given, to find the ratio of the radii of the Wheels and axles. Here, putting

p = the power acting on the laſt wheel,
w = the weight to be raiſed,
r = the radius of the axles,
R = the radius of the wheels,
n = the number of the wheels and axles;

then, by the general proportion, as $r^n : R^n :: p : w$; therefore $pR^n = wr^n$ is a general theorem, from whence may be found any one of theſe five letters or quantities, when the other four are given. Thus, to find n the number of Wheels: we have firſt

$$\frac{R^n}{r^n} = \frac{w}{p}, \text{ then } n = \frac{\log. w - \log. p}{\log. R - \log. r}.$$

And to find $\frac{R}{r}$, the ratio of the Wheel to the axle; it is

$$\frac{R}{r} = \sqrt[n]{\frac{w}{p}}.$$

Wheels *of a Clock*, &c, are, the crown wheel, contrat wheel, great wheel, ſecond wheel, third wheel, ſtriking wheel, detent wheel, &c.

Wheels *of Coaches, Carts, Waggons*, &c. With reſpect to Wheels of carriages, the following particulars are collected from the experiments and obſervations of Deſaguliers, Beighton, Camus, Ferguſon, Jacob, &c.

1. The uſe of Wheels, in carriages, is twofold; viz, that of diminiſhing or more eaſily overcoming the reſiſtance or friction from the carriage; and that of more eaſily overcoming obſtacles in the road. In the firſt caſe the friction on the ground is transferred in ſome degree from the outer ſurface of the Wheel to its nave and axle; and in the latter, they ſerve eaſily to raiſe the carriage over obſtacles and aſperities met with on the roads. In both theſe caſes, the height of the Wheel is of material conſideration, as the ſpokes act as levers, the top of an obſtacle being the fulcrum, their length enables the carriage more eaſily to ſurmount them; and the greater proportion of the Wheel to the axle ſerves more eaſily to diminiſh or to overcome the friction of the axle. See Jacob's Obſervations on Wheel Carriages, p. 23 &c.

2. The Wheels ſhould be exactly round; and the fellies at right angles to the naves, according to the inclination of the ſpokes.

3. It is the moſt general opinion, that the ſpokes be ſomewhat inclined to the naves, ſo that the Wheels may be diſhing or concave. Indeed if the Wheels were always to roll upon ſmooth and level ground, it would be beſt to make the ſpokes perpendicular to the naves, or to the axles; becauſe they would then bear the weight of the load perpendicularly. But becauſe the ground is commonly uneven, one Wheel often falls into a cavity or rut, when the other does not, and then it bears much more of the weight than the other does; in which caſe it is beſt for the Wheels to be diſhed, becauſe the ſpokes become perpendicular in the rut, and therefore have the greateſt ſtrength when the obliquity of the road throws moſt of the weight upon them; whilſt thoſe on the high ground have leſs weight to bear, and therefore need not be at their full ſtrength.

4. The axles of the Wheels ſhould be quite ſtraight, and perpendicular to the ſhafts, or to the pole. When the axles are ſtraight, the rims of the Wheels will be parallel to each other, in which caſe they will move the eaſieſt, becauſe they will be at liberty to proceed ſtraight forwards. But in the uſual way of practice, the ends of the axles are bent downwards; which always keeps the ſides of the Wheels that are next the ground nearer to one another than their upper ſides are; and this not only makes the Wheels drag ſideways as they go along, and gives the load a much greater power of cruſhing them than when they are parallel to each other, but alſo endangers the overturning the carriage when a Wheel falls into a hole or rut, or when the carriage goes on a road that has one ſide lower than the other, as along the ſide of a hill. Mr. Beighton however has offered ſeveral reaſons to prove that the axles of Wheels ought not to be ſtraight; for which ſee Deſaguliers's Exp. Phil. vol. 2, Appendix.

5. Large Wheels are found more advantageous for rolling than ſmall ones, both with regard to their power as a longer lever, and to the degree of friction, and to the advantage in getting over holes, ruts, and ſtones,

ſtones, &c. If we conſider Wheels with regard to the friction upon their axles, it is evident that ſmall Wheels, by turning oftener round, and ſwifter about the axles, than large ones, muſt have much more friction. Again, if we conſider Wheels as they ſink into holes or ſoft earth, the large Wheels, by ſinking leſs, muſt be much eaſier drawn out of them, as well as more eaſily over ſtones and obſtacles, from their greater length of lever or ſpokes. Deſaguliers has brought this matter to a mathematical calculation, in his Experim. Philoſ. vol. 1, p. 171, &c. See alſo Jacob's Obſerv. p. 63.

From hence it appears then, that Wheels are the more advantageous as they are larger, provided they are not more than 5 or 6 feet diameter; for when they exceed theſe dimenſions, they become too heavy; or if they are made light, their ſtrength is proportionably diminiſhed, and the length of the ſpokes renders them more liable to break: beſides, horſes applied to ſuch Wheels would not be capable of exerting their utmoſt ſtrength, by having the axles higher than their breaſts, ſo that they would draw downwards; which is even a greater diſadvantage than ſmall Wheels have in occaſioning the horſes to draw upwards.

6. Carriages with 4 Wheels, as waggons or coaches, are much more advantageous than carriages with 2 Wheels, as carts and chaiſes; for with 2 wheels it is plain the tiller horſe carries part of the weight, in one way or other: in going down hill, the weight bears upon the horſe; and in going up hill, the weight falls the other way, and lifts the horſe, which is ſtill worſe. Beſides, as the Wheels ſink into the holes in the roads, ſometimes on one ſide, ſometimes on the other, the ſhafts ſtrike againſt the tiller's ſides, which deſtroys many horſes: moreover, when one of the Wheels ſinks into a hole or rut, half the weight falls that way, which endangers the overturning of the carriage.

7. It would be much more advantageous to make the 4 Wheels of a coach or waggon large, and nearly of a height, than to make the fore Wheels of only half the diameter of the hind Wheels, as is uſual in many places. The fore Wheels have commonly been made of a leſs ſize than the hind ones, both on account of turning ſhort, and to avoid cutting the braces. Crane-necks have alſo been invented for turning yet ſhorter, and the fore Wheels have been lowered, ſo as to go quite under the bend of the crane-neck.

It is held, that it is a great diſadvantage in ſmall Wheels, that as their axle is below the bow of the horſes breaſts, the horſes not only have the loaded carriage to draw along, but alſo part of its weight to bear, which tires them ſoon, and makes them grow much ſtiffer in their hams, than they would be if they drew on a level with the fore axle.

But Mr. Beighton diſputes the propriety of fixing the line of traction on a level with the breaſt of a horſe, and ſays it is contrary to reaſon and experience. Horſes, he ſays, have little or no power to draw but what they derive from their weight; without which they could not take hold of the ground, and then they muſt ſlip, and draw nothing. Common experience alſo teaches, that a horſe muſt have a certain weight on his back or ſhoulders, that he may draw the better. And when a horſe draws hard, it is obſerved that he bends forward, and brings his breaſt near the ground; and then if the Wheels are high, he is pulling the carriage againſt the ground. A horſe tackled in a waggon will draw two or three ton, becauſe the point or line of traction is below his breaſt, by the lowneſs of the Wheels. It is alſo common to ſee, when one horſe is drawing a heavy load, eſpecially up hill, his fore feet will riſe from the ground; in which caſe it is uſual to add a weight on his back, to keep his fore part down, by a perſon mounting on his back or ſhoulders, which will enable him to draw that load, which he could not move before. The greateſt ſtreſs, or main buſineſs of drawing, ſays this ingenious writer, is to overcome obſtacles; for on level plains the drawing is but little, and then the horſe's back need be preſſed but with a ſmall weight.

8. The utility of broad Wheels, in amending and preſerving the roads, has been ſo long and generally acknowledged, as to have occaſioned the legiſlature to enforce their uſe. At the ſame time, the proprietors and drivers of carriages ſeem to be convinced by experience, that a narrow-wheeled carriage is more eaſily and ſpeedily drawn by the ſame number of horſes, than a broad-wheeled one of the ſame burthen: probably becauſe they are much lighter, and have leſs friction on the axle.

On the ſubject of this article, ſee Jacob's Obſerv. &c. on Wheel-Carriages, 1773, p. 81. Deſagul. Exper. Phil. vol. 1, p. 201. Ferguſon's Lect. 4to, p. 56. Martin's Phil. Brit. vol. 1, p. 229.

Blowing WHEEL, is a machine contrived by Deſaguliers, for drawing the foul air out of any place, or for forcing in freſh, or doing both ſucceſſively, without opening doors or windows. See Philoſ. Tranſ. number 437. The intention of this machine is the ſame as that of Hales's ventilator, but not ſo effectual, nor ſo convenient. See Deſag. Exper. Philoſ. vol. 2, p. 563, 568.—This Wheel is alſo called a *centrifugal Wheel*, becauſe it drives the air with a centrifugal force.

Water WHEEL, of a Mill, that which receives the impulſe of the ſtream by means of ladle-boards or float-boards. M. Parent, of the Academy of Sciences, has determined that the greateſt effect of an underſhot Wheel, is when its velocity is equal to the 3d part of the velocity of the water that drives it; but it ought to be the half of that velocity, as is fully ſhewn in the article Mill, pa. 111. In fixing an underſhot Wheel, it ought to be conſidered whether the water can run clear off, ſo as to cauſe no back-water to ſtop its motion. Concerning this article, ſee Deſagul. Exp. Philoſ. vol. 2, p. 422. Alſo a variety of experiments and obſervations relating to underſhot and overſhot Wheels, by Mr. Smeaton, in the Philoſ. Tranſ. vol. 51, p. 100.

WHIRL-POOL, an eddy, vortex, or gulph, where the water is continually turning round.

WHIRLING-TABLE, a machine contrived for repre-

repreſenting ſeveral phenomena in philoſophy, and nature; as, the principal laws of gravitation, and of the planetary motions in curvilinear orbits.

The figure of this inſtrument is exhibited fig. 1, pl. 35: where AA is a ſtrong frame of wood; B a winch fixed on the axis C of the wheel D, round which is the catgut ſtring F, which alſo goes round the ſmall wheels G and K, croſſing between them and the great wheel D. On the upper end of the axis of the wheel G, above the frame, is fixed the round board *d*, to which may be occaſionally fixed the bearer MSX. On the axis of the wheel H is fixed the bearer NTZ, and when the winch B is turned, the wheels and bearers are put into a Whirling motion. Each bearer has two wires W, X, and Y, Z, fixed and ſcrewed tight into them at the ends by nuts, on the outſide; and when the nuts are unſcrewed, the wires may be drawn out in order to change the balls U, V, which ſlide upon the wires by means of braſs loops fixed into the balls, and preventing their touching the wood below them. Through each ball there paſſes a ſilk line, which is fixed to it at any length from the centre of the bearer to its end, by a nut-ſcrew at the top of the ball; the ſhank of the ſcrew going into the centre of the ball, and preſſing the line againſt the under ſide of the whole which it goes through. The line goes from the ball, and under a ſmall pulley fixed in the middle of the bearer; then up through a ſocket in the round plate (S and T) in the middle of each bearer; then through a ſlit in the middle of the ſquare top (O and P) of each tower, and going over a ſmall pulley on the top comes down again the ſame way, and is at laſt faſtened to the upper end of the ſocket fixed in the middle of the round plate above mentioned. Each of theſe plates S and T has four round holes near their edges, by which they ſlide up and down upon the wires which make the corner of each tower. The balls and plates being thus connected, each by its particular line, it is plain that if the balls be drawn outward, or towards the end M and N of their reſpective bearers, the round plates S and T will be drawn up to the top of their reſpective towers O and P.

There are ſeveral braſs weights, ſome of two, ſome of three, and others of four ounces, to be occaſionally put within the towers O and P, upon the round plates S and T: each weight having a round hole in the middle of it, for going upon the ſockets or axes of the plates, and being ſlit from the edge to the hole, that it may ſlip over the line which comes from each ball to its reſpective plate.

For a ſpecimen of the experiments which may be made with this machine, may be ſubjoined the following.

1. Removing the bearer MX, put the loop of the line *b* to which the ivory ball *a* is faſtened over a pin in the centre of the board *d*, and turn the winch B; and the ball will not immediately begin to move with the board, but, on account of its inactivity, endeavour to remain in its ſtate of reſt. But when the ball has acquired the ſame velocity with the board, it will remain upon the ſame part of the board, having no relative motion upon it. However, if the board be ſuddenly ſtopped, the ball will continue to revolve upon it, until the friction thereof ſtops its motion: ſo that matter reſiſts every change of ſtate, from that of reſt to that of motion, and *vice verſa*.

2. Put a longer cord to this ball; let it down through the hollow axis of the bearer MX and wheel G, and fix a weight to the end of the cord below the machine; and this weight, if left at liberty, will draw the ball from the edge of the Whirling board to its centre. Draw off the ball a little from the centre, and turn the winch; then the ball will go round and round with the board, and gradually fly farther from the centre, raiſing up the weight below the machine. And thus it appears that all bodies, revolving in circles, have a tendency to fly off from thoſe circles, and muſt be retained in them by ſome power proceeding from or tending to the centre of motion. Stop the machine, and the ball will continue to revolve for ſome time upon the board; but as the friction gradually ſtops its motion, the weight acting upon it will bring it nearer and nearer to the centre in every revolution, till it brings it quite thither. Hence it appears, that if the planets met with any reſiſtance in going round the ſun, its attractive power would bring them nearer and nearer to it in every revolution, till they would fall into it.

3. Take hold of the cord below the machine with one hand, and with the other throw the ball upon the round board as it were at right angles to the cord, and it will revolve upon the board. Then, obſerving the velocity of its motion, pull the cord below the machine, and thus bring the ball nearer the centre of the board, and the ball will be ſeen to revolve with an increaſing velocity, as it approaches the centre: and thus the planets which are neareſt the ſun perform quicker revolutions than thoſe which are more remote, and move with greater velocity in every part of their reſpective circles.

4. Remove the ball *a*, and apply the bearer MX, whoſe centre of motion is in its middle at *w*, directly over the centre of the Whirling board *d*. Then put two balls (V and U) of equal weight upon their bearing wires, and having fixed them at equal diſtances from their reſpective centres of motion *w* and *x* upon their ſilk cords, by the ſcrew nuts, put equal weights in the towers O and P. Laſtly, put the catgut ſtrings E and F upon the grooves G and H of the ſmall wheels, which, being of equal diameters, will give equal velocities to the bearers above, when the winch B is turned; and the balls U and V will fly off toward M and N, and raiſe the weights in the towers at the ſame inſtant. This ſhews, that when bodies of equal quantities of matter revolve in equal circles with equal velocities, their centrifugal forces are equal.

5. Take away theſe equal balls, and put a ball of 6 ounces into the bearer MX, at a 6th part of the diſtance *wx* from the centre, and put a ball of one ounce into the oppoſite bearer, at the whole diſtance *xy* = *wx*; and fix the balls at theſe diſtances on their cords, by the ſcrew nuts at the top: then the ball U, which is 6 times as heavy as the ball V, will be at only a 6th part of the diſtance from its centre of motion; and conſequently will revolve in a circle of only a 6th part of the circumference of the circle in which V revolves. Let equal weights be put into the towers, and the winch be turned; which (as the catgut ſtring

is on equal wheels below, will cauſe the balls to revolve in equal times: but V will move 6 times as faſt as U, becauſe it revolves in a circle of 6 times its radius, and both the weights in the towers will riſe at once. Hence it appears, that the centrifugal forces of revolving bodies are in direct proportion to their quantities of matter multiplied into their reſpective velocities, or into their diſtance from the centres of their reſpective circles.

If theſe two balls be fixed at equal diſtances from their reſpective centres of motion, they will move with equal velocities; and if the tower O has 6 times as much weight put into it as the tower P has, the balls will raiſe their weights exactly at the ſame moment: i. e. the ball U, being 6 times as heavy as the ball V, has 6 times as much centrifugal force in deſcribing an equal circle with an equal velocity.

6. Let two balls, U and V, of equal weights, be fixed on their cords at equal diſtances from their reſpective centres of motion *w* and *x*; and let the catgut ſtring E be put round the wheel K (whoſe circumference is only half that of the wheel H or G) and over the pulley *s* to keep it tight, and let 4 times as much weight be put into the tower P as in the tower O. Then turn the winch B, and the ball V will revolve twice as faſt as the ball U in a circle of the ſame diameter, becauſe they are equidiſtant from the centres of the circles in which they revolve; and the weights in the towers will both riſe at the ſame inſtant; which ſhews that a double velocity in the ſame circle will exactly balance a quadruple power of attraction in the centre of the circle: for the weights in the towers may be conſidered as the attractive forces in the centres, acting upon the revolving balls; which moving in equal circles, are as if they both moved in the ſame circle. Whence it appears that, if bodies of equal weights revolve in equal circles with unequal velocities, their centrifugal forces are as the ſquares of the velocities.

7. The catgut ſtring remaining as before, let the diſtance of the ball V from the centre *x* be equal to 2 of the diviſions on its bearer; and the diſtance of the ball U from the centre *w* be 3 and a 6th part; the balls themſelves being equally heavy, and V making two revolutions by turning the winch, whilſt U makes one; ſo that if we ſuppoſe the ball V to revolve in one moment, the ball U will revolve in 2 moments, the ſquares of which are 1 and 4: therefore, the ſquare of the period of V is contained 4 times in the ſquare of the period of U. But the diſtance of V is 2, the cube of which is 8, and the diſtance of U is $3\frac{1}{6}$, the cube of which is 32 very nearly, in which 8 is contained 4 times: and therefore, the ſquares of the periods V and U are to one another as the cubes of their diſtances from *x* and *w*, the centres of their reſpective circles. And if the weight in the tower O be 4 ounces, or equal to the ſquare of 2, which is the diſtance of V from the centre *x*; and the weight in the tower P be 10 ounces, nearly equal to the ſquare of $3\frac{1}{6}$, the diſtance of U from *w*; it will be found upon turning the machine by the winch, that the balls U and V will raiſe their reſpective weights at very nearly the ſame inſtant of time. This experiment confirms the famous propoſition of Kepler, viz, that the ſquares of the periodical times of the planets round the ſun are in proportion as the cubes of their diſtances from him; and that the ſun's attraction is inverſely as the ſquare of the diſtance from his centre.

8. Take off the ſtring E from the wheels D and H, and let the ſtring F remain upon the wheels D and G; take away alſo the bearer MX from the Whirling-board *d*, and inſtead of it put on the machine AB (fig. 2), fixing it to the centre of the board by the pins *c* and *d*, ſo that the end *ef* may riſe above the board to an angle of 30 or 40 degrees. On the upper part of this machine, there are two glaſs tubes *a* and *b*, cloſe ſtopped at both ends, each tube being about three quarters full of water. In the tube *a* is a little quickſilver, which naturally falls down to the end *a* in the water; and in the tube *b* is a ſmall cork, floating on the top of the water, and ſmall enough to riſe or fall in the tube. While the board *b* with this machine upon it continues at reſt, the quickſilver lies at the bottom of the tube *a*, and the cork floats on the water near the top of the tube *b*. But, upon turning the winch and moving the machine, the contents of each tube fly off towards the uppermoſt ends, which are fartheſt from the centre of motion; the heavieſt with the greateſt force. Conſequently, the quickſilver in the tube *a* will fly off quite to the end *f*, occupying its bulk of ſpace, and excluding the water, which is lighter than itſelf: but the water in the tube *b*, flying off to its higher end *e*, will exclude the cork from that place, and cauſe it to deſcend toward the loweſt end of the tube; for the heavier body, having the greater centrifugal force, will poſſeſs the upper part of the tube, and the lighter body will keep between the heavier and the lower part.

This experiment demonſtrates the abſurdity of the Carteſian doctrine of vortices; for, if a planet be more denſe or heavy than its bulk of the vortex, it will fly off in it farther and farther from the ſun; if leſs denſe, it will come down to the loweſt part of the vortex, at the ſun: and the whole vortex itſelf, unleſs prevented by ſome obſtacle, would fly quite off, together with the planets.

9. If a body be ſo placed upon the Whirling-board of the machine (fig. 1.) that the centre of gravity of the body be directly over the centre of the board, and the board be moved ever ſo rapidly by the winch B, the body will turn round with the board, without removing from its middle; for, as all parts of the body are in equilibrio round its centre of gravity, and the centre of gravity is at reſt in the centre of motion, the centrifugal force of all parts of the body will be equal at equal diſtances from its centre of motion, and therefore the body will remain in its place. But if the centre of gravity be placed ever ſo little out of the centre of motion, and the machine be turned ſwiftly round, the body will fly off towards that ſide of the board on which its centre of gravity lies. Then if the wire C (fig. 3) with its little ball B be taken away from the ſemi-globe A, and the flat ſide *f* of the ſemi-globe be laid upon the Whirling-board, ſo that their centres may coincide; if then the board be turned ever ſo quickly by the winch, the ſemi-globe will remain where it was placed: but if the wire C be ſcrewed into the ſemi-globe at *d*, the whole becomes one body, whoſe centre of gravity is at or near *d*. Fix the pin *c* in

in the centre of the Whirling-board, and let the deep groove *b* cut in the flat ſide of the ſemi-globe be put upon the pin, ſo that the pin may be in the centre of A (ſee fig. 4) where the groove is to be repreſented at *b*, and let the board be turned by the winch, which will carry the little ball B (fig. 3) with its wire C, and the ſemi-globe A, round the centre-pin *c i*; and then, the centrifugal force of the little ball B, weighing one ounce, will be ſo great as to draw off the ſemi-globe A, weighing two pounds, until the end of the groove at *c* ſtrikes againſt the pin *c*, and ſo prevents A from going any farther: otherwiſe, the centrifugal force of B would have been great enough to have carried A quite off the whirling-board. Hence we ſee that, if the ſun were placed in the centre of the orbits of the planets, it could not poſſibly remain there; for the centrifugal forces of the planets would carry them quite off, and the ſun with them; eſpecially when ſeveral of them happened to be in one quarter of the heavens. For the ſun and planets are as much connected by the mutual attraction ſubſiſting between them, as the bodies A and B are by the wire C fixed into them both. And even if there were but one planet in the whole heavens to go round ever ſo large a ſun in the centre of its orbit, its centrifugal force would ſoon carry off both itſelf and the ſun: for the greateſt body placed in any part of free ſpace could be eaſily moved; becauſe, if there were no other body to attract it, it would have no weight or gravity of itſelf, and conſequently, though it could have no tendency of itſelf to remove from that part of ſpace, yet it might be very eaſily moved by any other ſubſtance.

10. As the centrifugal force of the light body B will not allow the heavy body A to remain in the centre of motion, even though it be 24 times as heavy as B; let the ball A (fig. 5) weighing 6 ounces be connected by the wire C with the ball B, weighing one ounce, and let the fork E be fixed into the centre of the Whirling-board; then, hang the balls upon the fork by the wire C in ſuch a manner that they may exactly balance each other, which will be when the centre of gravity between them, in the wire at *d*, is ſupported by the fork. And this centre of gravity is as much nearer to the centre of the ball A than to the centre B, as A is heavier than B; allowing for the weight of the wire on each ſide of the fork. Then, let the machine be moved, and the balls A and B will go round their common centre of gravity *d*, keeping their balance, becauſe either will not allow the other to fly off with it. For, ſuppoſing the ball B to be only one ounce in weight, and the ball A to be ſix ounces; then, if the wire C were equally heavy on each ſide of the fork, the centre of gravity *d* would be 6 times as far from the centre of B as from the centre of A, and conſequently B will revolve with a velocity 6 times as great as A does; which will give B 6 times as much centrifugal force as any ſingle ounce of A has; but then as B is only one ounce, and A ſix ounces, the whole centrifugal force of A will exactly balance that of B; and therefore, each body will detain the other, ſo as to make it keep in its circle.

Hence it appears, that the ſun and planets muſt all move round the common centre of gravity of the whole ſyſtem, in order to preſerve that juſt balance which takes place among them.

11. Take away the forks and balls from the Whirling-board, and place the trough AB (fig. 6) thereon, fixing its centre to that of the board by the pin H. In this trough are two balls D and E of unequal weights, connected by a wire *f*, and made to ſlide eaſily upon the wire ſtretched from end to end of the trough, and made faſt by nut ſcrews on the outſide of the ends. Place theſe balls on the wire *c*, ſo that their common centre of gravity *g*, may be directly over the centre of the Whirling-board. Then turn the machine by the winch ever ſo ſwiftly, and the trough and balls will go round their centre of gravity, ſo as neither of them will fly off; becauſe, on account of the equilibrium, each ball detains the other with an equal force acting againſt it. But if the ball E be drawn a little more towards the end of the trough at A, it will remove the centre of gravity towards that end from the centre of motion; and then, upon turning the machine, the little ball E will fly off, and ſtrike with a conſiderable force againſt the end A, and draw the great ball B into the middle of the trough. Or, if the great ball D be drawn towards the end B of the trough, ſo that the centre of gravity may be a little towards that end from the centre of motion; and the machine be turned by the winch, the great ball D will fly off, and ſtrike violently againſt the end B of the trough, and will bring the little ball E into the middle of it. If the trough be not made very ſtrong, the ball D will break through it.

12. Mr. Ferguſon has explained the reaſon why the tides riſe at the ſame time on oppoſite ſides of the earth, and conſequently in oppoſite directions, by the following new experiment on the Whirling-table. For this purpoſe, let *a b c d* (fig. 7) repreſent the earth, with its ſide *c* turned toward the moon, which will then attract the water ſo as to raiſe them from *c* to *g*: and in order to ſhew that they will riſe as high at the ſame time on the oppoſite ſide from *a* to *e*; let a plate AB (fig. 8) be fixed upon one end of the flat bar DC, with ſuch a circle drawn upon it as *a b c d* (fig. 7) to repreſent the round figure of the earth and ſea; and an ellipſe as *e f g h* to repreſent the ſwelling of the tide at *e* and *g*, occaſioned by the influence of the moon. Over this plate AB ſuſpend the three ivory balls *e*, *f*, *g*, by the ſilk lines *h*, *i*, *k*, faſtened to the tops of the wires H, I, K, ſo that the ball at *e* may hang freely over the ſide of the circle *e*, which is fartheſt from the moon M at the other end of the bar; the ball at *f* over the centre, and the ball at *g* over the ſide of the circle *g*, which is neareſt the moon. The ball *f* may repreſent the centre of the earth, the ball *g* water on the ſide next the moon, and the ball *e* water on the oppoſite ſide. On the back of the moon M is fixed a ſhort bar N parallel to the horizon, and there are three holes in it above the little weights *p*, *q*, *r*. A ſilken thread *o* is tied to the line *k* cloſe above the ball *g*, and paſſing by one ſide of the moon M goes through a hole in the bar N, and has the weight *p* hung to it. Such another thread *m* is tied to the line *i*, cloſe above the ball *f*, and, paſſing through the centre of the moon M and middle of the bar N, has the weight *q* hung to it which is lighter than the weight *p*. A third thread *m* is tied to the line *h*, cloſe

above the ball *e*, and, paſſing by the other ſide, of the moon M through the bar N, has the weight *r* hung to it, which is lighter than the weight *q*. The uſe of theſe three unequal weights is to repreſent the moon's unequal attraction at different diſtances from her; ſo that if they are left at liberty, they will draw all the three balls towards the moon with different degrees of force, and cauſe them to appear as in fig. 9, in which caſe they are evidently farther from each other than if they hung freely by the perpendicular lines *h*, *i*, *k*. Hence it appears, that as the moon attracts the ſide of the earth which is neareſt her with a greater degree of force than ſhe does the centre of the earth, ſhe will draw the water on that ſide more than the centre, and cauſe it to riſe on that ſide: and as ſhe draws the centre more than the oppoſite ſide, the centre will recede farther from the ſurface of the water on that oppoſite ſide, and leave it as high there as ſhe raiſed it on the ſide next her. For, as the centre will be in the middle between the tops of the oppoſite elevations, they muſt of courſe be equally high on both ſides at the ſame time.

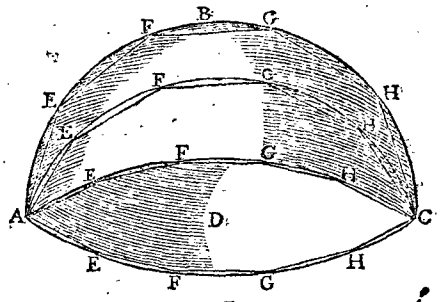
However, upon this ſuppoſition, the earth and moon would ſoon come together; and this would be the caſe if they had not a motion round their common centre of gravity, to produce a degree of centrifugal force, ſufficient to balance their mutual attraction. Such motion they have; for as the moon revolves in her orbit every month, at the diſtance of 240000 miles from the earth's centre, and of 234000 miles from the centre of gravity of the earth and moon, the earth alſo goes round the ſame centre of gravity every month at the diſtance of 6000 miles from it, i. e. from it to the centre of the earth. But the diameter of the earth being, in round numbers, 8000 miles, its ſide next the moon is only 2000 miles from the common centre of gravity of the earth and moon, its centre 6000 miles from it, and its fartheſt ſide from the moon 10000 miles. Conſequently the centrifugal forces of theſe parts are as 2000, 6000, and 10000; i. e. the centrifugal force of any ſide of the earth, when it is turned from the moon, is five times as great as when it is turned toward the moon. And as the moon's attraction, expreſſed by the number 6000 at the earth's centre, keeps the earth from flying out of this monthly circle, it muſt be greater than the centrifugal force of the waters on the ſide next her; and conſequently, her greater degree of attraction on that ſide is ſufficient to raiſe them; but as her attraction on the oppoſite ſide is leſs than the centrifugal force of the water there, the exceſs of this force is ſufficient to raiſe the water juſt as high on the oppoſite ſide.

To prove this experimentally, let the bar DC with its furniture be fixed on the Whirling-board of the machine (fig. 1.) by puſhing the pin P into the centre of the board; which pin is in the centre of gravity of the whole bar with its three balls, *e*, *f*, *g*, and moon M. Now if the Whirling-board and bar be turned ſlowly round by the winch, till the ball *f* hangs over the centre of the circle, as in fig. 10, the ball *g* will be kept towards the moon by the heavieſt weight *p* (fig. 8), and the ball *e*, on account of its greater centrifugal force, and the leſs weight *r*, will fly off as far to the other ſide, as in fig. 10. And thus, whilſt the machine is kept turning, the balls *e* and *g* will hang over the ends of the ellipſe *l f k*. So that the centrifugal force of the ball *e* will exceed the moon's attraction juſt as much as her attraction exceeds the centrifugal force of the ball *g*, whilſt her attraction juſt balances the centrifugal force of the ball *f*, and makes it keep in its circle. Hence it is evident, that the tides muſt riſe to equal heights at the ſame time on oppoſite ſides of the earth. See Ferguſon's Lectures on Mechanics, lect. 2, and Deſag. Ex. Phil. vol. 1, lect. 5.

WHIRLWIND, a wind that riſes ſuddenly, is exceedingly rapid and impetuous, in a Whirling direction, and often progreſſively alſo; but it is commonly ſoon ſpent.

Dr. Franklin, in his Phyſical and Meteorological Obſervations, read to the Royal Society in 1756, ſuppoſes a Whirlwind and a waterſpout to proceed from the ſame cauſe: their only difference being, that the latter paſſes over the water, and the former over the land. This opinion is corroborated by the obſervations of M. de la Pryme, and many others, who have remarked the appearances and effects of both to be the ſame. They have both a progreſſive as well as a circular motion; they uſually riſe after calms and great heats, and moſtly happen in the warmer latitudes: the wind blows every way from a large ſurrounding ſpace, both to the waterſpout and whirlwind; and a waterſpout has, by its progreſſive motion, paſſed from the ſea to the land, and produced all the phenomena and effects of a Whirlwind: ſo that there is no reaſon to doubt that they are meteors ariſing from the ſame general cauſe, and explicable upon the ſame principles, furniſhed by electrical experiments and diſcoveries. See HURRICANE, and WATERSPOUT. For Dr. Franklin's ingenious method of accounting for both theſe phenomena, ſee his Letters and Papers, &c, vol. 1, p. 191, 216, &c.

WHISPERING-*Places*, are places where a Whiſper, or other ſmall noiſe, may be heard from one part to another, to a great diſtance. They depend on a principle, that the voice, &c, being applied to one end of an arch, eaſily paſſes by repeated reflections to the other. Thus,



let ABC repreſent the ſegment of a ſphere; and ſuppoſe a low voice uttered at A, the vibrations extending themſelves every way, ſome of them will impinge upon the points E, E, &c; and thence be reflected to the points F, F, &c; thence to G, G, &c; till at laſt they meet in C; where by their union they cauſe a much ſtronger ſound than in any part of the ſegment whatever,

whatever, even louder than at the point from whence they ſet out. Accordingly, all the contrivance in a Whiſpering-place is, that near the perſon who Whiſpers, there be a ſmooth wall, arched either cylindrically, or elliptically, &c. A circular arch will do, but not ſo well.

Some of the moſt remarkable places for Whiſpering, are the following: viz, The priſon of Dionyſius at Syracuſe, which increaſed a ſoft Whiſper to a loud noiſe; or a clap of the hand to the report of a cannon, &c. The aqueducts of Claudius, which carried a voice 16 miles: beſide divers others mentioned by Kircher in his Phonurgia. In England, the moſt conſiderable Whiſpering places are, the dome of St. Paul's church, London, where the ticking of a watch may be heard from ſide to ſide, and a very ſoft Whiſper may be ſent all round the dome: this Dr. Derham found to hold not only in the gallery below, but above upon the ſcaffold, where a Whiſper would be carried over a perſon's head round the top of the arch, though there be a large opening in the middle of it into the upper part of the dome. And the celebrated Whiſpering-place in Glouceſter cathedral, which is only a gallery above the eaſt end of the choir, leading from one ſide of it to the other. See Birch's Hiſt. of the Royal Soc. vol. 1, pa. 120.

WHISTON (William), an Engliſh divine, philoſopher, and mathematician, of uncommon parts, learning, and extraordinary character, was born the 9th of December 1667, at Norton in the county of Leiceſter, where his father was rector. He was educated under his father till he was 17 years of age, when he was ſent to Tamworth ſchool, and two years after admitted of Clare-hall, Cambridge, where he purſued his ſtudies, and particularly the mathematics, with great diligence. During this time he became afflicted with a great weakneſs of ſight, owing to cloſe ſtudy in a whitened room; which was in a good meaſure relieved by a little relaxation from ſtudy, and taking off the ſtrong glare of light by hanging the place oppoſite his ſeat with green.

In 1693 he was made maſter of arts and fellow of the college, and ſoon after commenced one of the tutors; but his ill ſtate of health ſoon after obliged him to relinquiſh this profeſſion. Having entered into orders, in 1694 he became chaplain to Dr. More, biſhop of Norwich; and while in this ſtation he publiſhed his firſt work, intitled, *A New Theory of the Earth &c*; in which he undertook to prove that the Moſaic doctrine of the earth was perfectly agreeable to reaſon and philoſophy: which work, having much ingenuity, though it was written againſt by Mr. John Keill, brought conſiderable reputation to the author.

In the year 1698, biſhop More gave him the living of Loweſtoff in Suffolk, where he immediately went to reſide, and devoted himſelf with great diligence to the diſcharge of that truſt.—In the beginning of this century he was made Sir Iſaac Newton's deputy, and afterwards his ſucceſſor in the Lucaſian profeſſorſhip of mathematics; when he reſigned his living at Loweſtoff, and went to reſide at Cambridge. From this time his publications became very frequent, both in theology and mathematics. Thus, in 1702 he publiſhed, A Short View of the Chronology of the Old Teſtament, and of the Harmony of the four Evangeliſts.—In 1707, *Prælectiones Aſtronomicæ*; beſide eight Sermons on the Accompliſhment of the Scripture Prophecies, preached at Boyle's lecture; and Newton's Arithmetica Univerſalis.—In 1708, Tacquet's Euclid, with ſelect Theorems of Archimedes; the former of which had accidentally been his firſt introduction to the ſtudy of the mathematics.—In the ſame year he drew up an Eſſay upon the Apoſtolical Conſtitutions, which the Vice-chancellor refuſed his licence for printing. The author tells us, he had read over the two firſt centuries of the church, and found that the Euſebian or Arian doctrine was chiefly the doctrine of thoſe ages, which, though deemed heterodox, he thought it his duty to diſcover.—In 1709, he publiſhed a volume of Sermons and Eſſays on various ſubjects.—In 1710, Prælectiones Phyſico-Mathematicæ, which with the Prælectiones Aſtronomicæ, were tranſlated and publiſhed in Engliſh. And it may be ſaid, with no ſmall honour to the memory of Mr. Whiſton, that he was one of the firſt who explained the Newtonian philoſophy in a popular way, ſo as to be intelligible to the generality of readers.—Among other things alſo, he tranſlated the Apoſtolical Conſtitutions into Engliſh, which favoured the doctrine of the ſupremacy of the father and ſubordination of the ſon, vulgarly called the Arian hereſy: Upon which his friends began to be alarmed for him; and the conſequence ſhewed it was not groundleſs; for, Oct. 30, 1710, he was deprived of his profeſſorſhip, and expelled the univerſity of Cambridge, after he had been formally convened and interrogated for ſome days together.—At the concluſion of this year, he wrote his Hiſtorical preface, afterwards prefixed to his Primitive Chriſtianity Revived, containing the reaſons for his diſſent from the commonly received notions of the Trinity, which work he publiſhed the next year, in 4 volumes 8vo, for which the Convocation fell upon him moſt vehemently.

In 1713, he and Mr. Ditton compoſed their ſcheme for finding the longitude, which they publiſhed the year following, a method which conſiſted in meaſuring diſtances by means of the velocity of ſound; ſome more particulars of which are related in the life of Mr. Ditton.—In 1719, he publiſhed an ironical Letter of Thanks to doctor Robinſon, biſhop of London, for his late Letter to his clergy againſt the uſe of New Forms of Doxology. And, the ſame year, a Letter to the earl of Nottingham, Concerning the Eternity of the Son of God, and his Holy Spirit.—In 1720, he was propoſed by Sir Hans Sloane and Dr. Halley to the Royal Society as a member; but was refuſed admittance by Sir Iſaac Newton the preſident.

On Mr. Whiſton's expulſion from Cambridge, he went to London, where he conferred with Doctors Clarke, Hoadly, and other learned men, who endeavoured to moderate his zeal, which however he would not ſuffer to be tainted or corrupted, and many were not much ſatisfied with the authority of theſe conſtitutions, but approved his integrity. Mr. Whiſton now ſettled in London with his family; where, without ſuffering his zeal to be intimidated, he continued to write, and to propagate his Primitive Chriſtianity with as much ardour as if he had been in the moſt flouriſhing circumſtances; which however were ſo bad, that, in

1721, a ſubſcription was made for the ſupport of his family, which amounted to 470l. For though he drew ſome profits from reading aſtronomical and philoſophical lectures, and alſo from his publications, which were very numerous, yet theſe of themſelves were very inſufficient: nor, when joined with the benevolence and charity of thoſe who loved and eſteemed him for his learning, integrity, and piety, did they prevent his being frequently in great diſtreſs.—In 1722 he publiſhed an Eſſay towards reſtoring the true text of the Old Teſtament.—In 1724, The Literal Accompliſhment of Scripture Prophecies.—Alſo, The Calculation of Solar Eclipſes without Parallaxes.—In 1726, Of the Thundering Legion &c.—In 1727, A Collection of Authentic Records belonging to the Old and New Teſtament.—In 1730, Memoirs of the Life of Dr. Samuel Clarke.—In 1732, A Vindication of the Teſtimony of Phlegon, or an Account of the Great Darkneſs and Earthquake at our Saviour's Paſſion, deſcribed by Phlegon.—In 1736, Athanaſian Forgeries, &c. And the Primitive Euchariſt revived.—In 1737, The Aſtronomical Year, particularly of the Comet foretold by Sir Iſaac Newton.—Alſo the Genuine Works of Flavius Joſephus.—In 1739, Mr. Whiſton put in his claim to the mathematical profeſſorſhip at Cambridge, then vacant by the death of Dr. Saunderſon, in a letter to Dr. Aſhton, the maſter of Jeſus-college; but no regard was paid to it.—In 1745, he publiſhed his Primitive New Teſtament in Engliſh.—In 1748, his Sacred Hiſtory of the Old and New Teſtament. Alſo, Memoirs of his own Life and Writings, which are very curious.

Whiſton continued many years a member of the eſtabliſhed church; but at length forſook it, on account of the reading of the Athanaſian Creed, and went over to the Baptiſts; which happened while he was at the houſe of Samuel Barker, Eſq. at Lindon in Rutlandſhire, who had married his daughter; where he died, after a week's illneſs, the 22d of Auguſt 1752, at upwards of 84 years of age.—We have mentioned the principal of his writings in the foregoing memoir; to which may be added, Chronological Tables, publiſhed in 1750.

The character of this conſcientious and worthy man has been attempted by two very able perſonages, who were well acquainted with him, namely, biſhop Hare and Mr. Collins, who unite in giving him the higheſt applauſes, for his integrity, piety, &c.—Mr. Whiſton left ſome children behind him; among them, Mr. John Whiſton, who was for many years a very conſiderable bookſeller in London.

WHITE, one of the colours of bodies. Though White cannot properly be ſaid to be one colour, but rather a compoſition of all the colours together: for Newton has demonſtrated that bodies only appear White by reflecting all the kinds of coloured rays alike; and that even the light of the ſun is only White, becauſe it conſiſts of all colours mixed together.

This may be ſhewn mechanically in the following manner: Take ſeven parcels of coloured fine powders, the ſame as the primary colours of the rainbow, taking ſuch quantities of theſe as ſhall be proportional to the reſpective breadths of theſe colours in the rainbow, which are of red 45 parts, orange 27, yellow 48, green 60, blue 60, indigo 40, and of violet 80; then mix intimately together theſe ſeven parcels of powders, and the mixture will be a pretty White colour: and this is only ſimilar to the uniting the priſmatic colours together again, to form a White ray or pencil of light of the whole of them. The ſame thing is done conveniently thus: Let the flat upper ſurface of a top be divided into 360 equal parts, all around its edge; then divide the ſame ſurface into ſeven ſectors in the proportion of the numbers above, by ſeven radii or lines drawn from the centre; next let the reſpective colours be painted in a lively manner on theſe ſpaces, but ſo as the edge of each colour may be made nearly like the colour next adjoining, that the ſeparation may not be well diſtinguiſhed by the eye; then if the top be made to ſpin, the colours will thus ſeem to be mixed all together, and the whole ſurface will appear of a uniform whiteneſs: and if a large round black ſpot be painted in the middle, ſo as there may be only a broad flat ring of colours around it, the experiment will ſucceed the better. See Newton's Optics, prop. 6, book 1; and Ferguſon's Tracts, pa. 296.

White bodies are found to take heat ſlower than black ones; becauſe the latter abſorb or imbibe rays of all kinds and colours, and the former reflect them. Hence it is that black paper is ſooner put in flame, by a burning-glaſs, than White; and hence alſo black clothes, hung up in the ſun by the dyers, dry ſooner than white ones.

WHITEHURST (John), an ingenious Engliſh philoſopher, was born at Congleton in the county of Cheſhire, the 10th of April 1713, being the ſon of a clock and watch-maker there. Of the early part of his life but little is known; he who dies at an advanced age, leaving few behind him to communicate anecdotes of his youth. On his quitting ſchool, where it ſeems the education he received was very defective, he was bred by his father to his own profeſſion, in which he ſoon gave hopes of his future eminence.

It was very early in life that, from his vicinity to the many ſtupendous phenomena in Derbyſhire, which were conſtantly preſented to his obſervation, his attention was excited to enquire into the various cauſes of them.

At about the age of 21, his eagerneſs after new ideas carried him to Dublin, having heard of an ingenious piece of mechaniſm in that city, being a clock with certain curious appendages, which he was very deſirous of ſeeing, and no leſs ſo of converſing with the maker. On his arrival however, he could neither procure a ſight of the former, nor draw the leaſt hint from the latter concerning it. Thus diſappointed, he fell upon an expedient for accompliſhing his deſign; and accordingly took up his reſidence in the houſe of the mechanic, paying the more liberally for his board, as he had hopes from thence of more readily obtaining the indulgence wiſhed for. He was accommodated with a room directly over that in which the favourite piece was kept carefully locked up: and he had not long to wait for his gratification: for the artiſt, while one day employed in examining his machine, was ſuddenly called down ſtairs; which the young enquirer happening to overhear, ſoftly ſlipped into the room, inſpected the machine, and, preſently ſatisfying himſelf as to the ſecret, eſcaped undiſ-

covered to his own apartment. His end thus compaſſed, he ſhortly after bid the artiſt farewell, and returned to his father in England.

About two or three years after his return from Ireland, he left Congleton, and entered into buſineſs for himſelf at Derby, where he ſoon got into great employment, and diſtinguiſhed himſelf very much by ſeveral ingenious pieces of mechaniſm, both in his own regular line of buſineſs, and in various other reſpects, as in the conſtruction of curious thermometers, barometers, and other philoſophical inſtruments, as well as in ingenious contrivances for water-works, and the erection of various larger machines: being conſulted in almoſt all the undertakings in Derbyſhire, and in the neighbouring counties, where the aid of ſuperior ſkill, in mechanics, pneumatics, and hydraulics, was requiſite.

In this manner his time was fully and uſefully employed in the country, till, in 1775, when the act paſſed for the better regulation of the gold coin, he was appointed ſtamper of the money-weights; an office conferred upon him, altogether unexpectedly, and without ſolicitation. Upon this occaſion he removed to London, where he ſpent the remainder of his days, in the conſtant habits of cultivating ſome uſeful parts of philoſophy and mechaniſm. And here too his houſe became the conſtant reſort of the ingenious and ſcientific at large, of whatever nation or rank, and this to ſuch a degree, as very often to impede him in the regular proſecution of his own ſpeculations.

In 1778, Mr. Whitehurſt publiſhed his Inquiry into the Original State and Formation of the Earth; of which a ſecond edition appeared in 1786, conſiderably enlarged and improved; and a third in 1792. This was the labour of many years; and the numerous inveſtigations neceſſary to its completion, were in themſelves alſo of ſo untoward a nature, as at times, though he was naturally of a ſtrong conſtitution, not a little to prejudice his health. When he firſt entered upon this ſpecies of reſearch, it was not altogether with a view to inveſtigate the formation of the earth, but in part to obtain ſuch a competent knowledge of ſubterraneous geography as might become ſubſervient to the purpoſes of human life, by leading mankind to the diſcovery of many valuable ſubſtances which lie concealed in the lower regions of the earth.

May the 13th, 1779, he was elected and admitted a Fellow of the Royal Society. He was alſo a member of ſome other philoſophical ſocieties, which admitted him of their reſpective bodies, without his previous knowledge; but ſo remote was he from any thing that might favour of oſtentation, that this circumſtance was known only to a very few of his moſt confidential friends. Before he was admitted a member of the Royal Society, three ſeveral papers of his had been inſerted in the Philoſophical Tranſactions, viz, Thermometrical Obſervations at Derby, in vol. 57; An Account of a Machine for raiſing Water, at Oulton, in Cheſhire, in vol. 65; and Experiments on Ignited Subſtances, vol. 66: which three papers were printed afterwards in the collection of his works in 1792.

In 1783 he made a ſecond viſit to Ireland, with a view to examine the Giant's Cauſeway, and other northern parts of that iſland, which he found to be chiefly compoſed of volcanic matter: an account and repreſentations of which are inſerted in the latter editions of his Inquiry. During this excurſion, he erected an engine, for raiſing water from a well, to the ſummit of a hill, in a bleaching ground, at Tullidoi, in the county of Tyrone; it is worked by a current of water, and for its utility is perhaps unequalled in any country.

In 1787 he publiſhed, An Attempt toward obtaining Invariable Meaſures of Length, Capacity, and Weight, from the Menſuration of Time. His plan is, to obtain a meaſure of the greateſt length that conveniency will permit, from two pendulums whoſe vibrations are in the ratio of 2 to 1, and whoſe lengths coincide nearly with the Engliſh ſtandard in whole numbers. The numbers which he has choſen ſhew much ingenuity. On a ſuppoſition that the length of a ſeconds pendulum, in the latitude of London, is 39$\frac{1}{8}$ inches, the length of one vibrating 42 times in a minute, muſt be 80 inches; and of another vibrating 84 times in a minute muſt be 20 inches; and their difference, 60 inches, or 5 feet, is his ſtandard meaſure. By the experiments however, the difference between the lengths of the two pendulum rods, was found to be only 59·892 inches, inſtead of 60, owing to the error in the aſſumed length of the ſeconds pendulum, 39$\frac{1}{8}$ inches being greater than the truth, which ought to be 39$\frac{1}{8}$ very nearly. By this experiment, Mr. Whitehurſt obtained a fact, as accurately as may be in a thing of this nature, viz, the difference between the lengths of two pendulum rods whoſe vibrations are known: a datum from whence may be obtained, by calculation, the true lengths of pendulums, the ſpaces through which heavy bodies fall in a given time, and many other particulars relating to the doctrine of gravitation, the figure of the earth, &c, &c.

Mr. Whitehurſt had been at times ſubject to ſlight attacks of the gout, and he had for ſeveral years felt himſelf gradually declining. By an attack of that diſeaſe in his ſtomach, after a ſtruggle of two or three months, it put an end to his laborious and uſeful life, on the 18th of February 1788, in the 75th year of his age, at his houſe in Bolt-court, Fleet-ſtreet, being the ſame houſe where another eminent ſelf-taught philoſopher, Mr. James Ferguſon, had immediately before him lived and died.

For ſeveral years before his death, Mr. Whitehurſt had been at times occupied in arranging and completing ſome papers, for a treatiſe on Chimneys, Ventilation, and Garden-ſtoves; which have ſince been collected and given to the public, by Dr. Willan, in 1794.

However reſpectable Mr. Whitehurſt may have been in mechanics, and thoſe parts of natural ſcience which he more immediately cultivated, he was of ſtill higher account with his acquaintance and friends on the ſcore of his moral qualities. To ſay nothing of the uprightneſs and punctuality of his dealings in all tranſactions relative to buſineſs; few men have been known to poſſeſs more benevolent affections than he, or, being poſſeſſed of ſuch, to direct them more judiciouſly to their proper ends. As to his perſon, he was above the middle ſtature, rather thin than otherwiſe, and of a countenance expreſſive at once of penetration and mildneſs. His fine gray locks, unpolluted by art, gave a venerable air to his whole appearance. In dreſs he was plain, in diet temperate, in his general intercourſe with mankind

mankind eaſy and obliging. In company he was cheerful or grave alike, according to the dictate of the occaſion; with now and then a peculiar ſpecies of humour about him, delivered with ſuch gravity of manner and utterance, that thoſe who knew him but ſlightly were apt to underſtand him as ſerious, when he was merely playful. But where any deſire of information on ſubjects in which he was converſant was expreſſed, he omitted no opportunity of imparting it.

WHITSUNDAY, the 50th day or ſeventh ſunday from Eaſter.—The ſeaſon properly called Pentecoſt, is popularly called *Whitſuntide*; becauſe, it is ſaid, in the primitive church, the newly baptized perſons came to church between Eaſter and Pentecoſt in *white* garments.

WILKINS (Dr. John), a very ingenious and learned Engliſh biſhop and mathematician, was the ſon of a goldſmith at Oxford, and born in 1614. After being educated in Greek and Latin, in which he made a very quick progreſs, he was entered a ſtudent of New-Inn in that univerſity, when he was but 13 years of age; but after a ſhort ſtay there, he was removed to Magdalen Hall; where he took his degrees. Having entered into holy orders, he firſt became chaplain to William Lord Say, and afterwards to Charles Count Palatine of the Rhine, with whom he continued ſome time. Adhering to the Parliament during the civil wars, they made him warden of Wadham college about the year 1648. In 1656 he married the ſiſter of Oliver Cromwell, then lord protector of England, who granted him a diſpenſation to hold his wardenſhip, notwithſtanding his marriage. In 1659, he was by Richard Cromwell made maſter of Trinity college in Cambridge; but ejected the year following, upon the reſtoration. He was then choſen preacher to the ſociety of Gray's Inn, and rector of St. Lawrence Jewry, London, upon the promotion of Dr. Seth Ward to the biſhoprick of Exeter. About this time he became a member of the Royal Society, was choſen of their council, and proved one of their moſt eminent members. He was afterwards made dean of Rippon, and in 1668 biſhop of Cheſter; but died of the ſtone in 1672, at 58 years of age.

Biſhop Wilkins was a man who thought it prudent to ſubmit to the powers in being; he therefore ſubſcribed to the ſolemn league and covenant, while it was enforced; and was equally ready to ſwear allegiance to king Charles when he was reſtored: this, with his moderate ſpirit towards diſſenters, rendered him not very agreeable to the churchmen; and yet ſeveral of them could not but give him one of the beſt of characters. Burnet writes, that "he was a man of as great a mind, as true a judgment, as eminent virtues, and of as good a ſoul, as any he ever knew: that though he married Cromwell's ſiſter, yet he made no other uſe of that alliance, but to do good offices, and to cover the univerſity of Oxford from the ſourneſs of Owen and Goodwin. At Cambridge, he joined with thoſe who ſtudied to propagate better thoughts, to take men off from being in parties, or from narrow notions, from ſuperſtitious conceits, and fierceneſs about opinions. He was alſo a great obſerver and promoter of experimental philoſophy, which was then a new thing, and much looked after. He was naturally ambitious, but was the wiſeſt clergyman I ever knew. He was a lover of mankind, and had a delight in doing good." The ſame hiſtorian mentions afterwards another quality which Wilkins poſſeſſed in a ſupreme degree, and which it was well for him he did, ſince he had great occaſion for the uſe of it; and that was, ſays he, "a courage, which could ſtand againſt a current, and againſt all the reproaches with which ill-natured clergymen ſtudied to load him."

Of his publications, which are all of them very ingenious and learned, and many of them particularly curious and entertaining, the firſt was in 1638, when he was only 24 years of age, viz, The Diſcovery of a New World; or, A Diſcourſe to prove, that it is probable there may be another Habitable World in the Moon; with a Diſcourſe concerning the Poſſibility of a Paſſage thither.—In 1640, A Diſcourſe concerning a New Planet, tending to prove that it is probable our earth is one of the Planets.—In 1641, Mercury; or, the Secret and Swift Meſſenger; ſhewing, how a man may with Privacy and Speed communicate his Thoughts to a Friend at any Diſtance, 8vo.—In 1648, Mathematical Magic; or, the Wonders that may be performed by Mathematical Geometry, 8vo. All theſe pieces were publiſhed entire in one volume 8vo, in 1708, under the title of, The Mathematical and Philoſophical Works of the right rev. John Wilkins, &c; with a print of the author and general title page handſomely engraven, and an account of his life and writings. To this collection is alſo ſubjoined an abſtract of a larger work, printed in 1668, folio, intitled, An Eſſay towards a Real Character and a Philoſophical Language. Theſe were all his mathematical and philoſophical works; beſide which, he wrote ſeveral tracts in theology, natural religion, and civil polity, which were much eſteemed for their piety and moderation, and went through ſeveral editions.

WINCH, a popular term for a windlaſs. Alſo the bent handle for turning round wheels, grind-ſtones, &c.

WIND, a current, or ſtream of air, eſpecially when it is moved by ſome natural cauſe.

Winds are denominated from the point of the compaſs or horizon they blow from; as the eaſt Wind, north Wind, ſouth Wind, &c.

Winds are alſo divided into ſeveral kinds; as *general*, *particular*, *perennial*, *ſtated*, *variable*, &c.

Conſtant or *Perennial* WINDS, are thoſe that always blow the ſame way; ſuch as the remarkable one between the two tropics, blowing conſtantly from eaſt to weſt, called alſo the *general trade-Wind*.

Stated or *Periodical* WINDS, are thoſe that conſtantly return at certain times. Such are the ſea and land breezes, blowing from land to ſea in the morning, and from ſea to land in the evening. Such alſo are the ſhifting or particular trade Winds, which blow one way during certain months of the year, and the contrary way the reſt of the year.

Variable or *Erratic* WINDS, are ſuch as blow without any regularity either as to time, place, or direction. Such as the Winds that blow in the interior parts of England, &c: though ſome of theſe claim their certain times of the day; as, the north-Wind is moſt frequent in the morning, the weſt-Wind about noon, and the ſouth-Wind in the night.

General

General WIND, is ſuch as blows at the ſame time the ſame way, over a very large tract of ground, moſt part of the year; as the general trade-Wind.

Particular WINDS, include all others, excepting the general trade Winds.

Thoſe peculiar to one little canton or province, are called *topical* or *provincial Winds*. The Winds are alſo divided, with reſpect to the points of the compaſs or of the horizon, into *cardinal* and *collateral*.

Cardinal WINDS, are thoſe blowing from the four cardinal points, eaſt, weſt, north, and ſouth.

Collateral WINDS, are the intermediate Winds between any two cardinal Winds, and take their names from the point of the compaſs or horizon they blow from.

In Navigation, when the Wind blows gently, it is called a *breeze*; when it blows harder, it is called a *gale*, or a *ſtiff gale*; and when it blows very hard, a *ſtorm*.

For a particular account of the trade-Winds, monſoons, &c, ſee Philoſ. Tranſ. number 183, or Abridg. vol. 2, p. 133. Alſo Robertſon's Navigation book 5, ſect. 6.

A Wind blowing from the ſea, is always moiſt; as bringing with it the copious evaporation and exhalations from the waters: alſo, in ſummer, it is cool; and in winter warm. On the contrary, a Wind from the continent, is always dry; warm in ſummer, and cold in winter. Our northerly and ſoutherly Winds however, which are uſually accounted the cauſes of cold and warm weather, Dr. Derham obſerves, are really rather the effect of the cold or warmth of the atmoſphere. Hence it is that we often find a warm ſoutherly Wind ſuddenly change to the north, by the fall of ſnow or hail; and in a cold froſty morning, we find the Wind north, which afterward wheels about to the ſoutherly quarter, when the ſun has well warmed the air; and again in the cold evening, turns northerly, or eaſterly.

Phyſical Cauſe of WINDS. Some philoſophers, as Deſcartes, Rohault, &c, account for the general Wind, from the diurnal rotation of the earth; and from this general Wind they derive all the particular ones. Thus, as the earth turns eaſtward, the particles of the air near the equator, being very light, are left behind; ſo that, in reſpect of the earth's ſurface, they move weſtwards, and become a conſtant eaſterly wind, as they are found between the tropics, in thoſe parallels of latitude where the diurnal motion is ſwifteſt. But yet, againſt this hypotheſis, it is urged, that the air, being kept cloſe to the earth by the principle of gravity, would in time acquire the ſame degree of velocity that the earth's ſurface moves with, as well in reſpect of the diurnal rotation, as of the annual revolution about the ſun, which is about 30 times ſwifter.

Dr. Halley therefore ſubſtitutes another cauſe, capable of producing a like conſtant effect, not liable to the ſame objections, but more agreeable to the known properties of the elements of air and water, and the laws of the motion of fluid bodies. And that is the action of the ſun's beams, as he paſſes every day over the air, earth, and water, combined with the ſituation of the adjoining continents. Thus, the air which is leſs rarefied or expanded by heat, muſt have a motion towards thoſe parts which are more rarefied, and leſs ponderous, to bring the whole to an equilibrium; and as the ſun keeps continually ſhifting to the weſtward, the tendency of the whole body of the lower air is that way. Thus a general eaſterly Wind is formed, which being impreſſed upon the air of a vaſt ocean, the parts impel one another, and ſo keep moving till the next return of the ſun, by which ſo much of the motion as was loſt, is again reſtored; and thus the eaſterly Wind is made perpetual. But as the air towards the north and ſouth is leſs rarefied than in the middle, it follows that from both ſides it ought to tend towards the equator.

This motion, compounded with the former eaſterly Wind, accounts for all the phenomena of the general trade-Winds, which, if the whole ſurface of the globe were ſea, would blow quite round the world; as they are found to do in the Atlantic and the Ethiopic oceans. But the large continents of land in this middle tract, being exceſſively heated, communicate their heat to the air above them, by which it is exceedingly rarefied, which makes it neceſſary that the cooler and denſer air ſhould ruſh in towards it, to reſtore the equilibrium. This is ſuppoſed to be the cauſe why, near the coaſt of Guinea, the wind always ſets in upon the land, blowing weſterly inſtead of eaſterly.

From the ſame cauſe it happens, that there are ſuch conſtant calms in that part of the ocean called the *rains*; for this tract being placed in the middle, between the weſterly Winds blowing on the coaſt of Guinea, and the eaſterly trade-Winds blowing to the weſtward of it; the tendency of the air here is indifferent to either, and ſo ſtands in equilibrio between both; and the weight of the incumbent atmoſphere being diminiſhed by the continual contrary Winds blowing from hence, is the reaſon that the air here retains not the copious vapour it receives, but lets it fall in ſo frequent rains.

It is alſo to be conſidered, that to the northward of the Indian ocean there is every where land, within the uſual limits of the latitude of 30°, viz, Arabia, Perſia, India, &c, which are ſubject to exceſſive heats when the ſun is to the north, paſſing nearly vertical; but which are temperate enough when the ſun is removed towards the other tropic, becauſe of a ridge of mountains at ſome diſtance within the land, ſaid to be often in winter covered with ſnow, over which the air as it paſſes muſt needs be much chilled. Hence it happens that the air coming, according to the general rule, out of the north-eaſt, to the Indian ſea, is ſometimes hotter, ſometimes colder, than that which, by a circulation of one current over another, is returned out of the ſouth-weſt; and conſequently ſometimes the under current, or Wind, is from the north-eaſt, ſometimes from the ſouth-weſt.

That this has no other cauſe, appears from the times when theſe Winds ſet, viz, in April: when the ſun begins to warm theſe countries to the north, the ſouth-weſt monſoons begin, and blow during the heats till October, when the ſun being retired, and all things growing cooler northward, but the heat increaſing to the ſouth, the north-eaſt Winds enter, and blow all the winter, till April again. And it is doubtleſs from the ſame principle, that to the ſouthward of the equator, in part of the Indian ocean, the north-weſt Winds ſucceed the ſouth-eaſt, when the ſun draws near the tropic

tropic of Capricorn. Philoſ. Tranſ. num. 183; or Abridg. vol. 2, pa. 193.

But ſome philoſophers, not ſatisfied with Dr. Halley's theory above recited, or thinking it not ſufficient for explaining the various phenomena of the Wind, have had recourſe to another cauſe, viz, the gravitation of the earth and its atmoſphere towards the ſun and moon, to which the tides are confeſſedly owing. They allege that, though we cannot diſcover aërial tides, of ebb or flow, by means of the barometer, becauſe columns of air of unequal height, but different denſity, may have the ſame preſſure or weight; yet the protuberance in the atmoſphere, which is continually following the moon, muſt, ſay they, occaſion a motion in all parts, and ſo produce a Wind more or leſs to every place, which conſpiring with, or being counteracted by the Winds ariſing from other cauſes, makes them greater or leſs. Several diſſertations to this purpoſe were publiſhed, on occaſion of the ſubject propoſed by the Academy of Sciences at Berlin, for the year 1746. But Muſſchenbroek will not allow that the attraction of the moon is the cauſe of the general Wind; becauſe the eaſt Wind does not follow the motion of the moon about the earth; for in that caſe there would be more than 24 changes, to which it would be ſubject in the courſe of a year, inſtead of two. Introd. ad Phil. Nat. vol. 2, pa. 1102.

And Mr. Henry Eeles, conceiving that the rarefaction of the air by the ſun cannot ſimply be the cauſe of all the regular and irregular motions which we find in the atmoſphere, aſcribes them to another cauſe, viz, the aſcent and deſcent of vapour and exhalation, attended by the electrical fire or fluid; and on this principle he has endeavoured to explain at large the general phenomena of the weather and barometer. Philoſ. Tranſ. vol. 49, pa. 124.

Laws of the Production of WIND.

The chief laws concerning the production of Wind, may be collected under the following heads.

1. If the ſpring of the air be weakened in any place more than in the adjoining places, a Wind will blow through the place where the diminution is; becauſe the leſs elaſtic or forcible will give way to that which is more ſo, and thence induce a current of air into that place, or a Wind. Hence, becauſe the ſpring of the air increaſes, as the compreſſing weight increaſes, and compreſſed air is denſer than that which is leſs compreſſed; all Winds blow into rarer air, out of a place filled with a denſer.

2. Therefore, becauſe a denſer air is ſpecifically heavier than a rarer; an extraordinary lightneſs of the air in any place muſt be attended with extraordinary Winds, or ſtorms. Now, an extraordinary fall of the mercury in the barometer ſhewing an extraordinary lightneſs of the atmoſphere, it is no wonder if that foretels ſtorms of Wind and rain.

3. If the air be ſuddenly condenſed in any place, its ſpring will be ſuddenly diminiſhed: and hence, if this diminution be great enough to affect the barometer, a Wind will blow through the condenſed air. But ſince the air cannot be ſuddenly condenſed, unleſs it has before been much rarefied, a Wind will blow through the air, as it cools, after having been violently heated.

4. In like manner, if air be ſuddenly rarefied, its ſpring is ſuddenly increaſed; and it will therefore flow through the air not acted on by the rarefying force. Hence a Wind will blow out of a place, in which the air is ſuddenly rarefied; and on this principle probably it is, that the ſun, by rarefying the air, muſt have a great influence on the production of Winds.

5. Moſt caves are found to emit Wind, either more or leſs. Muſſchenbroek has enumerated a variety of cauſes that produce Winds, exiſting in the bowels of the earth, on its ſurface, in the atmoſphere, and above it. See Introd. ad Phil. Nat. vol. 2, pa. 1116.

6. The riſing and changing of the Winds are determined by weathercocks, placed on the tops of high buildings, &c. But theſe only indicate what paſſes about their own height, or near the ſurface of the earth. And Wolfius aſſures us, from obſervations of ſeveral years, that the higher Winds, which drive the clouds, are different from the lower ones, which move the weathercocks. Indeed it is no uncommon thing to ſee one tier of clouds driven one way by a Wind, and another tier juſt over the former driven the contrary way, by another current of air, and that often with very different velocities. And the late experiments with air balloons have proved the frequent exiſtence of counter Winds, or currents of air, even when it was not otherwiſe viſible, nor at all expected; by which they have been found to take very different and unexpected courſes, as they have aſcended higher and higher in the atmoſphere.

Laws of the Force and Velocity of the WIND.

Wind being only air in motion, and the motion of a fluid againſt a body at reſt, creating the ſame reſiſtance as when the body moves with the ſame velocity through the fluid at reſt; it follows, that the force of the Wind, and the laws of its action upon bodies, may be referred to thoſe of their reſiſtance when moved through it; and as theſe circumſtances have been treated pretty fully under the article RESISTANCE *of the Air*, there is no occaſion here to make a repetition of them. We there laid down both the quantity and laws of ſuch a force, upon bodies of different ſhapes and ſizes, moving with all degrees of velocity up to 2000 feet per ſecond, and alſo for planes ſet at all degrees of obliquity, or inclination to the direction of motion; all which circumſtances having, for the firſt time, been determined by real experiments.

As to the Velocity of the Wind: philoſophers have made uſe of various methods for determining it. The method employed by Dr. Derham, was by letting light downy feathers fly in the air, and nicely obſerving the diſtance to which they were carried in any number of half ſeconds. He ſays that he thus meaſured the velocity of the Wind in the great ſtorm of Auguſt 1705, which he found moved at the rate of 33 feet in half a ſecond, or 45 miles per hour: whence he concludes, that the moſt vehement Wind does not fly at the rate of above 50 or 60 miles an hour; and that at a medium the velocity of Wind is at the rate of 12 or 15 miles per hour. Philoſ. Tranſ. number 313, or Abridg. vol. 4, p. 419.

Mr. Brice obſerves however, that experiments with feathers are liable to much uncertainty; as they hardly ever

ever go forward in a ſtraight direction, but ſpirally, or elſe irregularly from ſide to ſide, or up and down.

He therefore conſiders the motion of a cloud, by means of its ſhadow over the ſurface of the earth, as a much more accurate meaſure of the velocity of the Wind. In this way he found that the Wind, in a conſiderable ſtorm, moved at the rate of near 63 miles an hour; and when it blew a freſh gale, at the rate of 21 miles per hour; and in a ſmall breeze it was near 10 miles an hour. Philoſ. Tranſ. vol. 56, p. 226.

The velocity and force of the Wind are alſo determined experimentally by various machines, called *anemometers*, *wind-meaſurers*, or *wind-gages*; the deſcription of which ſee under theſe articles.

In the Philoſ. Tranſ. for 1759, p. 165, Mr. Smeaton has given a table, communicated to him by a Mr. Rouſe, for ſhewing the force of the Wind, with ſeveral different velocities, which I ſhall inſert below, as I find the numbers nearly agree with my own experiments made on the reſiſtance of the air, when the reſiſting ſurfaces are reduced to the ſame ſize, by a due proportion for the reſiſtance, which is in a higher degree than that of the ſurfaces.

N. B. The table of my reſults is printed in pa. 111, vol. 1, under the article ANEMOMETER; where it is to be noted, that the numbers in the third column of that table, for the velocity of the Wind per hour, are all erroneouſly printed, only the 4th part of what each of them ought to be; ſo that thoſe numbers muſt be all multiplied by 4.

A Table of the different Velocities and Forces of the Wind, according to their common appellations.

Velocity of the Wind		Perpendicular force on one ſq. foot, in averdupois pounds.	Common appellations of the Winds.
Miles in one hour.	= feet in one ſecond.		
1	1·47	·005	Hardly perceptible.
2	2·93	·020	Juſt perceptible.
3	4·40	·044	
4	5·87	·079	Gentle pleaſant wind.
5	7·33	·123	
10	14·67	·492	Pleaſant briſk gale.
15	22·00	1·107	
20	29·34	1·968	Very briſk.
25	36·67	3·075	
30	44·01	4·429	High Winds.
35	51·34	6·027	
40	58·68	7·873	Very high.
45	66·01	9·963	
50	73·35	12·300	A ſtorm or tempeſt.
60	88·02	17·715	A great ſtorm.
80	117·36	31·490	A hurricane.
100	146·70	49·200	A hurricane that tears up trees, and carries buildings &c before it.

The force of the Wind is nearly as the ſquare of the velocity, or but little above it, in theſe velocities. But the force is much more than in the ſimple ratio of the ſurfaces, with the ſame velocity, and this increaſe of the ratio is the more, as the velocity is the more. By accurate experiments with two planes, the one of 17¾ ſquare inches, the other of 32, which are nearly in the ratio of 5 to 9, I found their reſiſtances, with a velocity of 20 feet per ſecond, to be, the one 1·196 ounces, and the other 2·542 ounces; which are in the ratio of 8 to 17, being an increaſe of between ⅕ and ⅛ part more than the ratio of the ſurfaces.

WIND-*Gage*, in Pneumatics, an inſtrument ſerving to determine the velocity and force of the Wind. See ANEMOMETER, ANEMOSCOPE, and the article juſt above concerning the Force and Velocity of the Wind.

Dr. Hales had various contrivances for this purpoſe. He found (Statical Eſſays, vol. 2, p. 326) that the air ruſhed out of a ſmith's bellows, at the rate of 68¾ feet in a ſecond of time, when compreſſed with a force of half a pound upon every ſquare inch lying on the whole upper ſurface of the bellows. The velocity of the air, as it paſſed out of the trunk of his ventilators, was found to be at the rate of 3000 feet in a minute, which is at the rate of 34 miles an hour. The ſame author ſays, that the velocity with which impelled air paſſes out at any orifice, may be determined by hanging a light valve over the noſe of a bellows, by pliant leathern hinges, which will be much agitated and lifted up from a perpendicular to a more than horizontal poſition by the force of the ruſhing air. There is alſo another more accurate way, he ſays, of eſtimating the velocity of air, viz. by holding the orifice of an inverted glaſs ſiphon full of water, oppoſite to the ſtream of air, by which the water will be depreſſed in one leg, and raiſed in the other, in proportion to the force with which the water is impelled by the air. Deſcrip. of Ventilators, 1743, p. 12. And this perhaps gave Dr. Lind the idea of his Wind-gage, deſcribed below.

M. Bouguer contrived a ſimple inſtrument, by which may be immediately diſcovered the force which the Wind exerts on a given ſurface. This is a hollow tube AABB (fig. 14, pl. 30), in which a ſpiral ſpring CD is fixed, that may be more or leſs compreſſed by a rod FSD, paſſing through a hole within the tube at AA. Then having obſerved to what degree different forces or given weights are capable of compreſſing the ſpiral, mark diviſions on the rod in ſuch a manner, that the mark at S may indicate the weight requiſite to force the ſpring into the ſituation CD: afterwards join at right angles to this rod at F, a plane ſurface CFE of any given area at pleaſure; then let this inſtrument be oppoſed to the Wind, ſo that it may ſtrike the ſurface perpendicularly, or parallel to the rod; then will the mark at S ſhew the weight to which the force of the Wind is equivalent.

Dr. Lind has alſo contrived a ſimple and eaſy apparatus of this kind, nearly upon the laſt idea of Dr. Hales mentioned above. This inſtrument is fully explained at the article ANEMOMETER, vol. 1, pa. 111, and a figure of it given, pl. 3, fig. 4.

Mr. Benjamin Martin, from a hint firſt ſuggeſted by Dr. Burton, contrived an anemoſcope, or Wind-gage, of a conſtruction like a Wind-mill, with four ſails; but the axis which the ſails turn, is not cylindrical, but conical, like the fuſee of a watch; about this fuſee winds a cord, having a weight at the end, which is

wound always, by the force of the Wind, upon the ſails, till the weight juſt balances that force, which will be at a thicker part of the fuſee when the Wind is ſtrong, and at a ſmaller part of it when it is weaker. But although this inſtrument ſhews when a Wind is ſtronger or weaker, it will neither ſhew what is the actual velocity of the Wind, nor yet its force upon a ſquare foot of direct ſurface; becauſe the ſails are ſet at an uncertain oblique angle to the Wind, and this acts at different diſtances from the axis or centre of motion. Martin's Phil. Brit. vol. 2, p. 211. See the fig. 5, plate 3, vol. 1.

WIND-*Gun*, the ſame as AIR-*Gun*; which ſee.

WIND-*Mill*, a kind of mill which receives its motion from the impulſe of the Wind.

The internal ſtructure of the Windmill is much the ſame with that of watermills: the difference between them lying chiefly in an external apparatus, for the application of the power. This apparatus conſiſts of an axis EF (fig. 11, pl. 36), through which paſs perpendicular to it, and to each other, two arms or yards, AB and CD, uſually about 32 feet long: on theſe yards are formed a kind of ſails, vanes, or flights, in a trapezoid form, with parallel ends; the greater of which HI is about 6 feet, and the leſs FG are determined by radii drawn from the centre E, to I and H.

Theſe ſails are to be capable of being always turned to the wind, to receive its impulſe: for which purpoſe there are two different contrivances, which conſtitute the two different kinds of Windmills in common uſe.

In the one, the whole machine is ſupported upon a moveable arbor, or axis, fixed upright on a ſtand or foot; and turned round occaſionally to ſuit the wind, by means of a lever.

In the other, only the cover or roof of the machine, with the axis and ſails, in like manner turns round with a parallel or horizontal motion. For this purpoſe, the cover is built turret-wiſe, and encompaſſed with a wooden ring, having a groove, at the bottom of which are placed, at certain diſtances, a number of braſs truckles; and within the groove is another ring, upon which the whole turret ſtands. To the moveable ring are connected beams *ab* and *fe*; and to the beam *ab* is faſtened a rope at *b*, having its other end fitted to a windlaſs, or axis-in-peritrochio: this rope being drawn through the iron hook G, and the windlaſs turned, the ſails are moved round, and ſet fronting the wind, or with the axis pointing ſtraight againſt the wind.

The internal mechaniſm of a Windmill is exhibited in fig. 12; where AHO is the upper room, and HoZ the lower one; AB the axle-tree paſſing through the mill; STVW the ſails covered with canvas, ſet obliquely to the wind, and turning round in the order of the letters; CD the cogwheel, having about 48 cogs or teeth, *a*, *a*, *a*, &c, which carry round the lantern EF, having 8 or 9 trundles or rounds *c*, *c*, *c*, &c, together with its upright axis GN; IK is the upper millſtone, and LM the lower one; QR is the bridge, ſupporting the axis or ſpindle GN; this bridge is ſupported by the beams *cd*, XY, wedged up at *c*, *d* and X; ZY is the lifting tree, which ſtands upright; *ab* and *ef* are levers, whoſe centres of motion are Z and *e*; *fghi* is a cord, with a ſtone *i*, going about the pins *g* and *h*, and ſerving as a balance or counterpoiſe. The ſpindle *t*N is fixed to the upper millſtone IK, by a piece of iron called the rynd, and fixed in the lower ſide of the ſtone, which is the only one that turns about, and its whole weight reſts upon a hard ſtone, fixed in the bridge QR at N. The trundle EF, and its axis G*t*, may be taken away; for it reſts by its lower part at *t* by a ſquare ſocket, and the top runs in the edge of the beam *w*. By bearing down the end *f* of the lever *fe*, *b* is raiſed, which raiſes ZY, and this raiſes YX, which lifts up the bridge QR, with the axis NG, and the upper ſtone IK; and thus the ſtones are ſet at any diſtance. The lower or immoveable ſtone is fixed upon ſtrong beams, and is broader than the upper one: the flour is conveyed through the tunnel *no* into a cheſt; P is the hopper, into which is put the corn, which runs through the ſpout *r* into the hole *t*, and ſo falls between the ſtones, where it is ground to meal. The axis G*t* is ſquare, which ſhaking the ſpout *r*, as it goes round, makes the corn run out; *rs* is a ſtring going about the pin *s*, and ſerving to move the ſpout nearer to the axis or farther from it, ſo as to make the corn run faſter or ſlower, according to the velocity and force of the wind. And when the wind is ſtrong, the ſails are only covered in part, or on one ſide, or perhaps only one half of two oppoſite ſails. Toward the end B of the axletree is placed another cogwheel, trundle, and millſtones, with an apparatus like that juſt deſcribed; ſo that the ſame axis moves two ſtones at once; and when only one pair is to grind, one of the trundles and its ſpindle are taken out: *xyl* is a girth of pliable wood, fixed at the end *x*; the other end *l* being tied to the lever *km*, moveable about *k*; and the end *m* being put down, draws the girth *xyl* cloſe to the cogwheel, which gently and gradually ſtops the motion of the mill, when required: *pq* is a ladder for aſcending to the higher part of the mill; and the corn is drawn up by means of a rope, rolled about the axis AB, when the mill is at work. See MILL.

Theory of the WINDMILL, *Poſition of the Sails, &c.*

Were the ſails ſet ſquare upon their arms or yards, and perpendicular to the axletree, or to the wind, no motion would enſue, becauſe the direct wind would keep them in an exact balance. But by ſetting them obliquely to the common axis, like the ſails of a ſmoke-jack, or inclined like the rudder of a ſhip, the wind, by ſtriking the ſurface of them obliquely, turns them about. Now this angle which the ſails are to make with their common axis, or the degree of *weathering*, as the mill-wrights call it, ſo as that the wind may have the greateſt effect, is a matter of nice enquiry, and has much occupied the thoughts of the mathematician and the artiſt.

In examining the compound motions of the rudder of a ſhip, we find that the more it approaches to the direction of the keel, or to the courſe of the water, the more weakly this ſtrikes it; but, on the other hand, the greater is the power of the lever to turn the veſſel about. The obliquity of the rudder therefore has, at the ſame time, both an advantage and a diſadvantage. It has been a point of inquiry therefore to find the poſition of the rudder when the ratio of the advantage over the diſadvantage is the greateſt. And *M.* Renau, in his

his theory of the working of ships, has found, that the best situation of the rudder is when it makes an angle of about 55 degrees with the keel.

The obliquity of the sails, with regard to their axis, has precisely the same advantage, and disadvantage, with the obliquity of the rudder to the keel. And M. Parent, seeking by the new analysis the most advantageous situation of the sails on the axis, finds it the same angle of about 55 degrees. This obliquity has been determined by many other mathematicians, and found to be more accurately 54° 44′. See Maclaurin's Fluxions, p. 733; Simpson's Fluxions, prob. 17, p. 521; Martin's Philos. Britan. vol. 1, p. 220, vol. 2, p. 212; &c.

This angle, however, is only that which gives the wind the greatest force to put the sail in motion, but not the angle which gives the force of the wind a maximum upon the sail when in motion: for when the sail has a certain degree of velocity, it yields to the wind; and then that angle must be increased, to give the wind its full effect. Maclaurin, in his Fluxions, p. 734, has shewn how to determine this angle.

It may be observed, that the increase of this angle should be different according to the different velocities from the axletree to the further extremity of the sail. At the beginning, or axis, it should be 54° 44′; and thence continually increasing, giving the vane a twist, and so causing all the ribs of the vane to lie in different planes.

It is farther observed, that the ribs of the vane or sail ought to decrease in length from the axis to the extremity, giving the vane a curvilinear form; so that no part of the force of any one rib be spent upon the rest, but all move on independent of each other. The twist above mentioned, and the diminution of the ribs, are exemplified in the wings of birds.

As the ends of the sail nearest the axis cannot move with the same velocity which the tips or farthest ends have, although the wind acts equally strong upon them both, Mr. Ferguson (Lect. on Mech. pa. 52) suggests, that perhaps a better position than that of stretching them along the arms directly from the centre of motion, might be, to have them set perpendicularly across the farther ends of the arms, and there adjusted lengthwise to the proper angle: for in that case both ends of the sails would move with the same velocity; and being farther from the centre of motion they would have so much the more power, and then there would be no occasion for having them so large as they are generally made; which would render them lighter, and consequently there would be so much the less friction on the thick neck of the axle, when it turns in the wall.

Mr. Smeaton (Philos. Trans. 1759), from his experiments with Windmill sails, deduces several practical maxims: as,

1. That when the wind falls upon a concave surface, it is an advantage to the power of the whole, though every part, taken separately, should not be disposed to the best advantage. By several trials he has found that the curved form and position of the sails will be best regulated by the numbers in the following table.

6th Parts of the radius or sail.	Angle with the axis.	Angle with the plane of motion.	
1	72°	18°	
2	71	19	
3	72	18	middle.
4	74	16	
5	77½	12½	
6	83	7	end.

2. That a broader sail requires a greater angle; and that when the sail is broader at the extremity, than near the centre, this shape is more advantageous than that of a parallelogram.

3. When the sails, made like sectors of circles, joining at the centre or axis, filled up about 7-8ths of the whole circular space, the effect was the greatest.

4. The velocity of Windmill sails, whether unloaded, or loaded so as to produce a maximum of effect, is nearly as the velocity of the Wind; their shape and position being the same.

5. The load at the maximum is nearly, but somewhat less than, as the square of the velocity of the wind.

6. The effects of the same sails at a maximum, are nearly, but somewhat less than, as the cubes of the velocity of the wind.

7. In sails of a similar figure and position, the number of *turns* in a given time, are reciprocally as the radius or length of the sail.

8. The effects of sails of similar figure and position, are as the square of their length.

9. The velocity of the extremities of Dutch mills, as well as of the enlarged sails, in all their usual positions, is considerably greater than the velocity of the wind.

M. Parent, in considering what figure the sails of a Windmill should have, to receive the greatest impulse from the wind, finds it to be a sector of an ellipsis, whose centre is that of the axletree of the mill; and the less semiaxis the height of 32 feet; as for the greater, it follows necessarily from the rule that directs the sail to be inclined to the axis in the angle of 55 degrees.

On this foundation he assumes four such sails, each being a quarter of an ellipse; which he shews will receive all the wind, and lose none, as the common ones do. These 4 surfaces, multiplied by the lever, with which the wind acts on one of them, express the whole power the wind has to move the machine, or the whole power the machine has when in motion.

A Windmill with 6 elliptical sails, he shews, would still have more power than one with only four. It would only have the same surface with the four; since the 4 contain the whole space of the ellipsis, as well as the 6. But the force of the 6 would be greater than that of the 4, in the ratio of 245 to 231. If it were desired to have only two sails, each being a semiellipsis, the surface would be still the same; but the power would be diminished by near 1-3d of that with 6 sails; because the greatness of the sectors would much shorten the lever with which the wind acts.

The same author has also considered which form, among the rectangular sails, will be most advantageous;

i. e. that which ſhall have the product of the ſurface by the lever of the wind, the greateſt. The reſult of this enquiry is, that the width of the rectangular ſail ſhould be nearly double its length; whereas uſually the length is made almoſt 5 times the width.

The power of the mill, with four of theſe new rectangular ſails, M. Parent ſhews, will be to the power of four elliptic ſails, nearly as 13 to 23; which leaves a conſiderable advantage on the ſide of the elliptic ones; and yet the force of the new rectangular ſails will ſtill be conſiderably greater than that of the common ones.

M. Parent alſo conſiders what number of the new ſails will be moſt advantageous; and finds that the fewer the ſails, the more ſurface there will be, but the power the leſs. Farther, the power of a Windmill with 6 ſails is denoted by 14, that of another with 4 will be as 13, and another with 2 ſails will be denoted by 9. That as to the common Windmill, its power ſtill diminiſhes as the breadth of the ſails is ſmaller, in proportion to the length: and therefore the uſual proportion of 5 to 1 is exceedingly diſadvantageous.

WINDWARD, in Sea Language, denotes any thing towards that point from whence the wind blows, in reſpect of a ſhip.

Sailing to WINDWARD. See SAILING.

WINDWARD *Tide*, denotes a tide that runs againſt the wind.

WINDAGE *of a Gun*, is the difference between the diameter of the bore of the gun and the diameter of the ball.

Heretofore the Windage appointed in the Engliſh ſervice, viz, 1-20th of the diameter of the ball, which has been uſed almoſt from the beginning, has been far too much, owing perhaps to the firſt want of roundneſs in the ball, or to ruſt, foulneſs, or irregularities in the bore of the gun. But lately a beginning has been made to diminiſh the Windage, which cannot fail to be of very great advantage; as the ſhot will both go much truer, and have leſs room to bounce about from ſide to ſide, to the great damage of the gun; and beſides much leſs powder will ſerve for the ſame effect, as in ſome caſes $\frac{1}{3}$ or $\frac{1}{2}$ the inflamed powder eſcapes by the Windage. The French allowance of Windage is 1-25th of the diameter of the ball.

WINDLASS, or WINDLACE, a particular machine uſed for raiſing heavy weights, as guns, ſtones, anchors, &c.

This is a very ſimple machine, conſiſting only of an axis or roller, ſupported horizontally at the two ends by two pieces of wood and a pulley: the two pieces of wood meet at top, being placed diagonally ſo as to prop each other; and the axis or roller goes through the two pieces, and turns in them. The pulley is faſtened at top, where the pieces join. Laſtly, there are two ſtaves or hand ſpikes which go through the roller, to turn it by; and the rope, which comes over the pulley, is wound off and on the ſame.

WINDLASS, in a Ship, is an inſtrument in ſmall ſhips, placed upon the deck, juſt abaft the foremaſt. It is made of a long and thick piece of timber, either cylindrical, or octagonal, &c, in form of an axletree, placed horizontally acroſs the ſhip, a foot or more above the deck; and it is turned about by the help of hand-ſpikes put into holes made for that purpoſe.

This machine will purchaſe or raiſe much more than a capſtan, and that without any danger to thoſe that heave; for if in heaving the Windlaſs about, any of the handſpikes ſhould happen to ſlip or break, the Windlaſs will ſtop of itſelf, as it does at the end of every pull or heave of the men, being prevented from returning by means of a catch that falls into notches. See fig. 15, pl. 35.

WINDOW, q. d. *wind-door*, an aperture or opening in the wall of a houſe, to admit the air and light.

Before the uſe of glaſs became general, which was not till towards the end of the 12th century, the Windows in England ſeem generally to have been compoſed of paper, oiled, both to defend it againſt the weather, and to make it more tranſparent; as now is ſometimes uſed in workſhops and unfiniſhed buildings. Some of the better ſort were furniſhed with lattices of wood or ſheets of linen. Theſe it ſeems were fixed in frames, called *capſamenta*, and hence our *caſements* ſtill ſo common in ſome of the counties.

The chief rules with regard to Windows are, 1. That they be as few in number, and as moderate in dimenſions, as may be conſiſtent with other reſpects; inaſmuch as all openings are weakenings.

2. That they be placed at a convenient diſtance from the angles or corners of the buildings: both for ſtrength and beauty.

3. That they be made all equal one with another, in their rank and order; ſo that thoſe on the right hand may anſwer to thoſe on the left, and thoſe above be right over thoſe below: both for ſtrength and beauty.

As to their dimenſions, care is to be taken, to give them neither more nor leſs than is needful; regard being had to the ſize of the rooms, and of the building. The apertures of Windows in middle-ſized houſes, may be from 4 to 5 feet; in the ſmaller ones leſs; and in large buildings more. And the height may be double their width at the leaſt: but in lofty rooms, or large buildings, the height may be a 4th, or 3d, or half their breadth more than the double.

Such are the proportions for Windows of the firſt ſtory; and the breadth muſt be the ſame in the upper ſtories; but as to the height, the ſecond ſtory may be a 3d part lower than the firſt, and the third ſtory a 4th part lower than the ſecond.

WINTER, one of the four ſeaſons or quarters of the year.

Winter properly commences on the day when the ſun's diſtance from the zenith of the place is the greateſt, or when his declination is the greateſt on the contrary ſide of the equator; and it ends on the day when that diſtance is a mean between the greateſt and leaſt, or when he next croſſes the equinoctial.

At and near the equator, the Winter, as well as the other ſeaſons, return twice every year; but all other places have only one Winter in the year; which in the northern hemiſphere begins when the ſun is in the tropic of Capricorn, and in the ſouthern hemiſphere when he is in the tropic of Cancer: ſo that all places in the ſame hemiſphere have their Winter at the ſame time.

Notwithſtanding the coldneſs of this ſeaſon it is proved in aſtronomy, that the ſun is really nearer to the earth in our Winter than in ſummer: the reaſon of the

effect

defect of heat being owing to the lowneſs of the ſun, or to the obliquity of his rays.

WOLFF, WOLFIUS, (CHRISTIAN), baron of the Roman empire, privy counſellor to the king of Pruſſia, and chancellor to the univerſity of Halle in Saxony, as well as member of many of the literary academies in Europe, was born at Breſlau in 1679. After ſtudying philoſophy and mathematics at Breſlau and Jena, he obtained permiſſion to give lectures at Leipſic; which, in 1703, he opened with a diſſertation called *Philoſophia Practica Univerſalis, Methodo Mathematica conſcripta*, which ſerved greatly to enhance the reputation of his talents. He publiſhed two other diſſertations the ſame year; the firſt *De Rotis Deutatis*, the other *De Algorithmo Infiniteſimali Differentiali*; which obtained him the honourable appellation of Aſſiſtant to the Faculty of Philoſophy at Leipſic.

He now accepted the profeſſorſhip of mathematics at Halle, and was elected into the ſociety at Leipſic, at that time engaged in publiſhing the *Acta Eruditorum*. After having inſerted in this work many important pieces relating to mathematics and phyſics, he undertook, in 1709, to teach all the various branches of philoſophy, beginning with a ſmall Logical treatiſe in Latin, being Thoughts on the Powers of the Human Underſtanding. He carried himſelf through theſe great purſuits with amazing aſſiduity and ardour: the king of Pruſſia rewarded him with the office of counſellor to the court in 1721, and augmented the profits of that poſt by very conſiderable appointments: he was alſo choſen a member of the Royal Society of London and of Pruſſia.

In the midſt of all this proſperity however, Wolff raiſed an eccleſiaſtical ſtorm againſt himſelf, by a Latin oration he delivered in praiſe of the Chineſe philoſophy: every pulpit immediately reſounded againſt his tenets; and the faculty of theology, who entered into a ſtrict examination of his productions, reſolving that the doctrine he taught was dangerous to the laſt degree, an order was obtained in 1723 for diſplacing him, and commanding him to leave Halle in 24 hours.

Wolff now retired to Caſſel, where he obtained the profeſſorſhip of mathematics and philoſophy in the univerſity of Marbourg, with the title of Counſellor to the Landgrave of Heſſe; to which a profitable penſion was annexed. Here he renewed his labours with redoubled ardour; and it was in this retreat that he publiſhed the greateſt part of his numerous works.

In 1725, he was declared an honorary profeſſor of the academy of ſciences at Peterſburg, and in 1733 was admitted into that of Paris. The king of Sweden alſo declared him one of the council of regency; but the pleaſing ſituation of his new abode, and the multitude of honours which he had received, were too alluring to permit him to accept of many advantageous offers; among which was the office of preſident of the academy at Peterſburg.

The king of Pruſſia too, who was now recovered from the prejudices he had been made to conceive againſt Wolff, wanted to re-eſtabliſh him in the univerſity of Halle in 1733, and made another attempt to effect it in 1739; which Wolff for a time thought fit to decline, but at laſt ſubmitted: he returned therefore in 1741, inveſted with the characters of privy counſellor, vice chancellor, and profeſſor of the law of nature and of nations. The king afterwards, upon a vacancy, raiſed him to the dignity of chancellor of the univerſity; and the elector of Bavaria created him a baron of the empire. He died at Halle in Saxony, of the gout in his ſtomach, in 1754, in the 76th year of his age, after a life filled up with a train of actions as wiſe and ſyſtematical as his writings, of which he compoſed in Latin and German more than 60 diſtinct pieces. The chief of his mathematical compoſitions, is his *Elementa Matheſeos Univerſæ*, the beſt edition of which is that of 1732 at Geneva, in 5 vols 4to; which does not however compriſe his Mathematical Dictionary in the German language, in 1 vol. 8vo, nor many other diſtinct works on different branches of the mathematics, nor his Syſtem of Philoſophy, in 23 vols. in 4to.

WORKING *to Windward*, in Sea Language, is the operation by which a ſhip endeavours to make a progreſs againſt the wind.

WREN (Sir CHRISTOPHER), a great philoſopher and mathematician, and one of the moſt learned and eminent architects of his age, was the ſon of the rev. Chriſtopher Wren, dean of Windſor, and was born at Knoyle in Wiltſhire in 1632. He ſtudied at Wadham college, Oxford; where he took the degree of maſter of arts in 1653, and was choſen fellow of Allſouls college there. Soon after, he became one of that ingenious and learned ſociety, who then met at Oxford for the improvement of natural and experimental philoſophy, and which at length produced the Royal Society.

When very young, he diſcovered a ſurpriſing genius for the mathematics, in which ſcience he made great advances before he was 16 years of age.—In 1657 he was made profeſſor of aſtronomy in Greſham college, London; and his lectures, which were much frequented, tended greatly to the promotion of real knowledge: in his inaugural oration, among other things, he propoſed ſeveral methods by which to account for the ſhadows returning backward 10 degrees on the dial of king Ahaz, by the laws of nature. One ſubject of his lectures was upon teleſcopes, to the improvement of which he had greatly contributed: another was on certain properties of the air, and the barometer. In the year 1658 he read a deſcription of the body and different phaſes of the planet Saturn; which ſubject he propoſed to inveſtigate while his colleague, Mr. Rooke, then profeſſor of geometry, was carrying on his obſervations upon the ſatellites of Jupiter. The ſame year he communicated ſome demonſtrations concerning cycloids to Dr. Wallis, which were afterwards publiſhed by the doctor at the end of his treatiſe upon that ſubject. About that time alſo, he reſolved the problem propoſed by Paſcal, under the feigned name of John de Montford, to all the Engliſh mathematicians; and returned another to the mathematicians in France, formerly propoſed by Kepler, and then reſolved likewiſe by himſelf, to which they never gave any ſolution.—In 1660, he invented a method for the conſtruction of ſolar eclipſes: and in the latter part of the ſame year, he with ten other gentlemen formed themſelves into a ſociety, to meet weekly, for the improvement of natural and experimental philoſophy; being the foundation of the Royal Society.—In the beginning of 1661, he was choſen Savilian profeſſor of aſtronomy at Oxford,

in

In the room of Dr. Seth Ward; where he was the ſame year created Doctor of Laws.

Among his other accompliſhments, Dr. Wren had gained ſo conſiderable a ſkill in architecture, that he was ſent for the ſame year, from Oxford, by order of king Charles the 2d, to aſſiſt Sir John Denham, ſurveyor general of the works.—In 1663, he was choſen fellow of the Royal Society; being one of thoſe who were firſt appointed by the Council after the grant of their charter. Not long after, it being expected that the king would make the ſociety a viſit, the lord Brounker, then preſident, by a letter requeſted the advice of Dr. Wren, concerning the experiments which might be moſt proper on that occaſion: to whom the doctor recommended principally the Torricellian experiment, and the weather needle, as being not mere amuſements, but uſeful, and alſo neat in their operation. Indeed upon many occaſions Dr. Wren did great honour to that illuſtrious body, by many curious and uſeful diſcoveries, in aſtronomy, natural philoſophy, and other ſciences, related in the Hiſtory of the Royal Society, where Dr. Sprat has inſerted them from the regiſters and other books of the ſociety to 1665. Among others of his productions there enumerated, is a lunar globe; repreſenting the ſpots and various degrees of whiteneſs upon the moon's ſurface, with the hills, eminences and cavities: the whole contrived ſo, that by turning it round to the light, it ſhews all the lunar phaſes, with the various appearances that happen from the ſhadows of the mountains and valleys, &c: this lunar model was placed in the king's cabinet. Another of theſe productions, is a tract on the Doctrine of Motion that ariſes from the impact between two bodies, illuſtrated by experiments. And a third is, The Hiſtory of the Seaſons, as to the temperature, weather, productions, diſeaſes, &c, &c. For which purpoſe he contrived many curious machines, ſeveral of which kept their own regiſters, tracing out the lines of variations, ſo that a perſon might know what changes the weather had undergone in his abſence: as windgages, thermometers, barometers, hygrometers, raingages, &c.—He made alſo great additions to the new diſcoveries on pendulums; and among other things ſhewed, that there may be produced a natural ſtandard for meaſure from the pendulum for common uſe.—He invented many ways to make aſtronomical obſervations more eaſy and accurate: He fitted and hung quadrants, ſextants, and radii more commodiouſly than formerly: he made two teleſcopes to open with a joint like a ſector, by which obſervers may infallibly take a diſtance to half minutes, &c. He made many ſorts of retes, ſcrews, and other devices, for improving teleſcopes to take ſmall diſtances, and apparent diameters, to ſeconds: He made apertures for taking in more or leſs light, as the obſerver pleaſes, by opening and ſhutting, the better to fit glaſſes for crepuſculine obſervations.—He added much to the theory of dioptrics; much to the manufacture of grinding good glaſſes: He attempted, and not without ſucceſs, the making of glaſſes of other forms than ſpherical. He exactly meaſured and delineated the ſpheres of the humours of the eye, the proportions of which to one another were only gueſſed at before: a diſcuſſion ſhewing the reaſons why we ſee objects erect, and that reflection conduces as much to viſion as refraction. He diſplayed a natural and eaſy theory of refractions, which exactly anſwered every experiment. He fully demonſtrated all dioptrics in a few propoſitions, ſhewing not only, as in Kepler's Dioptrics, the common properties of glaſſes, but the proportions by which the individual rays cut the axis, and each other, upon which the charges of the teleſcopes, or the proportion of the eye-glaſſes and apertures, are demonſtrably diſcovered.—He made conſtant obſervations on Saturn, and a true theory of that planet, before the printed diſcourſe by Huygens, on that ſubject, appeared.—He made maps of the Pleiades and other teleſcopic ſtars: and propoſed methods to determine the great queſtion as to the earth's motion or reſt, by the ſmall ſtars about the pole to be ſeen in large teleſcopes.—In navigation he made many improvements. He framed a magnetical terella, which he placed in the midſt of a plane board with a hole, into which the terella is half immerſed, till it be like a globe with the poles in the horizon: the plane is then duſted over with ſteel filings from a ſieve: the duſt, by the magnetical virtue, becomes immediately figured into furrows that bend like a ſort of helix, proceeding as it were out at one pole, and returning in by the other; the whole plane becoming figured like the circles of a planiſphere.—It being a queſtion in his time among the problems of navigation, to what mechanical powers ſailing againſt the wind was reducible; he ſhewed it to be a wedge: and he demonſtrated, how a tranſient force upon an oblique plane would cauſe the motion of the plane againſt the firſt mover: and he made an inſtrument mechanically producing the ſame effect, and ſhewed the reaſon of ſailing on all winds. The geometrical mechaniſm of rowing, he ſhewed to be a lever on a moving or cedent fulcrum: for this end, he made inſtruments and experiments, to find the reſiſtance to motion in a liquid medium; with other things that are the neceſſary elements for laying down the geometry of ſailing, ſwimming, rowing, flying, and conſtructing of ſhips.—He invented a very ſpeedy and curious way of etching. He ſtarted many things towards the emendation of water-works. He likewiſe made ſome inſtruments for reſpiration, and for ſtraining the breath from fuliginous vapours, to try whether the ſame breath, ſo purified, will ſerve again.—He was the firſt inventor of drawing pictures by microſcopical glaſſes. He found out perpetual, or at leaſt longlived lamps, for keeping a perpetual regular heat, in order to various uſes, as hatching of eggs and inſects, production of plants, chemical preparations, imitating nature in producing foſſils and minerals, keeping the motion of watches equal, for the longitude and aſtronomical uſes.—He was the firſt author of the anatomical experiment of injecting liquor into the veins of animals. By this operation, divers creatures were immediately purged, vomited, intoxicated, killed, or revived, according to the quality of the liquor injected. Hence aroſe many other new experiments, particularly that of tranſfuſing blood, which has been proſecuted in ſundry curious inſtances. This is a ſhort account of the principal diſcoveries which Dr. Wren preſented, or ſuggeſted, to the Royal Society, or were improved by him.

As to his architectural works: It has before been obſerved

obſerved that he had been ſent for to aſſiſt Sir John Denham. In 1665 he travelled into France, to examine the moſt beautiful edifices and curious mechanical works there, when he made many uſeful obſervations. Upon his return home, he was appointed architect, and one of the commiſſioners for repairing St. Paul's cathedral. Within a few days after the fire of London, 1666, he drew a plan for a new city, and preſented it to the king; but it was not approved of by the parliament. In this model, the chief ſtreets were to croſs each other at right angles, with leſſer ſtreets between them; the churches, public buildings, &c, ſo diſpoſed as not to interfere with the ſtreets, and four piazzas placed at proper diſtances.—Upon the death of Sir John Denham, in 1668, he ſucceeded him in the office of ſurveyor-general of the king's works; and from this time he had the direction of a great many public edifices, by which he acquired the higheſt reputation. He built the magnificent theatre at Oxford, St. Paul's cathedral, the Monument, the modern part of Hampton Court, Chelſea-college, one of the wings of Greenwich hoſpital, the churches of St. Stephen Walbrook, and St. Mary-le-bow, with upwards of 60 other churches and public works, which that dreadful fire made neceſſary. In the management of which buſineſs, he was aſſiſted in the meaſurements, and laying out of private property, by the ingenious Dr. Robert Hook. The variety of buſineſs in which he was by this means engaged, requiring his conſtant attendance and concern, he reſigned his Savilian profeſſorſhip at Oxford in 1673; and the year following he received from the king the honour of knighthood.—He was one of the commiſſioners who, on the motion of Sir Jonas Moore, ſurveyor-general of the ordnance, had been appointed to find out a proper place for erecting an obſervatory; and he propoſed Greenwich, which was approved of; the foundation ſtone of which was laid the 10th of Auguſt 1675, and the building was preſently finiſhed under the direction of Sir Jonas, with the advice and aſſiſtance of Sir Chriſtopher.

In 1680 he was choſen preſident of the Royal Society; afterwards appointed architect and commiſſioner of Chelſea-college; and in 1684, principal officer or comptroller of the works in Windſor-caſtle. Sir Chriſtopher ſat twice in Parliament, as a repreſentative for two different boroughs. While he continued ſurveyor-general, his reſidence was in Scotland-yard; but after his removal from that office, in 1718, he lived in St. James's-ſtreet, Weſtminſter. He died the 25th of February 1723, at 91 years of age; and he was interred with great ſolemnity in St. Paul's cathedral, in the vault under the ſouth wing of the choir, near the eaſt end.

As to his perſon, Sir Chriſtopher Wren was of a low ſtature, and thin frame of body; but by temperance and ſkilful management he enjoyed a good ſtate of health, to a very unuſual length of life. He was modeſt, devout, ſtrictly virtuous, and very communicative of his knowledge. Beſides his peculiar eminence as an architect, his learning and knowledge were very extenſive in all the arts and ſciences, and eſpecially in the mathematics.

Sir Chriſtopher never printed any thing himſelf, but ſeveral of his works have been publiſhed by others; ſome in the Philoſophical Tranſactions, and ſome by Dr. Wallis and other friends.—His poſthumous works and draughts were publiſhed by his ſon.

WRIGHT (EDWARD), a noted Engliſh mathematician, who flouriſhed in the latter part of the 16th century, and beginning of the 17th; dying in the year 1615. He was contemporary with Mr. Briggs, and much concerned with him in the buſineſs of the logarithms, the ſhort time they were publiſhed before his death. He alſo contributed greatly to the improvement of navigation and aſtronomy. The following memoirs of him are tranſlated from a Latin paper in the annals of Gonvile and Caius college in Cambridge, viz, "This year (1615) died at London, Edward Wright of Garveſton in Norfolk, formerly a fellow of this college; a man reſpected by all for the integrity and ſimplicity of his manners, and alſo famous for his ſkill in the mathematical ſciences: ſo that he was not undeſervedly ſtyled a moſt excellent mathematician by Richard Hackluyt, the author of an original treatiſe of our Engliſh navigations. What knowledge he had acquired in the ſcience of mechanics, and how uſefully he employed that knowledge to the public as well as private advantage, abundantly appear both from the writings he publiſhed, and from the many mechanical operations ſtill extant, which are ſtanding monuments of his great induſtry and ingenuity. He was the firſt undertaker of that difficult but uſeful work, by which a little river is brought from the town of Ware in a new canal, to ſupply the city of London with water; but by the tricks of others he was hindered from completing the work he had begun. He was excellent both in contrivance and execution, nor was he inferior to the moſt ingenious mechanic in the making of inſtruments, either of braſs or any other matter. To his invention is owing whatever advantage Hondius's geographical charts have above others; for it was Wright who taught Jodocus Hondius the method of conſtructing them, which was till then unknown; but the ungrateful Hondius concealed the name of the true author, and arrogated the glory of the invention to himſelf. Of this fraudulent practice the good man could not help complaining, and juſtly enough, in the preface to his treatiſe of the Correction of Errors in the Art of Navigation; which he compoſed with excellent judgment, and after long experience, to the great advancement of naval affairs. For the improvement of this art he was appointed mathematical lecturer by the Eaſt-India Company, and read lectures in the houſe of that worthy knight Sir Thomas Smith, for which he had a yearly ſalary of 50 pounds. This office he diſcharged with great reputation, and much to the ſatisfaction of his hearers. He publiſhed in Engliſh a book on the doctrine of the ſphere, and another concerning the conſtruction of ſun-dials. He alſo prefixed an ingenious preface to the learned Gilbert's book on the loadſtone. By theſe and other his writings, he has tranſmitted his fame to lateſt poſterity. While he was yet a fellow of this college, he could not be concealed in his private ſtudy, but was called forth to the public buſineſs of the nation, by the queen, about the year 1593. [Other accounts ſay 1589.] He was ordered to attend the earl of Cumberland in

ſome

ſome maritime expeditions. One of theſe he has given a faithful account of, in the manner of a journal or ephemeris, to which he has prefixed an elegant hydrographical chart of his own contrivance. A little before his death he employed himſelf about an Engliſh tranſlation of the book of logarithms, then lately diſcovered by lord Napier, a Scotchman, who had a great affection for him. This poſthumous work of his was publiſhed ſoon after, by his only ſon Samuel Wright, who was alſo a ſcholar of this college. He had formed many other uſeful deſigns, but was hindered by death from bringing them to perfection. Of him it may truly be ſaid, that he ſtudied more to ſerve the public than himſelf; and though he was rich in fame, and in the promiſes of the great, yet he died poor, to the ſcandal of an ungrateful age." So far the memoir; other particulars concerning him, are as follow.

Mr. Wright firſt diſcovered the true way of dividing the meridian line, according to which the Mercator's charts are conſtructed, and upon which Mercator's ſailing is founded. An account of this he ſent from Caius college, Cambridge, where he was then a fellow, to his friend Mr. Blondeville, containing a ſhort table for that purpoſe, with a ſpecimen of a chart ſo divided, together with the manner of dividing it. All which Blondeville publiſhed, in 1594, among his Exerciſes. And, in 1597, the reverend Mr. William Barlowe, in his Navigator's Supply, gave a demonſtration of this diviſion as communicated by a friend.

At length, in 1599, Mr. Wright himſelf printed his celebrated treatiſe, intitled, *The Correction of certain Errors in Navigation*, which had been written many years before; where he ſhews the reaſon of this diviſion of the meridian, the manner of conſtructing his table, and its uſes in navigation, with other improvements. In 1610 a ſecond edition of Mr. Wright's book was publiſhed, and dedicated to his royal pupil, prince Henry; in which the author inſerted farther improvements; particularly he propoſed an excellent way of determining the magnitude of the earth; at the ſame time recommending very judiciouſly, the making our common meaſures in ſome certain proportion to that of a degree on its ſurface, that they might not depend on the uncertain length of a barley-corn. Some of his other improvements were; The Table of Latitudes for dividing the meridian, computed as far as to minutes: An inſtrument, he calls the Sea-rings, by which the variation of the compaſs, the altitude of the ſun, and the time of the day, may be readily determined at once in any place, provided the latitude be known: The correcting of the errors ariſing from the eccentricity of the eye in obſerving by the croſs-ſtaff: A total amendment in the Tables of the declinations and places of the ſun and ſtars, from his own obſervations, made with a ſix-foot quadrant, in the years 1594, 95, 96, 97: A ſea-quadrant, to take altitudes by a forward or backward obſervation; having alſo a contrivance for the ready finding the latitude by the height of the pole-ſtar, when not upon the meridian. And that this book might be the better underſtood by beginners, to this edition is ſubjoined a tranſlation of Zamorano's Compendium; and added a large table of the variation of the compaſs as obſerved in very different parts of the world, to ſhew it is not occaſioned by any magnetical pole. The work has gone through ſeveral other editions ſince. And, beſide the books above mentioned, he wrote another on navigation, intitled, *The Haven-finding Art*. Other accounts of him ſay alſo, that it was in the year 1589 that he firſt began to attend the earl of Cumberland in his voyages. It is alſo ſaid that he made, for his pupil, prince Henry, a large ſphere with curious movements, which, by the help of ſpring-work, not only repreſented the motions of the whole celeſtial ſphere, but ſhewed likewiſe the particular ſyſtems of the ſun and moon, and their circular motions, together with their places and poſſibilities of eclipſing each other: there is in it a work for a motion of 17100 years, if it ſhould not be ſtopt, or the materials fail. This ſphere, though thus made at a great expence of money and ingenious induſtry, was afterwards in the time of the civil wars caſt aſide, among duſt and rubbiſh, where it was found, in the year 1646, by Sir Jonas Moore, who at his own expence reſtored it to its firſt ſtate of perfection, and depoſited it at his own houſe in the Tower, among his other mathematical inſtruments and curioſities.

X.

XEN XEN

XENOCRATES, an eminent philoſopher among the ancient Greeks, was born at Chalcedon, and died 314 years before Chriſt, at about 90 years of age. He became early a diſciple of Plato, ſtudying under this great maſter at the ſame time with Ariſtotle, though he was not poſſeſſed of equal talents; the former wanting a ſpur, and the latter a bridle. He was fond of the mathematics; and permitted none of his ſcholars to be ignorant of them. There was ſomething ſlovenly in the behaviour of Xenocrates; for which reaſon Plato frequently exhorted him to ſacrifice to the graces. Serioufneſs and ſeverity were always ſeen in his deport-

deportment: yet notwithſtanding this ſevere caſt of mind, he was very compaſſionate. There was ſomething extraordinary in the rectitude of his morals: he was abſolute maſter of his paſſions; and was not fond of pleaſure, riches, or applauſe. Indeed, ſo great was his reputation for ſincerity and probity, that he was the only perſon whom the magiſtrates of Athens diſpenſed from confirming his teſtimony with an oath. And yet he was ſo ill treated by them, as to be ſold becauſe he could not pay the poll-tax laid upon foreigners. Demetrius Phalereus bought Xenocrates, paid the debt to the Athenians, and immediately gave him his liberty. At Alexander's requeſt, he compoſed a treatiſe on the Art of Reigning; 6 books on Nature; 6 books on Philoſophy; one on Riches, &c; but none of them have come down to theſe times:—His theology it ſeems was but poor ſtuff: Cicero refutes him in the firſt book of the Nature of the Gods.

XENOPHANES, a Greek philoſopher, born in Colophon, was, according to ſome authors, the diſciple of Archelaus; in which caſe he muſt have been contemporary with Socrates. Others relate, that he taught himſelf all he knew, and that he lived at the ſame time with Anaximander: according to which account he muſt have flouriſhed before Socrates, and about the 60th Olympiad, as Diogenes Laertius affirms. He founded the Eleatic ſect; and wrote ſeveral poems on philoſophical ſubjects; as alſo a great many on the foundation of Colophon, and on that of the colony of Elea. He wrote alſo againſt Homer and Heſiod. He was baniſhed from his country, withdrew to Sicily, and lived in Zanche and Catana. His opinion with regard to the nature of God differs not much from that of Spinoza.—When he ſaw the Egyptians pour forth lamentations during their feſtivals, he thus adviſed them: "If the objects of your worſhip are Gods, do not weep: if they are men, offer not ſacrifices to them." The anſwer he made to a man with whom he refuſed to play at dice, is highly worthy of a philoſopher: This man calling him a coward, "Yes, replied he, I am exceſſively ſo with regard to all ſhameful actions."

XENOPHON, a celebrated Greek general, philoſopher, and hiſtorian, was born at Athens, and became early a diſciple of Socrates, who, ſays Strabo, ſaved his life in battle. About the 50th year of his age he engaged in the expedition of Cyrus, and accompliſhed his immortal retreat in the ſpace of 15 months. The jealouſy of the Athenians baniſhed him from his native city, for engaging in the ſervice of Sparta and Cyrus. On his return therefore he retired to Scillus, a town of Elis, where he built a temple to Diana, which he mentions in his epiſtles, and devoted his leiſure to philoſophy and rural ſports. But commotions ariſing in that country, he removed to Corinth, where it ſeems he wrote his Grecian Hiſtory, and died at the age of 90, in the year 360 before Chriſt.

By his wife Phileſia he had two ſons, Diodorus and Gryllus. The latter rendered himſelf immortal by killing Epaminondas in the famous battle of Mantinea, but periſhed in that exploit, which his father lived to record.

The beſt editions of his works are thoſe of Franckfort in 1674, and of Oxford, in Greek and Latin, in 1703, 5 vols. 8vo. Separately have been publiſhed his *Cyropædia*, Oxon. 1727, 4to, and 1736, 8vo. *Cyri Anabaſis*, Oxon. 1735, 4to, and 1747, 8vo, *Memorabilia Socratis*, Oxon. 1741, 8vo.—His *Cyropædia* has been admirably tranſlated into Engliſh by Spelman.

XIPHIAS, in Aſtronomy, is the Dorado or Sword-fiſh, a conſtellation of the ſouthern hemiſphere; being one of the new conſtellations added by modern aſtronomers; and conſiſting of 6 ſtars only. See DORADO.

Y.

YEA

YARD, a lineal meaſure, or meaſure of length, uſed in England and Spain chiefly to meaſure cloth, ſtuffs, &c. The Yard was ſettled by Henry the 1ſt, from the length of his own arm.

The Engliſh Yard contains 3 feet; and it is equal
to 4-5ths of the Engliſh ell,
to 7-9ths of the Paris ell,
to 4-3ds of the Flemiſh ell,
to 56-51ſts of the Spaniſh vara or Yard.

YARD, or *Golden* YARD, is alſo a popular name given to the 3 ſtars which compoſe the belt of Orion.

YEAR, in the full extent of the word, is a ſyſtem or cycle of ſeveral months, uſually 12. Others define Year, in the general, a period or ſpace of time, meaſured out by the revolution of ſome celeſtial body in its orbit. Thus, the time in which the fixed ſtars make a revolution, is called the *great Year*; and the times in which Jupiter, Saturn, the Sun, Moon, &c, complete their courſes, and return to the ſame point of the zodiac, are reſpectively called the Years of Jupiter, and Saturn, and the Solar, and Lunar Years, &c.

As Year denoted originally a revolution, and was not limited to that of the ſun; accordingly we find by the oldeſt accounts, that people have, at different times, expreſſed other revolutions by it, particularly that of the moon: and conſequently that the Years of ſome accounts, are to be reckoned only months, and ſometimes periods of 2, or 3, or 4 months. This will help us greatly in underſtanding the accounts that certain nations give of their own antiquity, and perhaps

haps of the age of men. We read expreſsly, in ſeveral of the old Greek writers, that the Egyptian Year, at one period, was only a month; and we are farther told that at other periods it was 3 months, or 4 months: and it is probable that the children of Iſrael followed the Egyptian account of their Years. The Egyptians talked, almoſt 2000 years ago, of having accounts of events 48 thouſand Years diſtance. A great deal muſt be allowed to fallacy, on the above account; but beſide this, the Egyptians had, in the time of the Greeks, the ſame ambition which the Chineſe have at preſent, and wanted to paſs themſelves upon that people, as theſe others do upon us, for the oldeſt inhabitants of the earth. They had recourſe alſo to the ſame means, and both the preſent and the early impoſtors have pretended to ancient obſervations of the heavenly bodies, and recounted eclipſes in particular, to vouch for the truth of their accounts. Since the time in which the ſolar Year, or period of the earth's revolution round the ſun, has been received, we may account with certainty; but for thoſe remote ages, in which we do not know of a certainty what is meant by the term Year, it is impoſſible to form any conjecture of the duration of time in the accounts. The Babylonians pretend to an antiquity of the ſame romantic kind; they talk of 47 thouſand Years in which they had kept obſervations; but we may judge of theſe as of the others, and of the obſervations as of the Years. The Egyptians ſpeak of the ſtars having four times altered their courſes in that period which they claim for their hiſtory, and that the ſun ſet twice in the eaſt. They were not ſuch perfect aſtronomers, but, after a round-about voyage, they might perhaps miſtake the eaſt for the weſt when they came in again.

YEAR, or SOLAR YEAR, properly, and by way of eminence ſo called, is the ſpace of time in which the ſun moves through the 12 ſigns of the ecliptic. This, by the obſervations of the beſt modern aſtronomers, contains 365 days, 5 hours, 48 min. 48 ſeconds: the quantity aſſumed by the authors of the Gregorian calendar is 365 days, 5 hours, 49 min. But in the civil or popular account, this Year only contains 365 days; except every 4th Year, which contains 366.

The viciſſitude of ſeaſons ſeems to have given occaſion to the firſt inſtitution of the Year. Man, naturally curious to know the cauſe of that diverſity, ſoon found it was the proximity and diſtance of the ſun; and therefore gave the name Year to the ſpace of time in which that luminary performed his whole courſe, by returning to the ſame point of his orbit. According to the accuracy in their obſervations, the Year of ſome nations was more perfect than that of others, but none of them quite exact, nor whoſe parts did not ſhift with regard to the parts of the ſun's courſe.

According to Herodotus, it was the Egyptians who firſt formed the Year, making it to contain 360 days, which they ſubdivided into 12 months, of 30 days each. Mercury Triſmegiſtus added 5 days more to the account. And on this footing it is ſaid that Thales inſtituted the Year among the Greeks; though that form of the Year did not hold throughout all Greece. Alſo, the Jewiſh, Syrian, Roman, Perſian, Ethiopic, Arabic, &c Years, were all different. In fact, conſidering the imperfect ſtate of aſtronomy in thoſe ages, it is no wonder that different people ſhould diſagree in the calculation of the ſun's courſe. We are even aſſured by Diod. Siculus, lib. 1. Plutarch, in Numa, and Pliny, lib. 7, cap. 48, that the Egyptian Year itſelf was at firſt very different from that now repreſented.

The ſolar Year is either *aſtronomical* or *civil*.

The *Aſtronomical Solar* YEAR, is that which is determined preciſely by aſtronomical obſervations; and is of two kinds, *tropical*, and *ſidereal* or *aſtral*.

Tropical, or *Natural* YEAR, is the time the ſun takes in paſſing through the zodiac; which, as before obſerved, is 365 d. 5 h. 48 m. 48 ſec.; or 365 d. 5 h. 49 min. This is the only proper or natural Year, becauſe it always keeps the ſame ſeaſons to the ſame months.

Sidereal or *Aſtral* YEAR, is the ſpace of time the ſun takes in paſſing from any fixed ſtar, till his return to it again. This conſiſts of 365 d. 6 h. 9 m. 17 ſec.; being 20 m. 29 ſec. longer than the true ſolar year.

Lunar YEAR, is the ſpace of 12 lunar months. Hence, from the two kinds of ſynodical lunar months, there ariſe two kinds of lunar Years; the one *aſtronomical*, the other *civil*.

Lunar Aſtronomical YEAR, conſiſts of 12 lunar ſynodical months; and therefore contains 354d. 8 h. 48 m. 38 ſec. and is therefore 10d. 21 h. 0 m. 10 ſ. ſhorter than the ſolar Year. A difference which is the foundation of the Epact.

Lunar Civil YEAR, is either common or emboliſmic.

The *Common Lunar* YEAR conſiſts of 12 lunar civil months; and therefore contains 354 days. And

The *Emboliſmic* or *Intercalary Lunar* YEAR, conſiſts of 13 lunar civil months, and therefore contains 384 days.

Thus far we have conſidered Years and months, with regard to aſtronomical principles, upon which the diviſion is founded. By this, the various forms of civil Years that have formerly obtained, or that do ſtill obtain, in divers nations, are to be examined.

Civil YEAR, is that form of Year which every nation has contrived or adopted, for computing their time by. Or the civil is the tropical Year, conſidered as only conſiſting of a certain number of whole days: the odd hours and minutes being ſet aſide, to render the computation of time, in the common occaſions of life, more eaſy. As the tropical Year is 365 d. 5 h. 49 m. or almoſt 365 d. 6 h. which is 365 days and a quarter; therefore if the civil Year be made 365 days, every 4th year it muſt be 366 days, to keep nearly to the courſe of the ſun. And hence the civil Year is either *common* or *biſſextile*. The

Common Civil YEAR, is that conſiſting of 365 days; having ſeven months of 31 days each, four of 30 days, and one of 28 days; as indicated by the following well known memorial verſes:

Thirty days hath September,
April, June, and November;
February twenty-eight alone,
And all the reſt have thirty-one.

Biſſextile or *Leap* YEAR, conſiſts of 366 days; having one day extraordinary; called the intercalary, or biſſextile day; and takes place every 4th Year. This additional day to every 4th Year, was firſt introduced

by Julius Cæsar; who, to make the civil Years keep pace with the tropical ones, contrived that the 6 hours which the latter exceeded the former, ſhould make one day in 4 years, and be added between the 24th and 23d of February, which was their 6th of the calends of March; and as they then counted this day twice over, or had *bis ſexto calendas*, hence the Year itſelf came to be called *bis ſextus*, and *biſſextile*.

However, among us, the intercalary day is not introduced by counting the 23d of February twice over, but by adding a day at the end of that month, which therefore in that Year contains 29 days.

A farther reformation was made in this year by Pope Gregory. See *Gregorian* YEAR, CALENDAR, BISSEXTILE, and LEAP-*Year*.

The Civil or Legal Year, in England, formerly commenced on the day of the Annunciation, or 25th of March; though the hiſtorical Year began on the day of the Circumciſion, or 1ſt of January; on which day the German and Italian Year alſo begins. The part of the Year between theſe two terms was uſually expreſſed both ways: as 1745-6, or $174\frac{5}{6}$. But by the act for altering the ſtile, the civil Year now commences with the 1ſt of January.

Ancient Roman YEAR. This was the lunar Year, which, as firſt ſettled by Romulus, contained only ten months, of unequal numbers of days in the following order: viz,

March 31; April 30; May 31; June 30; Quintilis 31; Sextilis 30; September 30; October 31; November 30; December 30; in all 304 days; which came ſhort of the true lunar Year by 50 days; and of the ſolar by 61 days. Hence, the beginning of Romulus's Year was vague, and unfixed to any preciſe ſeaſon; to remove which inconvenience, that prince ordered ſo many days to be added yearly as would make the ſtate of the heavens correſpond to the firſt month, without calling them by the name of any month.

Numa Pompilius corrected this irregular conſtitution of the Year, compoſing two new months, January and February, of the days that were uſed to be added to the former Year. Thus Numa's year conſiſted of 12 months, of different days, as follow; viz,

January - 29;	February 28;	March - - 31;
April - - 29;	May - - 31;	June - - - 29;
Quintilis 31;	Sextilis 29;	September 29;
October - 31;	November 29;	December 29;

in all 355 days; therefore exceeding the quantity of a lunar civil Year by one day; that of a lunar aſtronomical Year by $15^h\ 11^m\ 22^s$; but falling ſhort of the common ſolar Year by 10 days; ſo that its beginning was ſtill vague and unfixed.

Numa, however, deſiring to have it begin at the winter ſolſtice, ordered 22 days to be intercalated in February every 2d Year, 23 every 4th, 22 every 6th, and 23 every 8th Year.

But this rule failing to keep matters even, recourſe was had to a new way of intercalating; and inſtead of 23 days every 8th Year, only 15 were to be added. The care of the whole was committed to the pontifex maximus; who however, neglecting the truſt, let things run to great confuſion. And thus the Roman Year ſtood till Julius Cæsar reformed it. See CALENDAR. And for the manner of reckoning the days of the Roman months, ſee CALENDS, NONES, and IDES.

Julian YEAR. This is in effect a ſolar Year, commonly containing 365 days; though every 4th Year, called Biſſextile, it contains 366. The months of the Julian Year, with the number of their days, ſtood thus:

January - 31;	February - 28;	March - 31;
April - - 30;	May - - 31;	June - - 30;
July - - 31;	Auguſt - - 31;	September 30;
October - 31;	November 30;	December 31.

But every Biſſextile Year had a day added in February, making it then to contain 29 days.

The mean quantity therefore of the Julian Year is $365\frac{1}{4}$ days, or $365^d\ 6^h$; exceeding the true ſolar Year by ſomewhat more than 11 minutes; an exceſs which amounts to a whole day in almoſt 131 years. Hence the times of the equinoxes go backward, and fall earlier by one day in about 130 or 131 Years. And thus the Roman Year ſtood, till it was farther corrected by pope Gregory.

For ſettling this Year, Julius Cæsar brought over from Egypt, Soſigenes, a celebrated mathematician; who, to ſupply the defect of 67 days, which had been loſt through the neglect of the prieſts, and to bring the beginning of the Year to the winter ſolſtice, made one Year to conſiſt of 15 months, or 445 days; on which account that Year was uſed to be called *annus confuſionis*, the *Year of confuſion*. See *Julian* CALENDAR.

Gregorian YEAR. This is the Julian Year corrected by this rule, viz, that inſtead of every ſecular or 100th Year being a biſſextile, as it would be in the former way, in the new way three of them are common Years, and only the 4th is biſſextile.

The error of 11 minutes in the Julian Year, by continual repetition, had accumulated to an error of 13 days from the time when Cæsar made his correction; by which means the equinoxes were greatly diſturbed. In the Year 1582, the equinoxes were fallen back 10 days, and the full moons 4 days, more backward than they were in the time of the Nicene council, which was in the Year 325; viz, the former from the 20th of March to the 10th, and the latter from the 5th to the 1ſt of April. To remedy this increaſing irregularity, pope Gregory the 13th, in the year 1582, called together the chief aſtronomers of his time, and concerted this correction, throwing out the 10 days above mentioned. He exchanged the lunar cycle for that of the epacts, and made the 4th of October of that Year to be the 15th; by that means reſtoring the vernal equinox to the 21ſt of March. It was alſo provided, by the omiſſion of 3 intercalary days in 400 Years, to make the civil Year keep pace nearly with the ſolar Year, for the time to come. See CALENDAR.

In the Year 1700, the error of 10 days was grown to 11; upon which, the proteſtant ſtates of Germany, to prevent farther confuſion, adopted the Gregorian correction. And the ſame was accepted alſo in England in the year 1752, when 11 days were thrown out after the 2d of September that Year, by accounting the 3d to be the 14th day of the month: calling this the new ſtile, and the former the old ſtile. And the Gregorian, or

new ſtile, is now in like manner uſed in moſt countries of Europe.

Yet this laſt correction is ſtill not quite perfect; for as it has been ſhewn that in 4 centuries, the Julian Year gains $3^d\ 2^h\ 40^m$; and as it is only the 3 days that are kept out in the Gregorian Year; there is ſtill an exceſs of $2^h\ 40^m$ in 4 centuries, which amounts to a whole day in 36 centuries, or in 3600 Years. See CALENDAR, *New* or *Gregorian* STILE, &c.

Egyptian YEAR, called alſo the *Year of Nabonaſſar*, on account of the epoch of Nabonaſſar, is the ſolar Year of 365 days, divided into 12 months, of 30 days each, beſide 5 intercalary days, added at the end. The order and names of theſe months are as follow:

1. Thoth;	2. Paophi;	3. Athyr;
4. Chojac;	5. Tybi;	6. Mecheir;
7. Phamenoth;	8. Pharmuthi;	9. Pachon;
10. Pauni;	11. Epiphi;	12. Meſori.

As the Egyptian Year, by neglecting the 6 hours, in every 4 Years loſes a whole day of the Julian Year, its beginning runs through every part of the Julian Year in the ſpace of 1460 Years; after which, they meet again; for which reaſon it is called the *erratic* Year. And becauſe this return to the ſame day of the Julian Year, is performed in the ſpace of 1460 Julian Years, this circle is called the Sothic period.

This Year was applied by the Egyptians to civil uſes, till Anthony and Cleopatra were defeated; but the mathematicians and aſtronomers uſed it till the time of Ptolomy, who made uſe of it in his Almageſt; ſo that the knowledge of it is of great uſe in aſtronomy, for comparing the ancient obſervations with the modern.

The ancient Egyptians, we are told by Diodorus Siculus, (Plutarch, lib. 1, in the life of Numa, and Pliny, lib. 7, cap. 48) meaſured their Years by the courſe of the moon. At firſt they were only one month, then 3, then 4, like that of the Arcadians; and then 6, like that of the people of Acarnania. Thoſe authors add, that it is on this account that they reckon ſuch a vaſt number of Years from the beginning of the world; and that in the hiſtory of their kings, we meet with ſome who lived 1000, or 1200 Years. The ſame thing is maintained by Kircher; Oedip. Egypt. tom. 2, pa. 252. And a late author obſerves, that Varro has affirmed the ſame of all nations, that has been quoted of the Egyptians. By which means many account for the great ages of the more ancient patriarchs; expounding the gradual decreaſe in their ages, by the ſucceſſive increaſe of the number of months in their years.

Upon the Egyptians being ſubdued by the Romans, they received the Julian Year, though with ſome alteration; for they ſtill retained their ancient months, with the five additional days, and every 4th Year they intercalated another day, for the 6 hours, at the end of the Year, or between the 28th and 29th of Auguſt. Alſo, the beginning of their Year, or the firſt day of the month Thoth, anſwered to the 29th of Auguſt of the Julian Year, or to the 30th if it happened to be leap Year.

The Ancient Greek YEAR.—This was a lunar Year, conſiſting of 12 months, which at firſt had each 30 days, then alternately 29 and 30 days, computed from the firſt appearance of the new moon; with the addition of an emboliſmic month of 30 days, every 3d, 5th, 8th, 11th, 14th, 16th, and 19th Year of a cycle of 19 Years; in order to keep the new and full moons to the ſame terms or ſeaſons of the Year.

Their Year commenced with that new moon which was neareſt to the ſummer ſolſtice. And the order of the months, with the number of their days, were as follow: 1. Εκατομβαιων, of 29 days; 2. Μηταγειτνιων 30; 3. Βοηδρομιων 29; 4. Μαιμακτηριων 30; 5. Πυανεψιων 29; 6. Ποσειδεων 30; 7. Γαμηλιων 29; 8. Ανθεστηριων 30; 9. Ελαφηβολιων 29; 10. Μουνιχιων 30; 11. Οαργηλιων 29; 12. Σκιροφοριων 30.—But many of the Greek nations had other names for their months.

The Ancient Jewiſh YEAR.—This is a lunar Year, uſually conſiſting of 11 months, containing alternately 30 and 29 days. And it was made to agree with the ſolar Year, by adding 11, and ſometimes 12 days, at the end of the Year, or by an emboliſmic month. The order and quantities of the months were as follow: 1. Niſan or Abib 30 days; 2. Jiar or Zius 29; 3. Siban or Sievan 30; 4. Thamuz or Tamuz 29; 5. Ab 30; 6. Elul 29; 7. Tiſri or Ethanim 30; 8. Marcheſvam or Bul 29; 9. Ciſleu 30; 10. Tebeth 29; 11. Sabat or Schebeth 30; 12. Adar 30 in the emboliſmic year, but 29 in the common year.—Note, in the defective Year, Ciſleu was only 29 days; and in the redundant Year, Marcheſvam was 30.

The Modern Jewiſh YEAR is likewiſe lunar, conſiſting of 12 months in common Years, but of 13 in emboliſmic Years; which, in a cycle of 19 Years, are the 3d, 6th, 8th, 11th, 14th, 17th, and 19th. Its beginning is fixed to the new moon next after the autumnal equinox. The names and order of the months, with the number of the days, are as follow: 1. Tiſri 30 days; 2. Marcheſvan 29; 3. Ciſleu 30; 4. Tebeth 29; 5. Schebeth 30; 6. Adar 29; 7. Veadar, in the emboliſmic year, 30; 8. Niſan 30; 9. Iiar 29; 10. Sivan 30; 11. Thamuz 29; 12. Ab 30; 13. Elul 29.

The Syrian YEAR, is a ſolar one, having its beginning fixed to the beginning of October in the Julian Year; from which it only differs in the names of the months, the quantities being the ſame; as follow: 1. Tiſhrin, anſwering to our October, and containing 31 days; 2. Latter Tiſhrin, containing, like November, 30 days; 3. Canun 31; 4. Latter Canun 31; 5. Shabat 28, or 29 in a leap-year; 6. Adar 31; 7. Niſan 30; 8. Aiyar 31; 9. Haziram 30; 10. Thamuz 31; 11. Ab 31; 12. Elul 30.

The Perſian YEAR, is a ſolar one, of 365 days, conſiſting of 12 months of 30 days each, with 5 intercalary days added at the end. The months are as follow: 1. Afrudia meh; 2. Ardihaſcht meh; 3. Cardi meh; 4. Thir meh; 5. Merded meh; 6. Schabarir meh; 7. Mehar meh; 8. Aben meh; 9. Adar meh; 10. Di meh; 11. Behen meh; 12. Aſſirer meh. This Year is the ſame as the Egyptian Nabonaſſarean, and is called the *yezdegerdic Year*, to diſtinguiſh it from the fixed ſolar Year, called the Gelalean Year, which the Perſians began to uſe in the Year 1079, and which was

formed

formed by an intercalation, made ſix or ſeven times in four Years, and then once every 5th Year.

The Arabic, Mahometan, and Turkiſh YEAR, called alſo the Year of the *Hegira*, is a lunar Year, equal to $354^d\ 8^h\ 48^m$, and conſiſts of 12 months, containing alternately 30 and 29 days. Though ſometimes it contains 13 months; the names &c being as follow: 1. Muharram of 30 days; 2. Saphar 29; 3. Rabia 30; 4. Latter Rabia 29; 5. Jomada 30; 6. Latter Jomada 29; 7. Rajab 30; 8. Shaaban 29; 9. Ramadan 30; 10. Shawal 29; 11. Dulkaadah 30; 12. Dulheggia 29, but in the emboliſmic year 30. An intercalary day is added every 2d, 5th, 7th, 10th, 13th, 15th, 18th, 21ſt, 24th, 26th, 29th, in a cycle of 29 Years. The months commence with the firſt appearance of the new moons after the conjunctions.

Ethiopic YEAR, is a ſolar Year perfectly agreeing with the Actiac, except in the names of the months, which are; 1. Maſcaram; 2. Tykympt; 3. Hydar; 4. Tyſhas; 5. Tyr; 6. Jacatil; 7. Magabit; 8. Mijazia; 9. Ginbat; 10. Syne; 11. Hamel; 12. Hahaſe. Intercalary days 5. It commences with the Egyptian Year, on the 29th of Auguſt of the Julian Year.

YESDEGERDIC YEAR. See *Perſian* YEAR.

Z.

ZEN

ZENITH, in Aſtronomy, the vertical point, or point in the heavens directly overhead. Or, the Zenith is a point in the ſurface of the ſphere, from which a right line drawn through the place of any ſpectator, paſſes through the centre of the earth.

The Zenith of any place, is alſo the pole of the horizon, being 90 degrees diſtant from every point of it. And through the Zenith paſs all the azimuths, or vertical circles.

The point diametrically oppoſite to the Zenith, is called the *nadir*, being the point in the ſphere directly under our feet: and it is the Zenith to our antipodes, as our Zenith is their nadir.

ZENITH-*Diſtance*, is the diſtance of the ſun or ſtar from our Zenith; and is the complement of the altitude, or what it wants of 90 degrees.

ZENO, ELEATES, or of *Elea*, one of the greateſt philoſophers among the Ancients, flouriſhed about 500 years before the Chriſtian æra. He was the diſciple of Parmenides, and even, according to ſome writers, his adopted ſon. Ariſtotle aſſerts that he was the inventor of logic: but his logic ſeems to have been calculated and employed to perplex all things, and not to clear up any thing. For Zeno employed it only to diſpute againſt all comers, and to ſilence his opponents, whether they argued right or wrong. Among many other ſubtleties and embarraſſing arguments, he propoſed ſome with regard to motion, denying that ther was any ſuch thing in nature; and Ariſtotle, in the 6th book of his phyſics, has preſerved ſome of them, which are extremely ſubtile, eſpecially the famous argument named Achilles; which was to prove this propoſition, that the ſwifteſt animal could never overtake the ſloweſt, as a greyhound a tortoiſe, if the latter ſet out a little fore the former: for ſuppoſe the tortoiſe to be 100 yards before the dog, and that this runs 100 times as faſt as the other; then while the dog runs the firſt 100 yards, the tortoiſe runs 1, and is therefore 1 yard

ZEN

before the dog; again, while the dog runs over this yard, the tortoiſe will run the 100th part of a yard, and will be ſo much before the dog; and again, while the dog runs over this 100th part of a yard, the tortoiſe will have got the 100th part of that 100th part before him; and ſo on continually, ſays he, the dog will always be ſome ſmall part behind the tortoiſe. But the fallacy will ſoon be detected, by conſidering where the tortoiſe will be when the dog has run over 200 yards; for as the former can have run only two yards in the ſame time, and therefore muſt then be 98 yards behind the dog, he conſequently muſt have overtaken and paſſed the tortoiſe. It has been ſaid that, to prove to him, or ſome diſciple of his, that there is ſuch a thing as motion, Diogenes the Cynic roſe up and walked over the floor.—Zeno ſhewed great courage in ſuffering pain; for having joined with others to endeavour to reſtore liberty to his country, which groaned under the oppreſſion of a tyrant, and the enterprize being diſcovered, he ſupported with extraordinary firmneſs the ſharpeſt tortures. It is even ſaid that he had the courage to bite off his tongue, and ſpit it in the tyrant's face, for fear of being forced, by the violence of his torments, to diſcover his accomplices. Some ſay that he was pounded to death in a mortar.

ZENO, a celebrated Greek philoſopher, was born at Citium, in the Iſle of Cyprus, and was the founder of the Stoics; a ſect which had its name from that of a portico at Athens, where this philoſopher choſe to hold his diſcourſes. He was caſt upon that coaſt by ſhipwreck; and he ever after regarded this as a great happineſs, praiſing the winds for having ſo happily driven him into the port of Piræum.—Zeno was the diſciple of Crates, and had a great number of followers. He made the ſovereign good to conſiſt in dying in conformity to nature, guided by the dictates of right reaſon. He acknowledged but one God; and admitted an inevitable deſtiny over all events. His

ſervant taking advantage of this laſt opinion, cried, while he was beating him for diſhoneſty, "I was deſtined to ſteal;" to which Zeno replied, "Yes, and to be beaten too." This philoſopher uſed to ſay, "That if a wiſe man ought not to be in love, as ſome pretended, none would be more miſerable than beautiful and virtuous women, ſince they would have none for their admirers but fools." He alſo ſaid, "That a part of knowledge conſiſts in being ignorant of ſuch things as ought not to be known: that a friend is another ſelf: that a little matter gives perfection to a work, though perfection is not a little matter." He compared thoſe who ſpoke well and lived ill, to the money of Alexandria, which was beautiful, but compoſed of bad metal.—It is ſaid that being hurt by a fall, he took that as a ſign he was then to quit this life, and laid violent hands on himſelf, about 264 years before Chriſt.

Cleanthes, Cryſippus, and the other ſucceſſors of Zeno maintained, that with virtue we might be happy in the midſt even of diſgrace and the moſt dreadful torments. They admitted the exiſtence of only one God, the ſoul of the world, which they conſidered as his body, and both together forming a perfect being. It is remarked that, of all the ſects of the ancient philoſophers, this was one of thoſe which produced the greateſt men.

We ought not to confound the two Zenos above mentioned, with

ZENO, a celebrated Epicurean philoſopher, born at Sidon, who had Cicero and Pomponius Atticus for his diſciples, and who wrote a book againſt the mathematics, which, as well as that of Poſſidonius's refutation of it, is loſt; nor with ſeveral other Zenos mentioned in hiſtory.

ZENSUS, or ZENZUS, in Arithmetic and Algebra, a name uſed by ſome of the older authors, eſpecially in Germany, for a ſquare number, or the 2d power: being a corruption from the Italic *cenſi*, of Pacioli, Tartalea, &c, or the Latin *cenſus*, which ſignified the ſame thing.

ZETETICE, or ZETETIC *Method*, in Mathematics, was the method made uſe of to inveſtigate, or find out the ſolution of a problem; and was much the ſame thing as analytics, or the analytic method.

Vieta has an ingenious work of this kind in 5 books; *Zeteticorum libri quinque.*

ZOCCO, ZOCCOLO, ZOCLE, or SOCLE, in Architecture, a ſquare body, leſs in height than breadth, placed under the baſes of pedeſtals, ſtatues, vaſes, &c. See SOCLE and PLINTH.

ZODIAC, in Aſtronomy, an imaginary ring or broad circle, in the heavens, in form of a belt or girdle, within which the planets all make their excurſions. In the very middle of it runs the ecliptic, or path of the ſun in his annual courſe; and its breadth, comprehending the deviations or latitudes of the planets, is by ſome authors accounted 16°, ſome 18, and others 20 degrees.

The Zodiac, cutting the equator obliquely, makes with it the ſame angle as the ecliptic, which is its middle line, which angle, continually varying, is now nearly equal to 23° 28′; which is called the obliquity of the Zodiac or ecliptic, and is alſo the ſun's greateſt declination.

The Zodiac is divided into 12 equal parts, of 30 degrees each, called the ſigns of the Zodiac, being ſo named from the conſtellations which anciently paſſed them. But, the ſtars having a motion from weſt to eaſt, thoſe conſtellations do not now correſpond to their proper ſigns; from whence ariſes what is called the *preceſſion of the equinoxes.* And therefore when a ſtar is ſaid to be in ſuch a ſign of the Zodiac, it is not to be underſtood of that conſtellation, but only of that dodecatemory or 12th part of it.

Caſſini has alſo obſerved a tract in the heavens, within whoſe bounds moſt of the comets, though not all of them, are obſerved to keep, and which he therefore calls the *Zodiac of the comets.* This he makes as broad as the other Zodiac, and marks it with ſigns or conſtellations, like that; as Antinous, Pegaſus, Andromeda, Taurus, Orion, the Leſſer Dog, Hydra, the Centaur, Scorpion, and Sagittary.

ZODIACAL *Light*, a brightneſs ſometimes obſerved in the zodiac, reſembling that of the galaxy or milky way. It appears at certain ſeaſons, viz, towards the end of winter and in ſpring, after ſunſet, or before his riſing, in autumn and beginning of winter, reſembling the form of a pyramid, lying lengthways with its axis along the zodiac, its baſe being placed obliquely with reſpect to the horizon. This phenomenon was firſt deſcribed and named by the elder Caſſini, in 1683. It was afterwards obſerved by Fatio, in 1684, 1685, and 1686; alſo by Kirch and Eimmart, in 1688, 1689, 1691, 1693, and 1694. See Mairan, Suite des Mem. de l'Acad. Royale des Sciences 1731, pa. 3.

The Zodiacal light, according to Mairan, is the ſolar atmoſphere, a rare and ſubtile fluid, either luminous by itſelf, or made ſo by the rays of the ſun ſurrounding its globe; but in a greater quantity, and more extenſively, about his equator, than any other part.

Mairan ſays, it may be proved from many obſervations, that the ſun's atmoſphere ſometimes reaches as far as the earth's orbit, and there meeting with our atmoſphere, produces the appearance of an Aurora borealis.

The length of the Zodiacal light varies ſometimes in reality, and ſometimes in appearance only, from various cauſes.

Caſſini often mentions the great reſemblance between the Zodiacal light and the tails of comets. The ſame obſervation has been made by Fatio: and Euler endeavoured to prove that they were owing to ſimilar cauſes. See Decouverte de la Lumiere Celeſte que paroit dans le Zodiaque, art. 41. Lettre à M. Caſſini, printed at Amſterdam in 1686. Euler, in Mem. de l'Acad. de Berlin, tom. 2.

This light ſeems to have no other motion than that of the ſun itſelf: and its extent from the ſun to its point, is ſeldom leſs than 50 or 60 degrees in length, and more than 20 degrees in breadth: but it has been known to extend to 100 or 103°, and from 8 to 9° broad.

It is now generally acknowledged, that the electric fluid is the cauſe of the aurora borealis, aſcribed by

Mairan

Mairan to the ſolar atmoſphere, which produces the Zodiacal light, and which is thrown off chiefly and to the greateſt diſtance from the equatorial parts of the ſun, by means of the rotation on his axis, and extending viſibly as far as the orbit of the earth, where it falls into the upper regions of our atmoſphere, and is collected chiefly towards the polar parts of the earth, in conſequence of the diurnal revolution, where it forms the aurora borealis. And hence it has been ſuggeſted, as a probable conjecture, that the ſun may be the fountain of the electrical fluid, and that the Zodiacal light, and the tails of comets, as well as the aurora borealis, the lightning, and artificial electricity, are its various and not very diſſimilar modifications.

ZONE, in Geography and Aſtronomy, a diviſion of the earth's ſurface, by means of parallel circles, chiefly with reſpect to the degree of heat in the different parts of that ſurface.

The ancient aſtronomers uſed the term Zone, to explain the different appearances of the ſun and other heavenly bodies, with the length of the days and nights; and the geographers, as they uſed the climates, to mark the ſituation of places; uſing the term climate when they were able to be more exact, and the term Zone when leſs ſo.

The Zones were commonly accounted five in number; one a broad belt round the middle of the earth, having the equator in the very middle of it, and bounded, towards the north and ſouth, by parallel circles paſſing through the tropics of Cancer and Capricorn. This they called the *torrid Zone*, which they ſuppoſed not habitable, on account of its extreme heat. Though ſometimes they divided this into two equal torrid Zones, by the equator, one to the north, and the other ſouth; and then the whole number of Zones was accounted 6.

Next, from the tropics of Cancer and Capricorn, to the two polar circles, were two other ſpaces called *temperate Zones*, as being moderately warm; and theſe they ſuppoſed to be the only habitable parts of the earth.

Laſtly, the two ſpaces beyond the temperate Zones, about either pole, bounded within the polar circles, and having the poles in the middle of them, are the two *frigid* or *frozen Zones*, and which they ſuppoſed not habitable, on account of the extreme cold there.

Hence, the breadth of the torrid Zone, is equal to twice the greateſt declination of the ſun, or obliquity of the ecliptic, equal to 46° 56′, or twice 23° 28′. Each frigid Zone is alſo of the ſame breadth, the diſtance from the pole to the polar circle being equal to the ſame obliquity 23° 28′. And the breadth of each temperate Zone is equal to 43° 4′, the complement of twice the ſame obliquity. See theſe Zones exhibited in plate 35, fig. 16.

The difference of Zones is attended with a great diverſity of phenomena. 1. In the torrid Zone, the ſun paſſes through the zenith of every place in it twice a year; making as it were two ſummers in the year; and the inhabitants of this Zone are called *amphiſcians*, becauſe they have their noon-day ſhadows projected different ways in different times of the year, northward at one ſeaſon, and ſouthward at the other.

2. In the temperate and frigid Zones, the ſun riſes and ſets every natural day of 24 hours. Yet every where, but under the equator, the artificial days are of unequal lengths, and the inequality is the greater, as the place is farther from the equator. The inhabitants of the temperate Zones are called *heteroſcians*, becauſe their noon-day ſhadow is caſt the ſame way all the year round, viz, thoſe in the north Zone toward the north pole, and thoſe in the ſouth Zone toward the ſouth pole.

3. Within the frigid Zones, the inhabitants have their artificial days and nights extended out to a great length; the ſun ſometimes ſkirting round a little above the horizon for many days together: and at another ſeaſon never riſing above the horizon at all, but making continual night for a conſiderable ſpace of time. The inhabitants of theſe Zones are called *periſcians*, becauſe ſometimes they have their ſhadows going quite round them in the ſpace of 24 hours.

After l. 9, *add*, Since this article was printed, I obſerve, in the 3d volume of the Edinburgh Philoſophical Tranſactions, an account of a curious ſet of experiments, on the unequal refrangibility of light, with obſervations on Achromatic teleſcopes, by Dr. Robert Blair. This ingenious gentleman ſets out with obſerving, "If the theory of the Achromatic teleſcope is ſo complete as it has been repreſented, may it not reaſonably be demanded, whence it proceeds, that Hugenius and others could execute teleſcopes with ſingle object glaſſes 8 inches and upwards in diameter, while a compound object glaſs of half theſe dimenſions, is hardly to be met with? or how it can ariſe from any defect in the execution, that reflectors can be made ſo much ſhorter than Achromatic refractors of equal apertures, when it is well known that the latter are much leſs affected by any imperfections in the execution of the lenſes compoſing the object glaſs, than reflectors are by equal defects in the figure of the great ſpeculum?—The general anſwer made by artiſts to enquiries of this kind, is, that the fault lies in the imperfection of glaſs, and particularly in that kind of glaſs of which the concave lens of the compound object glaſs is formed, called flint glaſs.—It was in order to ſatisfy myſelf concerning the reality of this difficulty, and to attempt to remove it, that I engaged in the following courſe of experiments."

Dr. Blair deſcribes the apparatus and manner of making the experiments. He employed various priſms of different kinds of glaſs; alſo lenſes of glaſs, and of

A C H

a great variety of fluid mediums, having different degrees of refraction. Having detailed the whole at conſiderable length, for which a reference muſt be made to the work itſelf, and it is very deſerving of attentive peruſal, he concludes with the following recapitulation of the contents and ſcope of the whole diſcourſe.

"The unequal refrangibility of light, as diſcovered and fully explained by Sir Iſaac Newton, ſo far ſtands its ground uncontroverted, that when the refraction is made in the confine of any medium whatever, and a vacuum, the rays of different colours are unequally refracted, the red-making rays being the leaſt refrangible, and the violet-making rays the moſt refrangible.

"The diſcovery of what has been called a different diſperſive power in different refractive mediums, proves thoſe theorems of Sir Iſaac Newton not to be univerſal, in which he concludes that the difference of refraction of the moſt and leaſt refrangible rays, is always in a given proportion to the refraction of the mean refrangible ray. There can be no doubt that this poſition is true with reſpect to the mediums on which he made his experiments; but there are many exceptions to it.

"For the experiments of Mr. Dollond prove, that the difference of refraction between the red and violet rays, in proportion to the refraction of the whole pencil, is greater in ſome kinds of glaſs than in water, and greater in flint-glaſs than in crown-glaſs.

"The firſt ſet of experiments above recited, prove, that the quality of diſperſing the rays in a greater degree than crown-glaſs, is not confined to a few mediums, but is poſſeſſed by a great variety of fluids, and by ſome of theſe in a moſt extraordinary degree. Solutions of metals, eſſential oils, and mineral acids, with the exception of the vitriolic, are moſt remarkable in this reſpect.

"Some conſequences of the combinations of mediums of different diſperſive powers, which have not been ſufficiently attended to, are then explained. Although the greater refrangibility of the violet rays than of the red rays, when light paſſes from any medium whatever into a vacuum, may be conſidered as a law of nature, yet in the paſſage of light from one medium into another, it depends entirely on the qualities of the mediums, which of theſe rays ſhall be the moſt refrangible, or whether there ſhall be any difference in their refrangibility.

" The application of the demonſtrations of Hugenius to the correction of the aberration from the ſpherical figures of lenſes, whether ſolid or fluid, is then taken notice of, as being the next ſtep towards perfecting the theory of teleſcopes.

" Next it appears from trials made with object-glaſſes of very large apertures, in which both aberrations are corrected as far as the principles will admit, that the correction of colour which is obtained by the common combination of two mediums which differ in diſperſive power, is not complete. The homogeneal green rays emerge moſt refracted, next to theſe the united blue and yellow, then the indigo and orange united, and laſtly the united violet and red, which are leaſt refracted.

" If this production of colour were conſtant, and the length of the ſecondary ſpectrum were the ſame in all combinations of mediums when the whole refraction of the pencil is equal, the perfect correction of the aberration from difference of refrangibility would be impoſſible, and would remain an inſurmountable obſtacle to the improvement of dioptrical inſtruments.

" The object of the next experiment is, therefore, to ſearch, whether nature affords mediums which differ in the degree in which they diſperſe the rays compoſing the priſmatic ſpectrum, and at the ſame time ſeparate the ſeveral orders of rays in the ſame proportion. For if ſuch could be found, the above-mentioned ſecondary ſpectrum would vaniſh, and the aberration from difference of refrangibility might be removed. The reſult of this inveſtigation was unſucceſsful with reſpect to its principal object. In every combination that was tried, the ſame kind of uncorrected colour was obſerved, and it was thence concluded, that there was no direct method of removing the aberration.

" But it appeared in the courſe of the experiments, that the breadth of the ſecondary ſpectrum was leſs in ſome combinations than in others, and thence an indirect way opened, leading to the correction ſought after; namely by forming a compound concave lens of the materials which produce moſt colour, and combining it with a compound convex lens formed of the materials which produce leaſt colour; and it was obſerved in what manner this might be effected by means of three mediums, though apparently four are required.

" In ſearching for mediums beſt adapted for the above purpoſe, a very ſingular and important quality was detected in the muriatic acid. In all the diſperſive mediums hitherto examined, the green rays, which are the mean refrangible in crown-glaſs, were found among the leſs refrangible, and thence occaſion the uncorrected colour which has been deſcribed. In the muriatic acid, on the contrary, theſe ſame rays make a part of the more refrangible; and in conſequence of this, the order of the colours in the ſecondary ſpectrum, formed by a combination of crown glaſs with this fluid, is inverted, the homogeneal green being now the leaſt refrangible, and the united red and violet the moſt refrangible.

" This remarkable quality found in the marine acid led to complete ſucceſs in removing the great defect of optical inſtruments, that diſſipation or aberration of the rays, ariſing from their unequal refrangibility, which has rendered it impoſſible hitherto to converge all of them to one point either by ſingle or oppoſite refractions. A fluid in which the particles of marine acid and metalline particles hold a due proportion, at the ſame time that it ſeparates the extreme rays of the ſpectrum much more than crown-glaſs, refracts all the orders of rays exactly in the ſame proportion as the glaſs does; and hence rays of all colours, made to diverge by the refraction of the glaſs, may either be rendered parallel by a ſubſequent refraction made in the confine of the glaſs and this fluid, or by weakening the refractive denſity of the fluid, the refraction which takes place in the confine of it and glaſs, may be rendered as regular as reflexion, while the errors ariſing from unavoidable imperfections of workmanſhip, are far leſs hurtful than in reflexion, and the quantity of light tranſmitted by equal apertures of the teleſcopes much greater.

" Such are the advantages which the theory preſents. In reducing this theory to practice, difficulties muſt be expected in the firſt attempts. Many of theſe it was neceſſary to ſurmount before the experiments could be completed. For the delicacy of the obſervations is ſuch as to require a conſiderable degree of perfection in the execution of the object-glaſſes, in order to admit of the phenomena being rendered more apparent by means of high magnifying powers. Great pains ſeem to have been taken by mathematicians to little purpoſe, in calculating the radii of the ſpheres requiſite for Achromatic teleſcopes, from their not conſidering that the object-glaſs itſelf is a much nicer teſt of the optical properties of refracting mediums than the groſs experiments made by priſms, and that the reſults of their demonſtrations cannot exceed the accuracy of the data, however much they may fall ſhort of it.

" I ſhall conclude this paper, which has now greatly exceeded its intended bounds, by enumerating the ſeveral caſes of unequal refrangibility of light, that their varieties may at once be clearly apprehended.

" In the refraction which takes place in the confine of every known medium and a vacuum, rays of different colours are unequally refrangible, and the red-making rays are leaſt refrangible, and the violet-making rays are moſt refrangible.

" This difference of refrangibility of the red and violet rays is not the ſame in all mediums. Thoſe mediums in which the difference is greateſt, and which, by conſequence, ſeparate or diſperſe the rays of different colours moſt, have been diſtinguiſhed by the term diſperſive, and thoſe mediums which ſeparate the rays leaſt have been called indiſperſive. Diſperſive mediums differ from indiſperſive, and ſtill more from each other, in another very eſſential circumſtance.

" It appears from the experiments which have been made on indiſperſive mediums, that the mean refrangible light is always the ſame, and of a green colour.

" Now, in by far the largeſt claſs of diſperſive mediums, including flint glaſs, metallic ſolutions, eſſential oils, the green light is not the mean refrangible order, but forms one of the leſs refrangible orders of light, being found in the priſmatic ſpectrum nearer to the deep red than the extreme violet.

" In another claſs of diſperſive mediums, which includes the muriatic and nitrous acids, this ſame green light becomes one of the more refrangible orders, being now found nearer to the extreme violet than the deep red.

" Theſe

" Theſe are the varieties in the refrangibility of light, when the refraction takes place in the confine of a vacuum; and the phenomena will ſcarce differ ſenſibly in refractions made in the confine of denſe mediums and air.

" But when light paſſes from one denſe medium into another, the caſes of unequal refrangibility are more complicated.

" In refractions made in the confine of mediums which differ only in ſtrength, not in quality, as in the confine of water and crown-glaſs, or in the confine of the different kinds of diſperſive fluids more or leſs diluted, the difference of refrangibility will be the ſame as above ſtated in the confine of denſe mediums and air, only the whole refraction will be leſs.

" In the confine of an indiſperſive medium, and a rarer medium belonging to either claſs of the diſperſive, the red and violet rays may be rendered equally refrangible. If the diſperſive power of the rare medium be then increaſed, the violet rays will become the leaſt refrangible, and the red rays the moſt refrangible. If the mean refractive denſity of the two mediums be rendered equal, the red and violet rays will be refracted in oppoſite directions, the one towards, the other from the perpendicular.

" Thus it happens to the red and violet rays, whichſoever claſs of diſperſive mediums be employed. But the refrangibility of the intermediate orders of rays, and eſpecially of the green rays, will be different when the claſs of diſperſive mediums is changed.

" Thus, in the firſt caſe, where the red and violet rays are rendered equally refrangible, the green rays will emerge moſt refrangible if the firſt claſs of diſperſive mediums is uſed, and leaſt refrangible if the ſecond claſs is uſed. And in the other two caſes, where the violet becomes leaſt refrangible, and the red moſt refrangible, and where theſe two kinds of rays are refracted in oppoſite directions, the green rays will join the red if the firſt claſs of diſperſive mediums be employed, and will arrange themſelves with the violet if the ſecond claſs be made uſe of.

" Only one caſe more of unequal refrangibility remains to be ſtated; and that is, when light is refracted in the confine of mediums belonging to the two different claſſes of diſperſive fluids. In its tranſition, for example, from an eſſential oil, or a metallic ſolution, into the muriatic acid, the refractive denſity of theſe fluids may be ſo adjuſted, that the red and violet rays ſhall ſuffer no refraction in paſſing from the one into the other, how oblique ſoever their incidence be. But the green rays will then ſuffer a conſiderable refraction, and this refraction will be from the perpendicular, when light paſſes from the muriatic acid into the eſſential oil, and towards the perpendicular, when it paſſes from the eſſential oil into the muriatic acid. The other orders of rays will ſuffer ſimilar refractions, which will be greateſt in thoſe adjoining the green, and will diminiſh as they approach the deep red on the one hand, and the extreme violet on the other, where the refraction ceaſes entirely.

" The manner of the production of theſe effects, by the attraction of the ſeveral mediums, may be thus explained. We ſhall ſuppoſe the attractive forces, which produce the refractions of the red, green and violet light, to be repreſented by the numbers, 8, 12, and 16, in glaſs; 6, 9, 14, in the metallic ſolution; 6, 11, 14, in the muriatic acid; and 6, 10, 14, in a mixture of theſe two fluids. The exceſs of attraction of glaſs for the red and violet light is equal to 2, whichſoever of the three fluids be employed. The refraction of theſe two orders of rays will therefore be the ſame in all the three caſes. But the exceſs of attraction for the green light is equal to 3, when the metallic ſolution is uſed, and therefore the green light will be more refracted than the red and violet, in this caſe. When the muriatic acid is uſed, the exceſs of attraction of glaſs for the green light is only 1, and therefore the green light will now be leſs refracted than the red and violet.

" We ſhall next ſuppoſe the metallic ſolution and the acid to adjoin each other. The attractions of both theſe mediums, for the red light being 6, and for the violet light 14, theſe two orders of rays will ſuffer no refraction in the confine of the two fluids, the difference of their attractions being equal to nothing.

" But the attractive force of the metallic ſolution for the green ray being only 9, and that of the muriatic acid for the ſame ray being 11, the green light will be attracted towards the muriatic acid with the force 2; and therefore the difference between the refraction of the green light and the unrefracted red and violet light, which takes place in the confine of theſe fluids, will greatly exceed the difference of refraction of the green light, and equally refracted red and violet light, which is produced in the confine of glaſs and either of the fluids.

" Laſtly, in a mixture of the two kinds of fluids, the attraction for the red, green and violet rays, being 6, 10 and 14, and that of the glaſs, 8, 12 and 16, the exceſs of the attraction of the glaſs for the green rays, is the ſame which it is for the red and violet rays. Theſe three orders of rays will therefore ſuffer an equal refraction, being each of them attracted towards the glaſs with the force 2; and when this is the caſe, it appears, from the obſervations, that the indefinite variety of rays of intermediate colours and ſhades of colours, which altogether compoſe ſolar light, will alſo be regularly bent from their rectilinear courſe, conſtituting what has been termed a planatic refraction."

In ſhort, Dr. Blair ſays, that he " uſes more tranſparent mediums than the common ones; avoids or greatly diminiſhes the reflections at the ſurfaces of the mediums; applies fluid mediums more homogeneous than thick flint or crown glaſs, which at the ſame time diſperſe the different coloured rays of light in the ſame proportion, by which means an image is produced perfectly Achromatic, which is but imperfectly ſo in Dollond's object glaſſes made of flint and crown glaſs combined.

AFFECTED *Equations*, *add* (from Francis Maseres, Esq.)—"This expression of *Affected Equations* seems to require some further explanation. It was introduced by the celebrated Vieta, the great father and restorer of Algebra. He has many expressions peculiar to himself, and which have not been adopted by subsequent Algebraists. Amongst these are the following ones. He calls a set of quantities in continual geometrical proportion, (such as the quantities 1, x, x^2, x^3, x^4, x^5, x^6 x^7, &c,) a set of *scalar* quantities, or *magnitudines scalares*; and, when there are several of these *scalar* quantities mentioned together, (as in the compound quantity $x^5 + ax^4 - b^2x^3$,) he calls the highest quantity, or that which is farthest in the scale of quantities 1, x, x^2, x^3, x^4, x^5, x^6, x^7, &c. (to wit, the quantity x^5 in the said compound quantity $x^5 + ax^4 - b^2x^3$,) *the power* of the fundamental quantity x, or of the second term in the said scale; and he calls the lower scalar quantities which are involved in the second and third terms of the said compound quantity $x^5 + ax^4 - b^2x^3$, to wit, the quantities x^4 and x^3, (or, in our present language, the inferior powers of x,) scalar quantities of a *parodic* degree to x^5, or the power of the fundamental quantity x. This word *parodic* I take to be derived (though Vieta does not tell us so) from the Greek words παρὰ and ὁδὸς, which signify *near* and *a way* or *road*, because these inferior scalar quantities x^3 and x^4 lie *in the way* as you pass along in the scale of the aforesaid quantities 1, x, x^2, x^3, x^4, x^5, x^6 x^7, &c, from 1 to x^5, which he calls the power of x in the said compound quantity $x^5 + ax^4 - b^2x^3$. These inferior scalar quantities x^3 and x^4 are therefore *parodic*, or *situated in the way to*, or are *leading to*, the higher scalar quantity x^5. He then proceeds to define *a pure power* and *an affected power*, and tells us that *a pure power* is a scalar quantity that is not affected with any *parodic*, or *inferiour* scalar quantity, and that *an affected power* is a scalar quantity that is connected by addition, or subtraction with one, or more, *inferiour*, or *parodic*, scalar quantities, combined with co-efficients that raise them to the same dimension as the power itself, or make them *homogeneous* to it, and consequently capable of being added to it, or subtracted from it. Thus x^5 alone is a *pure power* of x, namely, its fifth power; and $x^5 + ax^4 - b^2x^3$ is *an affected power* of x, namely, its fifth power *affected by*, or *connected with*, the two *parodic*, or *inferiour*, scalar quantities x^3 and x^4, which are multiplied into bb and a, in order to make them *homogeneous* to, or *of the same dimension with*, x^5 itself, and capable of being added to it or subtracted from it. See Schooten's Edition of Vieta's works, published at Leyden in Holland in the year 1646, pages 3 and 4.

"This, then, being the meaning of the expression, *a pure power* and *an affected power*, the meaning of the corresponding expressions of *a pure equation* and *an affected equation* follows from it of course: *a pure equation* signifying an equation in which a pure power of an unknown quantity is declared to be equal to some known quantity; such as the equation $x^5 = 79$; and *an affected equation* signifying an equation in which a power of an unknown quantity affected by, or connected, either by addition or subtraction, with, some inferiour powers of the same unknown quantity, (multiplied into proper co-efficients in order to make them *homogeneous* to the said highest power of the said unknown quantity,) is declared to be equal to some known quantity; such as the equation $x^5 + ax^4 - b^2x^3 = 79$. This I take to be the original meaning of the expression *an affected equation*. But, as the language of *Vieta* has not been adopted by subsequent writers of Algebra, I should think it would be more convenient to call them by some other name. And, perhaps those of *binomial*, *trinomial*, *quadrinomial*, *quinquinomial*, and, in general, that of *multinomial* equations, would be as convenient as any. Thus, $xx + ax = rr$, and $x^3 + ax^2 = r^3$, and $x^3 + a^2x = r^3$, and $x^4 + a^3x = r^4$, and $x^4 + ax^3 = r^4$, might all be called *binomial* equations, because they would be equations in which a *binomial* quantity, or quantity consisting of two terms that involved the unknown quantity x, is declared to be equal to a known quantity; and, for a like reason, the equations $x^3 + ax^2 + b^2x = r^3$, and $x^4 - ax^3 + b^2x^2 = r^4$, and $x^4 - ax^3 + b^3x = r^4$, and $x^5 + ax^4 + b^2x^3 = r^5$, and $x^5 + ax^4 - b^2x^3 = r^5$, and $x^5 + b^2x^3 + c^4x = r^5$, might be called *trinomial* equations. And the like names might be given to equations of a greater number of terms. Dr. Hutton, I observe, in his excellent new Mathematical and Philosophical Dictionary, just now published, (Feb. 2. 1795,) calls them *compound* equations; which is likewise a very proper name for them, and less obscure than that of *affected* equations."

Pa. 76, col. 1, l. 25, *for* $\sqrt{3+1} - \sqrt{3-1}$, *read* $\sqrt{3+1} - \sqrt{3-1}$.

Pa. 94, col. 2, l. 34, *for* Spaniard, *read* Portuguese.

Pa. 95, col. 2, after l. 21, or the end of the paragraph relating to Dr. Barrow, add as follows:—Of these lectures, the 13th deserves the most special notice, being entirely employed upon Equations, delivered in a very curious way. He there treats of the nature and number of their roots, and the limits of their magnitudes, from the description of lines accommodated to each, viz, treating the subject as a branch of the doctrine of maxima and minima, which, in the opinion of some persons, is the right way of considering them, and far preferable to the so much boasted invention of the generation of Equations from each other discovered by Harriot and Descartes.

Pa. 97, col. 2, after l. 3, *add*—Dr. Waring and the Rev. M. Vince, of Cambridge, have both given many improve-

improvements and discoveries in series and in other branches of analysis. Those of Mr. Vince are chiefly contained in the latter volumes of the Philosophical Transactions; where also are several of Dr. Waring's; but the bulk of this gentleman's improvements are contained in his separate publications, particularly the *Meditationes Algebraicæ*, published in 1770; the *Proprietates Algebraicarum Curvarum*, 1772; and the *Meditationes Analyticæ*, 1776; an account of the chief contents of which, a friend has favoured me with, as follows.

Of Dr. Waring's Meditationes Algebraicæ.

The first chapter treats of the transformation of algebraical equations into others, of which the roots have given algebraical relation to the roots of the given equations.

The general resolution of this problem requires the finding the aggregates of each of the values of algebraical functions of the roots of the given equation: for this purpose the author begins with finding the sum of the m^{th} power of each of the roots of the equation $x^n - px^{n-1} + qx^{n-2} - \&c = 0$ by a series proceeding according to the dimensions of p the sum of the roots: this series (when continued in infinitum and converges) finds also the sum of any root of the above-mentioned quantities. From this series is deduced the law of the reversion of the series $y = ax + bx^2 + cx^3 + \&c$, which finds x in terms of y; and also the law of a series, which expresses the greatest or least roots, and their powers or roots of a given algebraical equation, and which may be applied whether that root is possible or impossible, if the root be much greater or less than each of the remaining ones. All the powers and roots of this series, when continued in infinitum, observe the same law.

On this subject are further added some elegant theorems; of which, one finds the sum of all quantities of this kind $\alpha^a\beta^b\gamma^c$, &c; where α, β, γ, &c, denote the roots of the given equation. This has been since published by the celebrated mathematician Mr. le Grange in the Academy of Sciences at Paris.

There is also added a method of considerable utility in these matters; viz, the assuming equations whose roots are known, and thence deducing the coefficients of the equations sought: and also from the terms of an inferior equation deducing the terms of a superior.

The second chapter principally treats of the limits and number of impossible and affirmative and negative roots of algebraical equations.

Some new properties are added, of the limiting equations resulting from multiplying the successive terms of the given equation into an arithmetical series; and a method of finding limits between each of the roots of a given equation, since published in the Berlin Acts, and also some new methods of finding equations whose roots are limits between the roots of other equations. In theor. 4 and 5 are contained quantities which are always greater than certain others, when they are all possible; from whence may be deduced Newton's and several other rules for finding the number of impossible roots: these rules may be rendered somewhat more general by multiplying the given equations into others, whose roots are all possible, and finding whether impossible roots may be deduced by the rule in the resulting equation, which cannot from it be discovered in the given one. A rule is given, deduced from each successive four terms of the given equation, and consequently much more general than rules deduced from each successive three terms. The former always discovers the true number of impossible roots contained in quadratic and cubic equations, the latter in quadratic only. There is also a rule given for finding the number of impossible roots from an equation, of which the roots are the squares, &c, of the roots of a given equation; and a second from an equation of which the roots are the squares of the differences of the roots of a given equation; and a third rule for finding an equation, of which the root is $z = nx^{n-1} - \overline{n-1}\,px^{n-2} + \&c$; if $x^n - px^{n-1} + qx^{n-2} - \&c = 0$ be the given equation, &c, these latter resolutions always discover the true number of impossible roots contained in cubic, biquadratic and sursolid equations; and also whether or not any impossible roots are contained in any given equation; and also from the last term whether the number of impossible roots contained be 2, 6, 10, &c, or 0, 4, 8, &c. The principle of a 4th rule is given by finding when two roots once, twice, thrice, &c, or four, &c, roots become equal. From a method given of finding the number of impossible roots contained in an equation involving only one unknown quantity, is deduced a method of discovering limits between which are contained any number of impossible roots in an equation involving two or more unknown quantities. From the number of impossible, affirmative and negative roots contained in a given equation, is delivered a method of finding the number of impossible, &c roots contained in an equation of which the roots have a given algebraical relation to the roots of the given equation.

The principles are subjoined of finding the number of affirmative and negative roots contained in an algebraical equation: but this necessarily supposes a method of finding the number of its impossible roots known. It is demonstrated, that if the equation $x^n - px^{n-1} + qx^{n-2} - \&c = 0$ be multiplied by $x - a$, then every change of signs in the given, will have one, or three, or five, &c in the resulting equation; and if it be multiplied by $x + a$, then every continuation from + to + or − to −, will produce one, or three, or five, &c such continuations in the resulting, whence every equation $x^n - px^{n-1} + \&c = 0$ will contain at least so many changes of signs in its successive terms as there are affirmative roots, and so many continued progresses from + to + and − to −, as there are negative. In a biquadratic $x^4 + px^3 + qx^2 + rx + s = 0$, of which two roots are impossible, and s an affirmative quantity, then it is demonstrated that the two possible ones will be both negative or both affirmative, according as $p^3 - 4pq + 8r$ is an affirmative or negative quantity, if the signs of the coefficients, p, q, r, s are neither all affirmative, nor alternately − and +. The number of impossible and affirmative and negative roots contained in the equation $x^n + Ax^m + B = 0$ is likewise given, &c. If $lx^m - px^{m-1} + qx^{m-2} - \&c = 0$ and $bx^n - ax^{n-1} + bx^{n-2} - \&c = v$, and further $bx^n - ax^{n-1} + bx^{n-2} \&c = 0$ and $lx^m - px^{m-1} + \&c = w$, then the content of all the values

of

of the quantity w will be to the content of all the values of the quantity v :: $\pm f^n : b^m$, from whence are deduced ſome properties of parabolic curves. *Ex. gr.* Let the equation expreſſing the relation between the abſciſs x and ordinate y be $y = ax^n + lx^{n-1} + cx^{n-2} +$ &c. Then will the content under the $(n-1)$ greateſt ordinates be to the ſquare of the content of all the diſtances between any two points in which the abſciſs cuts the curve :: $a^{n-1} : n^n - 2$. The quotient of the content of all the ſines divided by the content of all the coſines to the points in which the abſciſs cuts the curve, will be to the content of all the abovementioned greateſt ordinates :: $n^n a : 1$. Similar propoſitions are deduced concerning the ordinates to the points of contrary flexure, &c.

The third chapter is verſant, concerning, 1ſt finding the roots of equations or irrational quantities, which have given relations to each other: this is performed by ſubſtitution or diviſion and finding the common diviſors of the quantities reſulting; and 2d concerning more (n) equations containing a leſs number (m) of ſuppoſed unknown quantities, which conſequently require $n-m$ equations, ſince named equations of condition; theſe are likewiſe deduced from the method of finding common diviſors. 3dly, Concerning the reſolution of equations; in this caſe is given, 1. The reduction or reſolution of ſome recurring equations. 2. Some properties of the roots of the equation $x^n \pm 1 = 0$. 3. Reſolution of a biquadratic $x^4 + px^3 + qx^2 + rx + s = 0$, by reducing it to an equation $z^4 + az^2 + b = 0$. 4. A reſolution of the biquadratic $x^4 + 2px^3 = qx^2 + rx + s$ by adding $(p^2 + 2n)x^2 + 2pnx + n^2$ to both ſides of the equation, ſo as to complete the ſquare; and the deducing that the values of n are $\frac{\alpha\beta + \gamma\delta}{2}$, $\frac{\alpha\gamma + \beta\delta}{2}$, $\frac{\alpha\delta + \beta\gamma}{2}$; the values of $\sqrt{(q + p^2 + 2n)}$ are $\frac{\alpha + \beta - \gamma - \delta}{2}$, $\frac{\alpha + \gamma - \beta - \delta}{2}$, &c, and the values of $\sqrt{(s + n^2)}$ are $\frac{\alpha\beta - \gamma\delta}{2}$, $\frac{\alpha\gamma - \beta\delta}{2}$, &c; if α, β, γ, δ, are the roots of the given equation. 5. A reſolution of equations as general as any yet diſcovered, viz, the aſſuming $x = a\sqrt[n]{p} + b\sqrt[n]{p^2} + c\sqrt[n]{p^3} +$ &c; and exterminating the irrational quantities, viz, from aſſuming $x = a\sqrt[3]{p} + b\sqrt[3]{p^2}$ are deduced different reſolutions of cubic; from $x = a\sqrt[4]{p} + b\sqrt[4]{p^2} + c\sqrt[4]{p^3}$ different reſolutions of biquadric; from the equations $x = a\sqrt[n]{p} + b\sqrt[n]{p^2}$, $x = a\sqrt[m]{p} + b\sqrt[m]{p^{n-1}}$; $x = a\sqrt[n]{p} + b\sqrt[n]{p^3}$, $x = a\sqrt[3]{p} + \sqrt[n]{p^{n-2}}$, &c, are deduced De Moivre's equation, and ſeveral others of new formula not before delivered. 6. The reſolution $x = \sqrt[n]{\alpha} + \sqrt[n]{\beta} + \sqrt[n]{\gamma} +$ &c, firſt given by Euler, ſhewn to be a very particular; but this is rendered here much more general by aſſuming a more general reſolution. 7. The reſolution and reduction of equations from exterminating irrational quantities. 8. Reduction of ſome equations, when they are deduced from others by reducing them to the original equations. 9. The finding a quantity, which multiplied into a given irrational will produce a rational quantity, and thence deducing from a given equation involving irrational quantities the dimenſions to which the equation freed from them will aſcend. 10. Let P = a ſeries either aſcending or deſcending according to the dimenſions of x, from thence is deduced the ſum of a ſeries conſiſting of its alternate terms, or terms at (n) diſtance from each other. 11. It is proved, that Cardan's reſolution of a cubic, is a reſolution of an equation of 9 dimenſions or three different cubics: ſimilar principles are applied to ſome other equations. 12. General principles are given for the deducing the function of the roots of the given, which conſtitute the coefficients or roots of the transformed equation. E. g. Let a cubic equation $x^3 + qx - r = 0$ and $z - \frac{q}{3z} = x$, thence is ſhewn the function of the roots of x, which conſtitute z, and further the caſes of the cubic, which are reſolvable by the transformed equation, whoſe root is z: the ſame principles are applied to biquadratics. 13. The correſpondent impoſſible roots of a given irrational quantity are deduced; and alſo the different roots of a given reſolution. 14. The biquadratic of the formula $x^2 - 2(a + b\sqrt{-1})x - c - d\sqrt{-1} = 0$ is diſtinguiſhed into two quadratic equations involving only poſſible quantities, and thence every algebraic equation is proved to conſiſt of ſimple and quadratic diviſors involving only poſſible quantities. 15. A method is delivered of transforming irrational quantities into others; but it is cautioned, that in reduction and transformation correſpondent roots ſhould be uſed, otherwiſe it is probable that we ſhall fall into errors, of which examples are given. 16. The convergency of a root found by the common method of approximations is given; and it is diſcovered that the convergency principally depends on the quantity aſſumed for the root being much more near to one root than to any other; and independent of it, not on how near it is to a root.

The fourth chapter is principally converſant concerning more algebraical equations and their reductions to one. 1. It gives the law of the reſolution of any number of ſimple equations; and the reduction of n ſimple equations to $n - 1$ by means of others. 2. The method of reducing more (n) equations into one ſo as to exterminate $n - 1$ unknown quantities by the method of common diviſors, and further delivers the principles of inveſtigating the roots or values of the unknown quantities, which reſult from this, or, which is much the ſame, from the common method of Eraſmus Bartholinus, and which are not contained in the given equations. 3. If two algebraical equations of n and m dimenſions of the unknown quantities x and y are reduced to one ſo as to exterminate one of the unknown quantities, the principles are given of finding the dimenſions to which the other will aſcend: if it aſcends to $n \times m$ dimenſions; then the ſum of the roots depends on the terms of n and $n - 1$ dimenſions in the one, and m and $m - 1$ in the other, and ſimilarly of the products of every two; &c. From this principle are deduced ſeveral properties of algebraical curves. The

The same principles are applied to more equations involving more unknown quantities. 4. Some two equations of given formulæ are reduced to one so as to exterminate one unknown quantity. 5. Two equations are likewise reduced to one so as to exterminate unknown quantities by means of infinite series. 6. A method of finding whether some equations contain the same roots of the unknown quantities as others. 7. From the correspondent roots of the unknown quantities in given equations are found the constitution of their coefficients; and from thence the aggregates of the functions of the roots of two or more equations. 8. Some things are given concerning the transformations of more equations than one, of their impossible roots, of their roots which have a given relation to each other. 9. Some reductions and resolutions of more equations involving more unknown quantities. 10. If two equations similarly involve two unknown quantities x and y; then the equation of which the root is x or y is demonstrated to have twice the dimensions of the equation whose root is any rational function of $x + y$ or $x^2 + y^2$ or any rational recurring function of x and y; and if for y be substituted $-y$; then in the equation whose root is the resulting quantity the dimensions will be the same as in the equations whose root is x or y, but its formula will be of half the number of dimensions. The same principles are applied to more equations similarly involving more unknown quantities. 11. If there are two equations involving two unknown quantities, one deduced from the other, by some substitutions investigated from equations similarly involving two unknown quantities; then the equation whose root is one of the unknown quantities will be recurring. 12. Let A and B be functions of x and y, a method is given of finding, whether A is a function of B. 13. Methods of approximations to the roots of equations when they are unequal, or two or more nearly equal, possible or impossible; and also some remarks on the increments or decrements of the roots, in passing from one equation to others of the same number of dimensions are given.

The fifth chapter treats of rational and integral values of the unknown quantities of given equations.

1. It finds the rational and integral simple, quadratic, &c divisors (by a method different to Waesfaner's) of a given equation, which involves one or more unknown quantities. 2. If two equations involve two unknown quantities x and y; the same irrationality, which is contained in x will likewise be contained in its correspondent value of y, unless two or more values of the quantity (x or y) are equal, &c. 3. A method is given of finding integral correspondent values of the unknown quantities of two or more equations involving as many unknown quantities. 4. A method is also delivered of deducing when a given equation can be resolved by means of square, cube, &c roots; and when by similar methods it can be reduced to equations of $\frac{1}{2}$, $\frac{1}{3}$, &c, its dimensions. 5. A method is given of finding a quantity or number, in which are contained all the divisors of any given rational or integral quantities. 6. A method different from Schooten's, Newton's, and Euler's, of extracting the root of a binomial surd $a + \sqrt{b}$ is given, and the principle demonstrated on which all the rules are founded given by Schooten, viz, the multiplying the binomial surd so that the n^{th} root of $A^2 - B$ can be extracted, where $A + \sqrt{B}$ is the resulting surd; and it is further proved that multiplying the given surd $a + \sqrt{b}$ into 2^n will render Newton's resolution as general as the others; and lastly the extraction of the (m^{th}) root of the quantity $A + B\sqrt[n]{p} + C\sqrt[n]{p^2} + \dots + \sqrt[n]{p^{n-1}}$ is given. 7. The law of Dr. Wallis's approximations in terms of the successive quotients, as also of continual fractions is deduced. 8. A method of deducing the integral values of each of the unknown quantities x, y, z, v, &c, contained in the equation $ax + by + cz + dv \pm$ &c $+ f = 0$ in terms of quantities, for which may be assumed any whole numbers. 9. Two or more equations are reduced to one, so as to exterminate unknown quantities; and if the unknown quantities of the resulting equations be integral or fractional, then the unknown quantities of the given equations will also be integral or fractional. 10. Principles are delivered of deducing equations of which the unknown quantities admit of correspondent and known integral or rational values. 11. Correspondent integral or rational values of the unknown quantities in several equations are given, and from some values of the abovementioned kind given, are deduced others. 12. A method of denoting any numbers either by fours, fives, sixes, &c, and their powers; and similar properties deduced as in decimal arithmetic. 13. It is demonstrated that the sum of the divisors of the number $1.2.3 \dots x = N$ has to N a greater ratio than the sum of the divisors of any number L less than N has to L; and some other similar properties. 14. In the Philosophical Transactions are given properties similar to Mr. Euler's of the sum of divisors of the natural numbers, and some others. 15. Let $N = a^2 + rb^2$, where a, b, r, p and q are whole numbers, then N^{2m+1} and N^{2m+2} can be compounded by $(m + 1)$ different ways of the quantities $p^2 + rq^2$; the different ways were first given in the Medit. 16. Every number consists of 1, 2, 3 or 4 squares, and of 1, 2, 3, 4, ..9 cubes, and therefore if a number N is equal to 3 squares or 8 cubes, the problem may not be possible. 17. Let x and z be any whole numbers, and a and b numbers prime to each other, then $ax + bz$ can constitute any number, which exceeds $a \times b - a - b$. 18. Let r the greatest common divisor of m and $n - 1$, where n is a prime number; the number of remainders from the division of the number $1^m, 2^m, 3^m,$ &c, in infinitum by n will be $\frac{n-1}{r} + 1$: from which are deduced several propositions. 19. Sir John Wilson's property delivered and demonstrated, viz, $1.2.3 \dots n - 1 + 1$ will be divisible by n, if n be a prime number. 20. The sum of the powers $1^r + 2^r + 3^r + \dots x^r$ are found divisible by x. $x + 1$, if r be a whole number; from whence is deduced an elegant property of all parabolas correspondent to the property of Archimedes of the inscribed triangles in a conical parabola. 21. Some properties of exponential equations; several other new properties of algebraical quantities and equations are given in these Meditations. They were sent to the Royal Society in 1757, and since published in the years 1760, 62, and 69.

Properties

Properties of Algebraical Curves.

The equation expreſſing the relation between the abſciſs and its correſpondent ordinates of a curve is transformed into another which expreſſes the relation between different abſciſſæ and their ordinates, from which is deduced, that there may be n and not more different diameters in a curve of $n-1$ order, which cuts its ordinates in a given angle; and likewiſe that a diameter can have no more than $n-1$ different inclinations of its ordinates, unleſs the diameter be a general one. 2. The formula of the equations to curves, all whoſe diameters are parallel, or cut each other in a given point, or which have a general diameter to which the lines any how inclined are ordinates. 3. It is proved that there cannot be more than $\frac{n}{m}$ different inclinations of parallel ordinates, which cut the curve in $n-m$ points only, poſſible or impoſſible. 4. Something is added concerning diameters, which cut their ordinates on both ſides into equal parts. 5. It is demonſtrated that there are curves of any number of odd orders, that cut a right line in 2, 4, 6, &c, points only; and of any number of even orders that cut a right line in 3, 5, 7, &c points; and conſequently that the order of the curve cannot be denounced from the number of points, in which it cuts a right line. 6. The principles are delivered of finding the aſymptotes, parabolical legs, ovals, points, &c, of a curve, of which the equation marking the relation between the abſciſs and its ordinates is given; and alſo given the number of aſymptotes, parabolical legs of different kinds, ovals, points of different kinds, the leaſt order of a curve, which receives them, is deduced. 7. An equation expreſſing the relation between an abſciſs and its ordinates, is transformed into an equation expreſſing the relation between the diſtances from two or more points, the latter may be varied an infinite number of ways; and thence are deduced ſome properties. Many reſolutions of this kind are only reſolutions of a particular caſe contained in it; and conſequently can never be deduced from any general reaſoning; they are often deduced from ſome particular caſes, which are known to anſwer ſeveral conditions of the problem. Transformations of a given curve into others by ſubſtitutions, and properties of the loci of ſome points are deduced, from which Mr. Cotes's property of algebraical curves, and others of a ſimilar and ſomewhat different nature are derived. 8. Let a curve of n dimenſions have n aſymptotes, then the content of the n abſciſſæ will be to the content of the n ordinates, in the ſame ratio in the curve and aſymptotes, the ſum of their (n) ſubnormals to ordinates perpendicular to their abſciſſæ will be equal to the curve and the aſymptotes; and they will have the ſame central and diametrial curves. 9. Some propoſitions are added concerning the conſtruction of equations, and ſome equations are conſtructed from the principles of Sluſius.—If two curves of n and m dimenſions have a common aſymptote; or the terms of the equations to the curves of the greateſt dimenſions have a common diviſor, then the curves cannot interſect each other in $n \times m$ points, poſſible or impoſſible. If the two curves have a common general centre, and interſect each other in $n \times m$ points, then the ſum of the affirmative abſciſſæ &c to thoſe points will be equal to the ſum of the negative; and the ſum of the n ſubnormals to a curve which has a general centre will be proportional to the diſtance from that centre. 10. Something is added on the deſcription of curves. 11. No curve which has an hyperbolical leg of the conical kind can in general be ſquared. 12. It is demonſtrated that no oval figure, which does not interſect itſelf in a given point, can in general be expreſſed in finite algebraical terms. 13. Given an algebraical equation, and ſimilarly equations expreſſing a relation between x and y, &c; and alſo a fluxional quantity which is an algebraical function (z) of x and y and their fluxions; a method is given of deducing an equation whoſe root is z; and thence ſome properties of curves. 14. Properties ſimilar to the ſubſequent of conic ſections, are extended to curves of ſuperior orders, viz, if lines be drawn from given points in them in given angles to four lines inſcribed in the conic ſection, then will the rectangle under two of thoſe lines be to the rectangle under the other two in a given ratio. Several properties are added, which follow from the application of algebraical propoſitions invented in the Medit. Algebr. to curve lines.

The ſecond chapter treats of curvoids and epicurvoids, or curves generated by the rotation of given curves on right lines or curves, and gives a method of rectifying and ſquaring them; and from the radii of curvature of the generating curves being given, it deduces the length and radius of curvature of the curve generated at the correſpondent point; it alſo aſſerts that from them may be deduced the conſtruction of the fluxional equations of the different orders.

The third chapter treats of algebraical ſolids. 1. It deduces the equation to every ſection of a ſolid generated by the rotation of a curve round its axis; and from thence the different ſections generated by the rotation of conic ſections round their axis. 2. The equation to ſolids contains the relation between the two abſciſſæ and their ordinates, and the order of the ſolid may be diſtinguiſhed according to the dimenſions of the equation; or the ſolid may be defined by two equations expreſſing the relation between the three abovementioned quantities, and a fourth which may be the axis of the ſection: there is further given a method of deducing the equation to any ſection of theſe ſolids, and from it the equation to the curve projected on a plane by a given curve. 3. A method of deducing the projection of a curve or ſolid on each other. 4. If the equation be $x - a = 0$, (x being the diſtance from a given point) then it may denote the periphery of a circle if one plane, or the ſurface of a globe if it reſers to a ſolid. 5. Let x and y denote the diſtances from two reſpective points, then an equation expreſſing the relation between x and y deſigns the periphery of a curve, if contained in the ſame plane, or the ſurface of a ſolid generated by the rotation of a curve round its axis, paſſing through the two given points, if a ſolid. 6. An equation expreſſing the relation between lines drawn from three or more points may denote an equation to a ſolid. 7. If x, z and y denote the two abſciſſes and correſpondent ordinates to a ſolid, and the terms of x and y, or x and z, or y and z; or x, z and y be ſimilarly involved; then may the ſolid be divided into two or

or fix similar and equal parts; and if no unequal power of x or y or z; or x and y, &c; or x, y and z be contained in the equation, then the curve may further be divided in general into twice, four or fix times the preceding number of equal parts. 7. Curves of double curvature are defigned by two equations expreffing the relation between two abfciffæ and correfpondent ordinates, or between lines drawn from three or more points; fimilar properties may be deduced from thefe as from the equations to curves.

Chapter the 4th treats of the maxims and minims of polygons inferibed and circumfcribed about curves, and thence deduces certain quantities equal to each other, when maxims and minims are contained at every point of the curve: it further contains feveral properties of conic fections. 1. If any rectilinear figure circumfcribes an ellipfe, the content under the alternate fegments of the line made by the points in which the line touches the ellipfe will be equal. 2. If a right line cuts a conic fection, and the parts of the line without the conic fection on both fides are equal; and any rectilinear figure, which begins and ends at the bounds of the abovementioned line, be defcribed round the conic fection, then the contents under the alternate fegments of the circumfcribing lines as divided in the points of contact will be equal. 3. If two polygons be circumfcribed about an ellipfe, and the fides are cut by the points of contacts in the fame ratios in the one as in the other; then will the areas of the two polygons be equal. 4. If two lines cut a conic fection proportionally, i. e. they are divided by the conic fection in the fame ratio in the one as in the other, and if polygons be defcribed round the conic fection, terminated at the ends of thofe lines, of which the fides are divided by the points of contact in the fame ratio in the one as in the other, then will the area of the two polygons be equal, as likewife the curvilinear area. 5. If all the fides of two polygons inferibed in an ellipfe make the two angles at the fame point equal, and two polygons of this kind be inferibed in the curve, then will the fum of the fides of the one polygon be equal to the fum of the fides of the other. Several other fimilar properties are added, as alfo properties of folids generated by the rotation of a conic fection round its axis; to which I fhall mention the three or four following. 1. The diagonals of a parallelogram circumfcribing an ellipfe or hyperbola will be conjugate diameters. 2. The fections of a folid generated by the rotation of a conic fection round its axis, which pafs through its focus, will have that point for the focus of all the fections. 3. If 4 perpendiculars be drawn from any point in an hyperbola to its periphery; and two lines from the fame point to the afymptotes and the ordinates from the 4 points of the curve and the 2 of the afymptotes be drawn to the abfcifs; then will the fum of the refulting abfciffæ to the former be double to the fum of the abfciffæ to the latter. 4. If an arc of the periphery of a circle be divided into n equal parts, a, $2a$, $3a$, &c, and p = chord of the arc $180 - na$, and α and β be the roots of the quadratic $x^2 - pv + 1 = 0$ and radius 1: then will $\alpha^n + \beta^n$ = chord of the arc $180 - na$, from whence may be deduced the divifors of the quantity $x^{2n} - Ax^n + 1$; and alfo the equation whofe roots are the diftances of a point in the circle from thofe points of equal divifion, and further may be deduced the fum of all the values of any algebraical function of thofe lines.

Moft of the properties of circles given by Archimedes are extended to conic fections, and fome of the algebraical and geometrical properties of Pappus are rendered more general; and the principles invented applied to many other cafes. In the firft edition of this book publifhed in 1762 were nearly enumerated the lines of the fourth order on the fame principles as Newton's enumeration of lines of the third order; but this has fince been rejected by the author as not fufficiently diftinguifhing the curve, and as being of no great utility.

Meditationes Analyticæ.

The firft *chapter* treats of finding the fluxion of a fluent, when the quantity or fluent is confidered as generated by motion; or the parts from the whole when the whole or quantity is confidered as confifting of innumerable parts. It further gives the law of a feries, which expreffes the fluxion of an exponential of any order.

Chapter 2, is verfant about the fluents of fluxions. 1. It finds the general fluent of a fluxion $P\dot{x}$, when P is any algebraical function of x however irrational but not exponential; for which intent it inveftigates the common divifors of any two quantities contained under the different vincula; and thence the common divifors of the refulting divifors, and fo on; and likewife all the equal divifors contained in any of the abovementioned quantities; whence it fo reduces the quantity P, that no equal nor common divifors may be contained in any of the refulting quantities under the different vincula; and from the common method deduces the terms of a feries to the number, which the feries is fhewn to conft of, when it does not proceed in infinitum. 2. It demonftrates, that if the dimenfions of x in the denominator of P exceed its dimenfions in the numerator by 1, then the fluent cannot be expreffed in finite terms; and alfo if one factor of P be $(A \pm (A^2 + a)^{\frac{\mu}{2}})^{\lambda}$, where a is an invariable quantity, and in fome other cafes the fubftitution required muft be fomewhat different. 3. The fluents of fome fluential and exponential fluxions, or fluxions involving fluents and exponential quantities, are given. 4. A general method of difcovering whether the fluent of any fluxion of any order involving one, two or more variable quantities, and their fluxions, can be expreffed in terms of the variable quantities and their fluxions. 5. The correction of fluents of all orders, and thence the fluent contained between any values of the variable quantities and their fluxions, is given; in thefe corrections the fame roots of the irrational quantities are to be ufed in the correction as in the fluent. 6. From the transformation of equations and the principles before delivered, are deduced fluents equal to each other. 7. Some exponential quantities given which continually change from poffibility to impoffibility, and from impoffibility to poffibility. 8. Is a method of finding whether the fluent of any fluxion contained between any limits are finite or not. 9. The fum of the fluents of a fluxion which is an algebraical function of the letter x multiplied into $\dot{x}$ can always be expreffed by finite terms, circular arcs and logarithms, the extraction of the roots of equations being granted.

10. Some fluxions involving irrational quantities are reduced to others, in which no irrationality is contained. 11. The general principles of deducing whether the fluent of a given fluxion can generally be expreſſed by finite algebraical terms, their circular arcs and logarithms. 12. Some equal correſpondent fluents are found by ſubſtitutions deduced from equations in which two variable quantities are ſimilarly involved. 13. Some neceſſary corrections are given of finding the fluents of all the fluxions of the formula

$$x^{pn \pm \sigma n - 1} \dot{x} \times R^{m \pm \lambda} \times S^{o \pm \mu} \times T^{i \times \nu} \times \&c,$$

(where σ, λ, μ, ν, &c denote any whole numbers,

$$\text{and } R = e + fx^{n} + gx^{2n} + \ldots x^{\alpha n},$$

$$S = b + kx^{n} + lx^{2n} + \ldots x^{\beta n},$$

$$T = q + rx^{n} + sx^{2n} + \ldots x^{\gamma n}, \&c)$$

from $\alpha + \beta + \gamma +$ &c, independent fluents; but perhaps not from $\alpha + \beta + \gamma +$ &c fluents, which have different values of the quantities, σ, λ, μ, ν, &c. 14. The number of independent fluents of the formulæ $x^{\beta + \alpha n + \beta m} \times (a + bx^{n} + cx^{m})^{\lambda + \pi} \times \dot{x}$, where α, β and π denote whole affirmative numbers, &c; and the number of independent fluents of the formulæ $\dot{X} \int Y \dot{x}$, where $\dot{X}$ is a fluxion of which the fluent can be found, from which can be deduced all of the ſame formula, is immediately known from the number of independent fluents of the formula $Y\dot{x}$ and $XY\dot{x}$ which determine all of thoſe formulæ. 15. Let $a + bx^{n} + cx^{2n} + \ldots kx^{\mu n} = p$, and from ſome fluents of the fluxions of the formulæ $p \times x^{\mu n - 1} \dot{x}$, where μ is a whole affirmative number, are determined the remaining ones of the ſame formula. 16. Something is added concerning finding the value of a fraction, when both the numerator and denominator vaniſh; and laſtly from the fluents of ſome fluxions being given, the method of deducing the fluents of others.

Chapter 3, principally treats of algebraical and fluxional equations. 1. It gives the method of tranſforming two or more fluxional equations into one ſo as to exterminate one or more variable quantities and their fluxions, and finds the order of the reſulting equation. 2. It reduces ſome fluxional equations into more. 3. A method of reducing fluxional equations involving fluents ſo as to exterminate the fluents. 3. Some caſes are given, in which the two variable quantities contained in a given equation are expreſſed in terms of a third. 4. Given an algebraical equation expreſſing the relation between x and y; a method is given of finding the fluent of $y\dot{x}^{n}$ or other fluxions in finite terms of x and y, if they can be expreſſed by ſuch; or elſe by infinite ſeries; this was firſt taught in the Philoſophical Tranſactions in the year 1764. 5. Something is added concerning the correction of fluxional equations. 6. A method of inveſtigating, whether a given equation is the general fluent of a given fluxional equation. 7. The method of deducing, whether a given equation is a particular or general fluent of a given fluxional equation. In both by ſubſtituting for the fluxions their values deduced from the fluential equation their values &c in the fluxional, the fluxional muſt reſult $= 0$; and in the general fluent there muſt be contained ſo many invariable quantities to be aſſumed at will independently as is the order of the fluent; and in both all the variable quantities muſt neceſſarily be variable, and no function of them vaniſh out of the fluxional equation from the ſubſtitution; for then all the conditions of the fluxional equation are anſwered by the fluential. 8. An inveſtigation, when fluxional equations are integrable. 9. From ſome fluents are deduced others, *e. g.* if the area between any two ordinates to one abſciſſa can be general be found, then the area between any two ordinates of any other abſciſſa can be found &c. 10. From given fluxional equations and the fluents of ſome fluxions are deduced the fluents of many others. 11. The fluent of the firſt order of a fluxional equation of the nth order will have (n) different values and n different multipliers; and the fluent of the ſecond order $n \cdot \frac{n-1}{2}$ different values, &c. 12. Let $\alpha = 0$, $\beta = 0$, $\gamma = 0$, &c, (n) general fluents of the fluxional equation, $\lambda = 0$, then will any function of the fluents α, β, γ, &c be a fluent of the ſame fluxional equation $\lambda = 0$. 13. From aſſuming equations, which contain only ſimple powers of the invariable quantities to be aſſumed at will, may eaſily be deduced fluxional equations, of which the general reſolutions are known: 2. From aſſuming the values of any variable quantities and ſubſtituting then their fluxions for the variable quantities, &c. in any functions π, ϱ, &c of the variables aſſumed, let the quantities reſulting be A, B, &c; then generally will $\pi = A$, $\varrho = B$, &c. be fluxional equations, of which the particular fluentials are known. It may be obſerved in this place as before, that from no general reaſoning can particular fluents be deduced. 14. In the reſolution of fluxional equations it is obſerved, that from the logarithmic and exponential quantities contained in the fluxional, may be deduced by chapter 1 the exponentials &c contained in the fluential: 2, and in a ſimilar manner from the irrational quantities and denominators contained in it, the correſpondent irrational quantities and denominators contained in the fluential: 3, the greateſt dimenſions of y multiplied into $\dot{x}$ muſt be greater than thoſe of y into $\dot{y}$ by unity; when there are two of this kind &c, $\alpha y\dot{x} + \beta x\dot{y} = x^{m}y^{n}(\delta\dot{x} + \varepsilon\dot{y})$ the reſolution is given; and ſo of more. 15. In the given equation, if the fluxion of the greateſt order does not aſcend to one dimenſion only; then by extraction &c to reduce the equation, that it may aſcend to one dimenſion only; and thence find the fluent of any fluxion $P^{n}\dot{y} + Q^{n-1}\dot{y} +$ &c, $+ R'^{n}\dot{z} +$ &c. 16. Let a fluxional equation be given involving x and y, in which x flows uniformly, a method is given of finding whether it admits of a multiplier, which is a function of x only, and ſimilarly of multipliers of other formulæ. 17. The method of deducing the multipliers of fluxional equations by infinite ſeries. 18. Some fluxional equations are reduced by ſubſtitutions, which ſubſtitutions are commonly eaſily deducible from the fluxional equation given. 19. Somewhat concerning the reduction of ſome fluxional equations to homogeneous, and concerning homogeneous equations of different orders, and of reducing an homogeneous fluxional equation of n order to a fluxional equation of $n - 1$ order: and alſo

alſo of reducing m fluxional equations of n order to one of $mn-1$ orders, and ſo of all others to one degree leſs than the order generally occurring if they had not been homogeneous. 20. The ſubſtitution of an exponential for a variable quantity in equations which contain no exponential quantity; for ſometimes n has been ſubſtituted for a quantity which flows uniformly, and then w ſuppoſed to flow uniformly, which leads to a falſe reſolution. 21. A caution is given not to ſubſtitute homogeneous functions of no dimenſions for variable quantities; and in the general reſolution to obſerve, that there is contained an invariable quantity to be aſſumed at will, which is not contained in the fluxional equation. 22. Something more added concerning the fluents of $p^n\dot{y} + q^{n-1}\dot{x}\dot{y} + r^{n-3}\dot{y}\dot{x}^2 +$ &c, $= 0$, where p, q, r, &c. are functions of x, and ſo of ſome other fluxional equations. 23. Fluxional equations are deduced, of which the variable quantities cannot be expreſſed in terms of each other, but both may be expreſſed in terms of a third. 24. Every fluxion or fluent which is a function x, y, z, and $\dot{x}$, $\dot{y}$ &c. is expreſſed in terms of partial differences. 25. The reſolution of ſome equations expreſſing the relation between partial differences &c is given. 26. Some obſervations on finding the fluents of fluxions, when the variable quantities become infinite.

The ſecond book treats of increments and their integrals. 1. Some new laws of the increments are given. 2. The fluxion of the increment of P will be equal to the increment of the fluxion; where P is any function of x, if only the fluxion of the increment of x be equal to the increment of the fluxion. 3. Increments are reduced to others of given formulæ *e. g.* $\alpha + \frac{\beta}{x} + \frac{\gamma}{x(x+\dot{x})} +$, &c, and it is obſerved that if β be not $= 0$, then the integral cannot be found in finite terms of the variable quantity, &c. It may be obſerved, that Taylor, Monmort, &c, firſt found the integral of the two increments

$$\frac{1}{x.x-\dot{x}.x-2\dot{x}\ldots x-n-1\dot{x}} \text{ and } \frac{1}{x.x-\dot{x}\ldots x-n-1\dot{x}}$$

but did not proceed much further (correſpondent to the finding the fluxion of the fluent x^n); the increments of fluents have been ſince deduced, &c. In this book are diſcovered propoſitions correſpondent to moſt of the inventions in fluxions, *e. g.* a method of finding the integral of any increment expreſſed in algebraical or exponential terms of the variable quantity or quantities, and when the fluent cannot be expreſſed: it is obſerved that they cannot be expreſſed in finite terms of the variable x, &c, if the dimenſions of x, &c, in the denominator exceed its dimenſions in the numerator by 1; or if any factor in the denominator of the fraction reduced to its lower terms have not another contained likewiſe in the denominator, diſtant by a whole number, multiplied into the increment of x. —The increments of ſome integrals are deduced from the integrals of other increments; the integrals of ſome incremental equations from different methods; their general integrals, and particular corrections, &c, &c; but here it is to be obſerved, that the general problem of increments cannot be extended beyond the particular of fluxions, but ſomewhat more may be added, when both are joined together. The third book is verſant concerning infinite ſeries. 1. It gives the ratio of the apparent and real convergency. 2. A method of finding limits between which the ſum of the ſeries conſiſts; and alſo whether the ſum of the ſeries is finite or not from the terms being given or equation between the terms. 3. The convergency of the whole ſeries is judged from the ratio of convergency of the terms at an infinite diſtance. 4. The ſeries from the fluent converges, if the ſeries from the fluxion does, there are ſeveral propoſitions on infinite ſeries deducible from the common algebra. 5. Let an equation $0 = a - bx + cx^2 - dx^3 +$ &c; and $\frac{b}{a}$ much greater than $\frac{c}{b}$, $\frac{c}{b}$ than $\frac{d}{c}$; &c. then will all the roots be poſſible, and $\frac{a}{b}$ an approximation to the leaſt root, $\frac{b}{c}$ to the next, &c: if an equation $y^n + ay^{n-1} + \ldots + fy^{n-m} + gy^{n-m-1} + \ldots = 0$, and if one root be much leſs than any m root, but much greater than the remaining; or if the equation be $x^n - px^{n-1} + qx^{n-2} \ldots \pm gx^{n-m+1} \mp hx^{n-m} \pm ix^{n-m-1} \mp kx^{n-m-2} \pm$ &c. $= 0$, then will the approximation to the above root be $\frac{i}{h} - (\frac{k}{i} - \frac{gi^2}{h^3}) +$ &c. 6. Somewhat on the approximations when the approximation given is much more near to one, two, or more roots than to any other, and on the degree of convergency of the ſubſequent approximations deduced; and their ultimate approximations. 7. Given approximations to m roots of a given equation are deduced more near approximations to them. 8. The incremental equation given and applied to approximations. 9. From given approximations to two or more unknown quantities contained in two or more equations are deduced more near approximations to them, either when the approximations given are more near to one, or to two, or more roots of one or more of the unknown quantities than to any others, and ſo of infinite equations. 10. New ſeries are given for the fluents of different fluxions. 1. Log. $\overline{x \pm e} = \log. x \pm \frac{e}{x} - \frac{e^2}{2x^2} \pm$ &c.; the number whoſe log. is $v \pm e$ (if N be log. of v) $= N \pm Ne \pm \frac{Ne^2}{2} \pm$ &c; the log. of $\frac{a+x+e}{a-x-e} = \log. \frac{a+x}{a-x} + \frac{e}{a^2-x^2} -$ &c. The ſine of the arc $A \pm e$ is $S \pm Ce - \frac{1}{2}Se^2$, &c, and coſine of the ſame arc $= C \pm Se - \frac{1}{2.3}Ce^2 \pm$ &c. S and C being the ſine and coſine of A, the fluent of the fluxion of an elliptical arc $\frac{\sqrt{(1-cx^2)}\dot{x}}{\sqrt{(1-x^3)}}$ which differs little from the arc of a circle when e is a very ſmall quantity $= A - \frac{c}{2} \times \frac{1.A-xP}{2} -$ &c, where $A = \int \frac{\dot{x}}{P}$, $B = \frac{1A - xP}{2}$, $C =$

$C = \frac{3B - x^2P}{3}$, &c. and $P = \sqrt{1-x^2}$, and A = arc of a circle of which the fine is x.

A fimilar feries may be applied from the arc of an hyperbola or ellipfe, to find a correfpondent arc of an hyperbola or ellipfe not much different from the preceding. In this method the feries proceeds according to the dimenfions of fome fmall quantities, and the firft term of the feries is generally a near value of the quantity fought. Thefe feries properly inftituted will generally converge the fwifteft. 11. Something new is added concerning the fluent of the fluxional equation $\dot{y} = y\dot{z}^2$ viz $-y = E \times \text{fin. arc: } (z) + F + \text{cof. (ar. } (z)$; E and F being any quantities to be aflumed at will; and of correfpondent equations to logarithms, and finding their values when z is increafed by e. 12. A feries for the increafe of the arc from a fmall increafe of the tangent, fine, &c. 12. When the terms a and x of the binomial $a \pm x$ are equal, the cafes are given in which the feries $a^m \pm ma^{m-1}x + \&c, =$ $a \pm x^m$ or the feries $a^m x \pm \frac{m}{2}a^{m-1}x + \&c$, &c. will ultimately converge. 13. If any algebraical quantity V a function of x be reduced into a feries proceeding according to the dimenfions of x, a general method of finding what are the limits between which it converges; or the feries from $\int Vx$, &c; and the method of interpolations fo as to render them converging. 14. The convergency of different feries are compared together. *e. g.* is given $\int \frac{\dot{x}}{1+x} = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 -$, &c. $= \frac{x}{1+x} + \frac{x^2}{2(1+x)^2} + \frac{x^3}{3(1+x)^3} +$ &c. or $\int \frac{\dot{x}}{1 \pm x} = \frac{x}{1 \pm x} \pm \frac{x^2}{2(1+x)^2} +$ &c. there is an erratum contained in this example, for $a -$ is fometimes printed inftead of $a +$: this feries is eafily deduced from Bernouilli's method of deducing infinite feries, and has been fince printed in the Philofophical Tranfactions. 15. Given algebraical or fluxional equations, and a fluxional quantity, a method is given of finding a feries, which expreffes the fluent of the fluxional quantity, from which principles are deduced new feries for the area of a fegment of a circle, the periphery of the ellipfe, hyperbola, &c. 16. It is fhewn, that feriefes proceeding according to the dimenfions of a quantity x always diverge, when feriefes for the fame purpofe proceeding according to the reciprocal of its dimenfions converge; unlefs fometimes in the cafe when they both become the fame. 17. As feries proceeding in infinitum according to the dimenfions of the quantity x were firft invented or ufed for the finding the fluents of fluxions, it being reduced into terms, whofe fluents were known: fo in finding integrals of increments it may be neceffary to reduce the quantity into an infinite feries of terms, whofe integrals are known, and which converges. Examples of formulæ of feriefes of this kind are given. 18. Methods are given of finding the value of one unknown quantity contained in one or more equations involving more unknown quantities, and the law of their convergencies and the interpolations neceffary to render feriefes for finding fluents converging, fimilar principles may be applied to incremental and fluxional equations. 19. It is obferved, that in finding the value of any variable quantity in a feries proceeding according to the dimenfions of another, there will occur in a fluxional or incremental equation of (n) order in the feries n invariable quantities to be aflumed at will; and alfo the fluxional equations, &c. from whence they will arife. 20. The finding the integral of $\frac{z}{\dot{z}}$, &c. 21. From the correfpondent relation between the fums of two feries refulting, which are functions of a variable quantity y, when the relation between x and z two values of y are given, is given a method of finding the coefficients of the feries. 22. The rule generally called the reductio ad abfurdum extended to more fubftitutions.

The fourth book treats of the fummation of feries, a method of correfpondent values and feveral other problems. 1. Of finding the fum of a feries expreffed by a rational function of z into x^{nz}; where z denotes fucceffively the numbers 1, 2, 3, &c, in infinitum. 2. Given an equation expreffing the relation between the fucceffive fums, the relation between the fucceffive terms is known, and the *vice verfa*, &c. 3. It is found from an equation expreffing the relation between the fucceffive fums, terms and z the diftance from the firft term of the feries, whether the fum of the feries is finite or not. 4. The difference between z^{-o} and $\overline{z+1}_{-o}$, where z denotes the diftance from the firft term of the feries, will be $-o \times z^{-o-1}$, which is greater than the fimple ratio let o be as fmall as poffible, and confequently the fum of the feries finite. 5. If a feries $a + bx + cx^2 + x^3$, of which at an infinite diftance the preceding coefficients have to the fubfequent the ratio of $r : 1$, be multiplied into a function $= o$, when $x = b$, then if a be greater than r the feries will diverge; if lefs converge. 6. From adding feveral terms of one or more feries together may be formed a feries, of which the fum from the fums of the preceding feries is known. 6. Serieffes are formed, of which the fums are known from varying the divifors, &c. 7. From given feries are deduced others, of which the fums are known, and the fum of many feries are deduced from finding the fluxions of fluents and fluents of fluxions. 8. From the relation between the different terms given is deduced the correfpondent fluxional equation. 9. The finding the terms of any feries, which can be deduced from given feries; and thence deducing many feries of which the fums can be found from the fum of the given feries. 10 Series are given of which the fums can be found from finite terms, circular ares, logarithms, elliptical and hyperbolical arcs. 11. From a general expreffion, when algebraical, fluxional, incremental, &c. for the fum of a feries can be deduced a fimilar expreffion for the fum of every fecond, third, &c, terms. 12. An infinite feries may be a particular refolution of infinite fluxional equations. 13. The terms of fome feries may be infinite and their fums known. 14. The general fluent of $\dot{y}^n = y\dot{x}^n$ is given by a feries of the firft kind, and the fame of fome other fluxional equations. 15. A quantity is found which multiplied into a feries

more

more ſwiftly converging gives a given ſeries. 16. The firſt differences of the terms of ſome ſeries are given; if the terms are in geometrical ratio to each other the abovementioned differences will alſo be in geometrical ratio to each other: whence it appears, that the ſeries from this method of differences will converge leaſt when the given ſeries converges ſwifteſt, &c, but not always the contrary. Several other propoſitions are added concerning the method of differences applied to ſeries. 17. A parabolical hyperbolical curve is drawn through any number of points, as alſo an algebraical ſolid —. 18. Something is given concerning the convergency &c. of ſeries deduced from the differences of the numerators of a given ſeries, of which the denominators conſtitute a geometrical progreſſion. 19. A rule is given for rendering ſeries converging, in which it is obſerved that the ſum of ſo many terms ſhould be found that z the diſtance from the firſt term of the ſeries may exceed the greateſt root of the equation reſulting from the quantity which expreſſes the term made $= 0$. 20. An equation expreſſing the relation between the ſums and terms is reduced to an infinite fluxional equation expreſſing the relation between the ſum or term, its fluxions, and z the diſtance from the firſt term of the ſeries. 21. From a method being known of finding the ſum of a ſeries, which involves one variable only, is given a method of finding the ſum of ſeries which involve more variable quantities: and from aſſuming ſums of ſerieſes of this kind are deduced their terms. 22. The ſums of ſeries are found conſiſting of irrational terms. 23. The principle of the convergency of the approximations found in drawing parabolical curves through given points. 24. Something new is given concerning the interpolations of quantities.

25. $\frac{e^{\alpha x} + e^{\beta x} + e^{\gamma x} + \&c}{n} = 1 + \frac{x^n}{1.2 \ldots n} + \frac{x^{2n}}{1.2..2n} +$ &c. if α, β, γ, &c, are the roots of $x^n - 1 = 0$, &c. 26. Something is added concerning ſeries from $\int \frac{\dot{x}}{x} \int \frac{\dot{x}}{x} \int \frac{\dot{x}}{x}$, &c, $\times \int \frac{\dot{x}}{1 + ax^n}$. 27. Nandens's Problems are ſomewhat extended. 28. Something is added on changing continual fractions into others. 29. A method of transforming ſeries into continual factors.

30. A rule for finding the ſine and coſine of $\frac{n}{m}$ the arc; and transforming an algebraical equation into an equation expreſſed in terms of ſines and coſines, and thence from an approximation to the ſine is found one more near; the ſame might have been performed by tangents, cotangents, ſecants, cofecants, &c. 31. From ſome fluents given have been found others, and conſequently by reducing the fluents to infinite ſeries from ſome infinite ſeries given

may others be deduced. 32. The fluent of $\frac{x^\alpha \dot{x}}{1 \pm x^n}$ is found by approximation, where α is an irrational quantity, which method of finding approximations to the indices may be applied to other caſes. 33. The ſum of the fractions are found when the denominators $= 0$, and conſequently each particular infinite. 34. It is aſſerted, that the ſum of certain fractions given become $= 0$, when the terms are expreſſed by a fraction of which the denominator is a rational function of the diſtance from the firſt term of the ſeries. 35. $\int x^{\alpha - \beta - 1} \dot{x} \int x^{\beta - \gamma - 1} \dot{x} \int x^{\gamma - \delta - 1} \dot{x} \times$ P, where $P = Ax^n + Bx^{n+m} + Cx^{n+2m} + Dx^{n+3m} +$, &c, will be to $\int x^{\beta - \alpha - 1} \dot{x} \int x^{\alpha - \gamma - 1} \dot{x} \int x^{\gamma - \delta - 1} \dot{x} \int$ &c. $\times$ P :: x^α : x^β if the fluents are contained between the ſame values of x. 36. Are given ſome ſeries conſiſting of two, of which the one converges, when the other diverges, and conſequently the ſum of both diverges; &c. 37. From the law of a ſeries being given, the law of the ſeries which expreſſes the ſquare, or ſome function of the given ſeries, is found.

1. A method of differences, which deduces from the ſums given any ſucceſſive ſums, e. g. Let S^1, S^2, S^3, S^4, be the logarithms of the ratios $r : r + p$, $r : r + 2p$, $r : r + 3p$, $r : r + 4p$, then will the logarithm of $r : r + 5p$ be $5 \times (S^4 - S^3) + 10 (S^3 - S^2)$ nearly; then rules are given in general, and likewiſe their errors from the true values.

2. A method of correſpondent values is given, e. g. Let a, b, c, d, &c, be values of x; and S^a, S^b, S^c, S^d, &c, correſpondent values of y; then may

$$y = \frac{(x-b)(x-c)(x-d)\ \&c}{(a-b)(a-c)(a-d)\ \&c} \times S^a + \frac{(x-a)(x-c)(x-d)\ \&c}{(b-a)(b-c)(b-d)\ \&c} \times S^b + \&c.$$

3. If the formula of the ſeries be $A + Bx + Cx^2 +$ &c $= y$; or $y = \frac{x}{a} \times \frac{(x-b)(x-c)\ \&c}{(a-b)(a-c)\ \&c} \times S^a + \frac{x}{b} \times \frac{(x-a)(x-c)\ \&c}{(b-a)(b-c)\ \&c} \times S^b +$ &c; if the formula of the ſeries be $Ax + Bx^2 +$ &c $= y$, which anſwers to Briggs's or Newton's method of interpolations; or the ſeries will be

$$\frac{x^h}{a^h} \times \frac{(x^k - b^k)(x^k - c^k)(x^k - d^k)\ \&c}{(a^k - b^k)(a^k - c^k)(a^k - d^k)\ \&c} \times S^a + \frac{x^h}{b^h} \times \frac{(x^k - a^k)(x^k - c^k)(x^k - d^k)\ \&c}{(b^k - a^k)(b^k - c^k)(b^k - d^k)\ \&c} \times S^b +$$

&c; if the formula of the ſeries be $Ax^h + Bx^{h+k} + Cx^{h+2k} +$ &c, $= y$; a general formula, which includes the preceding.

5. The ſeries is given for deducing others when the number of correſpondent values given are either even or odd, and the values of x are equidiſtant from each other. 6. And alſo from correſpondent values of x and y to a number of equidiſtant values of x is deduced the value of y to the next ſucceſſive or any ſucceſſive value of x. 7. Some arithmetical theorems are deduced from the preceding propoſitions. 8. Another method is given of reſolving the preceding problem. 9. A method of correcting the ſolution from a ſolution given

given which finds (n) values of y to (n) given values of x true, and m falſe to (m) other values. 10. A ſimilar reſolution is added from correſpondent values of x, y, z, &c given; and more general reſolutions. 11. Given the reſolution of ſome caſes, and formula in which the general is contained, a method is given in ſome caſes of deducing it. 12. The principles of a method of deductions and reductions are added.

In a Pamphlet publiſhed at Cambridge, algebraical quantities are tranſlated into probable relations, and ſome theorems on probabilities thence deduced; to which are adjoined,

1. The theorem $\overline{a+b}\,.\,\overline{a+b\pm l}\,.\,\overline{a+b\pm 2l}\,.\,\overline{a+b\pm 2l}\ldots\overline{a+b\pm 2l}\ldots a+b\pm n-1l = a\cdot a\pm l\cdot a\pm 2l\ldots\overline{a\pm n-1l}+n\times a\,.\,\overline{a\pm l}\cdot\overline{a\pm 2l}\,..\,\overline{a\pm n-2l}\times b+n\,.\,\frac{n-1}{2}\,a\,.\,\overline{a\pm l}\cdot\overline{a\pm 2l}\ldots\overline{a\pm n-3l}\times b\,.\,\overline{b\pm l}+n\,.\,\frac{n-1}{2}\,.\,\frac{n-2}{3}\times a\,.\,\overline{a\pm l}\cdot\overline{a\pm 2l}\ldots\overline{a\pm n-4l}\times b\,.\,\overline{b\pm l}\cdot\overline{b\pm 2l}+$ &c; this becomes the binomial theorem when $l=0$; and it will afford anſwers to ſimilar caſes when the whole number of chances are increaſed or diminiſhed conſtantly by l, as the binomial does when they remain the ſame, a ſimilar multinomial theorem is given. In the ſame pamphlet are further added ſome new propoſitions on chances, on the values of lives, ſurvivorſhips, &c. In theſe books are alſo contained the inventions of others on ſimilar ſubjects, which in the prefaces are aſcribed to their reſpective authors.

In the Philoſophical Tranſactions are given ſome properties of numbers, &c, of which ſome have been publiſhed in the books above mentioned; to which may be ſubjoined ſomething in mixed mathematics, viz, a paper on central forces, which extends not only to central forces, but alſo to forces applied in any other direction, as in the direction of the tangent, and conſequently includes reſiſtances, &c. It gives a rule for finding the forces tending to two or more given points when the curve deſcribed and velocity of the body in every point of it is given, *e. g.* Let the curve be an ellipſe, and the velocity the ſame at every point, and the two centres of force be the foci of the ellipſe; then will the forces tending to the two foci be equal, and vary as the ſquare of the ſine of the angle contained between the diſtance from the centre of force to the point in which the body is ſituated, and the tangent to the curve at that point.

The method of deducing the fluxional equations which expreſs the curve deſcribed by a body acted on by any forces tending to given points, or applied in any given directions: ſome other propoſitions are contained on ſimilar ſubjects. 2. A paper on the fluxions of the attractions of lines, ſurfaces, and ſolids, and from the different methods of deducing them are found different fluents equal to each other: a third paper gives a ſolution of Kepler's problem of cutting the area of a circle deſcribed round a point by approximations, which alſo is applied to other caſes; this like-

wiſe contains ſome other problems. Many of theſe diſcoveries have ſince been publiſhed, ſome in the London, and other foreign tranſactions.

Let $e^l = N$, then will l denote the log. of N to the modulus e. If e the modulus $= 10$, then will the ſyſtem be the common or Briggs's ſyſtem of logarithms. Logarithms, and the ſums of ſome other ſerieſes, of the formulæ $ax^h + bx^{h+k}$ + &c may be deduced in a manner ſimilar to that which was uſed by the Ancients for finding the ſines of the arcs of circles.

To particulariſe the numerous propoſitions contained in theſe works, would exceed the limits of our deſign. Beſides thoſe already mentioned, others are interſperſed through the whole works.

ANEMOMETER, p. 111, col. 2, l. 1, *after* 12 ounces, *add* or $\frac{3}{4}$ of a pound. Owing to an overſight in the ſucceeding lines, of conſidering this 12 ounces as 12 pounds, in the calculations, ſeveral errors have been incurred, and the 3d column of the table of numbers, in that page, or the column for the velocity, has the numbers only $\frac{1}{4}$ of what they ought to be, or they require to be all multiplied by 4, the ſquare-root of 16, the number of ounces in a pound. Hence, in line 6, *for* $\sqrt{12}$ *r.* $\sqrt{\frac{3}{4}}$; l. 7 and 8, *for* $22\frac{3}{4}$ *r.* $91\frac{1}{5}$; l. 8, *for* $15\frac{1}{2}$ *r.* 62. And the whole ſucceeding table corrected will be as follows:

Table of the correſponding Height of Water, Force on a Square Foot, and Velocity of Wind,

Height of Water.	Force of Wind.	Velocity of Wind per Hour
Inches.	Pounds.	Miles.
$0\frac{1}{4}$	1·3	18·0
$0\frac{1}{2}$	2·6	25·6
1	5·2	36·0
2	10·4	50·8
3	15·6	62·0
4	20·8	76·0
5	26·0	80·4
6	31·25	88·0
7	36·5	95·2
8	41·7	101·6
9	46·9	108·0
10	52·1	113·6
11	57·3	119·2
12	62·5	124·0

In one inſtance Dr. Lind found that the force of the wind was ſuch as to be equal $34\frac{7}{8}$ pounds, on a ſquare foot; and this by proportion, in the foregoing table, will be found to anſwer to a velocity of 93 miles per hour.

ARCH, p. 137, col. 1, l. 29, *for* ſuch caſes as they, *read* ſuch caſes they. Line 30, *after* hanches, *add*, See BRIDGE.

ARCHIMEDES, p. 139, col. 1, l. 52 and 53, preface, a commentary, *read* preface. We find here alſo Eutocius's commentary. Pa. 59, *after* college, *add*, who had the ſole care of this edition.

ASSU-

ASSURANCE *on Lives.* Pa. 150, col. 2, in the 3d paragraph, for want of ſufficient information concerning the London and Royal Exchange Aſſurance Offices, that paragraph gives an imperfect and, in ſome reſpect, erroneous account of them: it refers to their ſtate 30 years ago, but the Companies have ſince that, altered their method of proceeding. Inſtead of that paragraph therefore, take the following account of their preſent conſtitution; viz,

The London ASSURANCE, is a corporation eſtabliſhed by a charter of king George the 1ſt, viz, in 1720; under power of which, Aſſurances are made from the riſk of ſea-voyages, and from the danger of fire to houſes and goods; the prices of which are regulated by the apparent riſk to be aſſured. They alſo make Aſſurances on lives; the prices of which are formed on an eſtimation of the probable duration of life at different ages, on the conſideration of the apparent health of the perſons to be aſſured, and of their avocations in life.

This corporation, and the Royal Exchange corporation, gave each the ſum of 150,000 pounds to government, for an *excluſive right* of making Aſſurances as *corporate bodies*. They are known to poſſeſs a large and undeniable fund to anſwer loſſes. And the prudent management of theſe corporations has enabled them, of late years, to increaſe gradually their dividends to the proprietors of their ſtock. This *excluſive privilege* to make Aſſurances as corporate bodies, is of great advantage and convenience to the public; and as they act under a common ſeal, the aſſured may have a ſpeedy and eaſy mode of recovering loſſes, and cannot be ſubject to any calls or deductions whatever. When their charters were granted to them, it was enacted, that if a proprietor of the ſtock of one corporation ſhould at the ſame time, directly or indirectly, be a proprietor of ſtock in the other corporation, the reſpective ſtock ſo held is to be forfeited, one moiety to the king, the other to the informer. This was evidently ſettled, to prevent their intereſt from becoming a joint one; ſo that they ſhould be made to act in competition to each other, for the greater benefit of the public.

The Royal Exchange ASSURANCE, is a corporation eſtabliſhed by charter, as above, under the power of which, Aſſurances are made from the riſk of ſea-voyages, and from the danger of fire to houſes and goods; the prices of which are regulated by the greater or leſs riſk ſuppoſed to be aſſured. They alſo make Aſſurances on lives, the prices of which are formed on eſtimation of the probable duration of life at different ages, and under different circumſtances. The preſent rates of Aſſurances on lives are as in the table below. And though a duty on theſe Aſſurances ſhould take place on the plan lately propoſed to the Houſe of Commons, there is no great probability that theſe prices will be increaſed.

This corporation has alſo, like the former, been empowered to grant life annuities by an act of parliament, which requires that the prices of the annuities ſhould be expreſſed in tables, hung up in ſome conſpicuous place in their offices, for public inſpection; and no agreement for any price is valid, but ſuch as ſhall be expreſſed in the tables laſt made and publiſhed by the corporation.

From the Office of the CORPORATION *of the* ROYAL EXCHANGE ASSURANCE, *on the* ROYAL EXCHANGE, LONDON.

By whom the Aſſurance is made.	Name, age, and deſcription of the life to be Aſſured.	Time for which the Aſſurance is made.	*Conditions of Aſſurance made by Perſons on their own Lives.*	Sum aſſured.	Rate *per* cent. *per* annum.
			The Aſſurance to be void if the perſon whoſe life is Aſſured ſhall depart beyond the limits of Europe, ſhall die upon the ſeas, or enter into or engage in any military or naval ſervice whatever, without the previous conſent of the company; or ſhall come by death by ſuicide, duelling, or the hand of Juſtice; or ſhall not be, at the time the Aſſurance is made, in good health.		

By whom the Aſſurance is made.	Name, age and deſcription of the life to be Aſſured.	Time for which the Aſſurance is made.	*Conditions of Aſſurance made by Perſons on the Lives of others.*	Sum aſſured.	Rate *per* cent. *per* annum.
			The Aſſurance to be void if the perſon whoſe life is Aſſured ſhall depart beyond the limits of Europe, ſhall die upon the ſeas, or enter into or engage in any military or naval ſervice whatever, without the previous conſent of the company; or ſhall not be at the time the Aſſurance is made in good health.		

Place and date of birth.
If had the ſmall-pox.
Whether in the army or navy.
The life Aſſured to appear at the office, or pay
10*s. per cent.* on Aſſurances for one year.
15*s. per cent.* for more than one year, and not exceeding ſeven years.
20*s. per cent.* if for the whole continuance of life.
} In the firſt payment only.

Reference to be made to two perſons of repute to aſcertain his or her identity.

*** Attendance daily from ten to half paſt two o'clock and from five to ſeven, Saturday in the afternoon excepted.

☞ The lives of perſons engaged in the army or navy may be Aſſured by ſpecial agreement.

N. B. THE CORPORATION ALSO GRANT ANNUITIES ON LIVES.

AUTOMATON. To the end of this article, in pa. 176, col. 2, may be added the following curious particulars, extracted from a letter of an ingenious gentleman ſince that article was publiſhed, viz, Thomas Collinſon, Eſq. nephew of the late ingenious Peter Collinſon, Eſq. F. R. S. "Turning over the leaves of your late valuable publication (ſays my worthy correſpondent), part 1. of the Mathematical and Philoſophical Dictionary, I obſerved under the article *Automaton*, the following:" 'But all theſe ſeem to be inferior to M. Kempell's cheſs-player, which may truly be conſidered as the greateſt maſter-piece in mechanics that ever appeared in the world;' (upon which Mr. Collinſon obſerves) "So it certainly would have been, had its ſcientific movements depended merely on mechaniſm. Being ſlightly acquainted with M. Kempell when he exhibited his cheſs-playing figure in London, I called on him about five years ſince at his houſe at Vienna; another gentleman and myſelf being then on a tour on the continent. The baron (for I think he is ſuch) ſhewed me ſome working models which he had lately made—among them, an improvement on Arkwright's cotton-mill, and alſo one which he thought an improvement on Boulton and Watt's laſt ſteam-engine. I aſked him after a piece of ſpeaking mechaniſm, which he had ſhewn me when in London. It ſpoke as before, and I gave the ſame word as I gave when I firſt ſaw it, *Exploitation*, which it diſtinctly pronounced with the French accent. But I particularly noticed, that not a word paſſed about the cheſs-player; and of courſe I did not aſk to ſee it.—In the progreſs of the tour I came to Dreſden, where becoming acquainted with Mr. Eden, our envoy there, by means of a letter given me by his brother lord Auckland, who was ambaſſador when I was at Madrid, he obligingly accompanied me in ſeeing ſeveral things worthy of attention. And he introduced my companion and myſelf to a gentleman of rank and talents, named Joſeph Freidrick Freyhere, who ſeems completely to have diſcovered the *Vitality* and ſoul of the cheſs-playing figure. This gentleman courteouſly preſented me with the treatiſe he had publiſhed, dated at Dreſden, Sept. 30, 1789, explaining its principles, accompanied with curious plates neatly coloured. This treatiſe is in the German language; and I hope ſoon to get a tranſlation of it. A well-taught boy, very thin and ſmall of his age (ſufficiently ſo that he could be concealed in a drawer almoſt immediately under the cheſs-board), agitated the whole. Even after this abatement of its being ſtrictly an automaton, much ingenuity remains to the contriver.—This diſcovery at Dreſden accounts for the ſilence about it at Vienna; for I underſtand, by Mr. Eden, that Mr. Freyhere had ſent a copy to baron Kempell: though he ſeems unwilling to acknowledge that Mr. F. has completely analyſed the whole.

"I know that long and unintereſting letters are formidable things to men who know the value of time and ſcience: but as this happens to be upon the ſubject, forgive me for adding one very admirable piece of mechaniſm to thoſe you have touched upon. When at Geneva, I called upon Droz, ſon of the original Droz of la Chaux de Fonds (where I alſo was). He ſhewed me an oval gold ſnuff box, about (if I recollect right) 4 inches and a half long, by 3 inches broad, and about an inch and a half thick. It was double, having an horizontal partition; ſo that it may be conſidered as one box placed on another, with a lid of courſe to each box—One contained ſnuff—In the other, as ſoon as the lid was opened, there roſe up a very ſmall bird, of green enamelled gold, ſitting on a gold ſtand. Immediately this minute curioſity wagged its rail, ſhook its wings, opened its bill of white enamelled gold, and poured forth, minute as it was (being only three quarters of an inch from the beak to the extremity of the tail) ſuch a clear melodious ſong, as would have filled a room of 20 or 30 feet ſquare with its harmony.—Droz agreed to meet me at Florence; and we viſited the Abbé Fontana together. He afterwards joined me at Rome, and exhibited his bird to the pope and the cardinals in the Vatican palace, to the admiration, I may ſay to the aſtoniſhment of all who ſaw and heard it."

Another extract from a ſecond letter upon the ſame ſubject, by Mr. Collinſon, is as follows: "Permit me to ſpeak of another Automaton of Droz's, which ſeveral years ſince he exhibited in England; and which, from my perſonal acquaintance, I had a commodious opportunity of particularly examining. It was a figure of a man, I think the ſize of life. It held in its hand a metal ſtyle; a card of Dutch vellum being laid under it. A ſpring was touched, which releaſed the internal clockwork from its ſtop, when the figure immediately began to draw. Mr. Droz happening once to be ſent for in a great hurry to wait upon ſome conſiderable perſonage at the weſt end of the town, left me in poſſeſſion of the keys, which opened the receſſes of all his machinery. He opened the drawing-maſter himſelf; wound it up; explained its leading parts; and taught me how to make it obey my requirings, as it had obeyed his own. Mr. Droz then went away. After the firſt card was finiſhed, the figure reſted. I put a ſecond; and ſo on, to five ſeparate cards, all different ſubjects: but five or ſix was the extent of its delineating powers. The firſt card contained, I may truly ſay, elegant portraits and likeneſſes of the king and queen, facing each other: and it was curious to obſerve with what preciſion the figure lifted up his pencil, in the tranſition of it from one point of the draft to another, without making the leaſt ſlur whatever: for inſtance, in paſſing from the forehead to the eye, noſe, and chin; or from the waving curls of the hair to the ear, &c. I have the cards now by me, &c, &c."

PAGE 195, col. 1, at the end of the article on Barometrical Meaſurements of Altitudes, *add*, See a learned paper in vol. 1. of the Tranſactions of the R. Soc. of Edinburgh, "On the Cauſes which affect the Accuracy of Barometrical Meaſurements; by John Playfair, A. M. F. R. S. Edin. and Profeſſor of Mathematics in the Univerſity of Edinburgh." Alſo another by Dr. Damen, late Profeſſor of Mathematics and Philoſophy in the Univerſity of Leyden, intitled, "Diſſertatio Phyſica & Mathematica de Montium Altitudine Barometro Metienda: Accedit Refractionis Aſtronomicæ Theoria; in 8vo, at the Hague, 1783.

Pa. 205, col. 1, after the life of Dan. Bernoulli, *add* the following life of James.

BERNOULLI (JAMES), another mathematical branch of the foregoing celebrated family. He was born at Baſil in October 1759; being the ſon of John Bernoulli, and grandſon of the firſt John Bernoulli, before mentioned, and the nephew of Daniel Bernoulli laſt noticed above. Our author's elder brother John, who ſtill lives at Berlin, is alſo well known in the republic of ſcience, particularly for his aſtronomical labours.

The gentleman to whom this article relates, was educated, as moſt of his relations had been, for the profeſſion of law: but his genius led him very early into the ſtudy of mathematics; and at 20 years of age he read public lectures on experimental philoſophy in the univerſity of Baſil, for his uncle Daniel Bernoulli, whom he hoped to have ſucceeded as profeſſor. Being diſappointed in this view, he reſolved to leave his native place, and to ſeek his fortune elſewhere; hence he accepted the office of ſecretary to Count Breuner, the emperor's envoy to the republic of Venice; and in this city he remained till the year 1786, when, on the recommendation of his countryman, M. Fuſs, he was invited to Peterſburgh to ſucceed M. Lexell in the academy there, where he continued till his death, which happened the 3d of July 1789, at not quite 30 years of age, and when he had been married only two months, to the youngeſt daughter of John Albert Euler, the ſon of the ſo celebrated Leonard Euler.

Impoſſible or Imaginary BINOMIAL. After this article, in pa. 208, the middle of col. 1, *add* what here follows.

In the foregoing article are given ſeveral rules for the roots of Binomials. Dr. Maſkelyne, the Aſtronomer Royal, has alſo given a method of finding any power of an Impoſſible Binomial, by another like Binomial. This rule is given in his Introduction prefixed to Taylor's Tables of Logarithms, pa. 56; and is as follows.

The logarithms of a and b being given, it is required to find the power of the Impoſſible Binomial

BIN

$a \pm \sqrt{-b^2}$ whoſe index is $\frac{m}{n}$, that is, to find $(a \pm \sqrt{-b^2})^{\frac{m}{n}}$ by another Impoſſible Binomial; and thence the value of $(a+\sqrt{-b^2})^{\frac{m}{n}} + (a-\sqrt{-b^2})^{\frac{m}{n}}$, which is always poſſible, whether a or b be the greater of the two.

Solution. Put $\frac{b}{a} = \text{tang. } z$. Then

$$(a \pm \sqrt{-b^2})^{\frac{m}{n}} = (a^2+b^2)^{\frac{m}{2n}} \times (\text{cof.} \tfrac{m}{n} z \pm \sqrt{-\text{ſin.}^2 \tfrac{m}{n} z}).$$

Hence $(a+\sqrt{-b^2})^{\frac{m}{n}} + (a-\sqrt{-b^2})^{\frac{m}{n}} = (a^2+b^2)^{\frac{m}{2n}} \times 2 \text{ cof.} \frac{m}{n} z = (a \times \text{ſec.} z)^{\frac{m}{n}} \times 2 \text{ coſin.} \frac{m}{n} z = (b \times \text{coſec } z.)^{\frac{m}{n}} \times 2 \text{ coſin.} \frac{m}{n} z$, where the firſt or ſecond of theſe two laſt expreſſions is to be uſed, according as z is an extreme or mean arc; or rather, becauſe $\frac{b}{a}$ is not only the tangent of z, but alſo of $z + 360°$, $z + 720°$, &c; therefore the factor in the anſwer will have ſeveral values, viz,

$2 \text{ cof.} \frac{m}{n} z$; $2 \text{ cof.} \frac{m}{n} (z+360°)$; $2 \text{ cof.} \frac{m}{n} (z + 720°)$; &c; the number of which, if m and n be whole numbers, and the fraction $\frac{m}{n}$ be in its leaſt terms, will be equal to the denominator n; otherwiſe infinite.

By Logarithms. Put $\log. b + 10 - \log. a = \log. \tan. z$. Then

$$\log. \left((a + \sqrt{-b^2})^{\frac{m}{n}} + (a - \sqrt{-b^2})^{\frac{m}{n}} \right) =$$

$$= \tfrac{m}{n} \times (\text{l.} a + 10 - \text{l. cof. } z) + \text{l. } 2 + \text{l. cof.} \tfrac{m}{n} z - 10$$

$$= \tfrac{m}{n} \times (\text{l.} b + 10 - \text{l. ſin. } z) + \text{l. } 2 + \text{l. cof.} \tfrac{m}{n} z - 10;$$

where the firſt or ſecond expreſſion is to be uſed, according as z is an extreme or mean arc. Moreover by taking ſucceſſively, l. cof. $\frac{m}{n} z$; l. cof. $\frac{m}{n} (z+360°)$; l. cof. $\frac{m}{n} (z+720°)$; &c, there will ariſe ſeveral diſtinct anſwers to the queſtion, agreeably to the remark above.

BINOMIAL *Theorem.* Francis Maſeres, Eſq. (Curſitor Baron of the Exchequer) has communicated

the following obſervations on the Binomial theorem, and its demonſtration; viz, About the year 1666 the celebrated Sir Iſaac Newton diſcovered that, if m were put for any whole number whatſoever, the coefficients of the terms of the mth power of $1 + x$ would be

$$1, \frac{m}{1}, \frac{m}{1}\cdot\frac{m-1}{2}, \frac{m}{1}\cdot\frac{m-1}{2}\cdot\frac{m-2}{3}, \text{ &c,}$$

till we come to the term $\frac{m-(m-1)}{m}$, which will be the laſt term. But how he diſcovered this propoſition, he has not told us, nor has he even attempted to give a demonſtration of it. Dr. John Wallis, of Oxford, informs us (in his Algebra, chap. 85, pa. 319) that he had endeavoured to find this manner of generating theſe coefficients one from another, but without ſucceſs; and he was greatly delighted with the diſcovery, when he found that Mr. Newton had made it. But he likewiſe has omitted to give a demonſtration of it, as well as Sir Iſaac Newton; and probably he did not know how to demonſtrate it.

Sir Iſaac Newton, after he had diſcovered this rule for generating the coefficients of the powers of $1 + x$ when the indexes of thoſe powers were whole numbers, conjectured that it might poſſibly be true likewiſe when they were fractions. He therefore reſolved to try whether it was or not, by applying it to ſuch indexes in a few eaſy inſtances, and particularly to the indexes $\frac{1}{2}$ and $\frac{1}{3}$, which, if the rule held good in the caſe of fractional indexes, would enable him to find ſerieſes equal to the values of $\overline{1+x}^{\frac{1}{2}}$ and $\overline{1+x}^{\frac{1}{3}}$, or the ſquare-root and the cube-root of the Binomial quantity $1 + x$. And, when he had in this manner obtained a ſeries for $\overline{1+x}^{\frac{1}{2}}$, which he ſuſpected to be equal to $\overline{1+x}^{\frac{1}{2}}$, or the ſquare root of $1 + x$, he multiplied the ſaid ſeries into itſelf, and found that the product was $1 + x$; and when he had obtained a ſeries for $\overline{1+x}^{\frac{1}{3}}$ he multiplied the ſaid ſeries twice into itſelf, and found that the product was $1 + x$; and thence he concluded that the former ſeries was really equal to the ſquare-root of $1 + x$, and that the latter ſeries was really equal to its cube-root. And from theſe and a few more ſuch trials, in which he found the rule to anſwer, he concluded univerſally that the rule was always true, whether the index m ſtood for a whole number or a fraction of any kind, as $\frac{1}{2}, \frac{1}{3}, \frac{2}{3}, \frac{3}{2}, \frac{5}{3}, \frac{0}{5}$, or, in general $\frac{p}{q}$.

After the diſcovery of this rule by Sir Iſaac Newton, and the publication of it by Dr. Wallis, in his Algebra, chap. 85, in the year 1685, (which I believe was the firſt time it was publiſhed to the world at large, though it was inſerted in Sir Iſaac Newton's firſt letter to Mr. Oldenburgh, the ſecretary to the Royal Society, dated June 13, 1676, and the ſaid letter was ſhewn to Mr. Leibnitz, and probably to ſome other of the learned mathematicians of that time) it remained for ſome years without a demonſtration, either in the caſe of integral powers or of roots. At laſt however it was demonſtrated in the caſe of integral powers by means of the properties of the figurate numbers, by that learned, ſagacious, and accurate mathematician Mr. James Bernoulli, in the 3d chapter of the 2d part of his excellent treatiſe *De Arte Conjectandi*, or, *On the Art of forming reaſonable Conjectures concerning Events that depend on Chance*; which appears to me to be by much the beſt written treatiſe on the doctrine of Chances that has yet been publiſhed, though Mr. Demoivre's book on the ſame ſubject may have carried the doctrine ſomething further. This treatiſe of Mr. James Bernoulli's was not publiſhed till the year 1713, which was ſome years after his death, which happened in Auguſt 1705; but there is reaſon to think that it was compoſed in the latter years of the preceding century, about the years 1696, 1697, 1698, 1699, and 1700, and even that ſome parts of it, or ſome of the propoſitions inſerted in it, had been found out by the author in the years 1689, 1690, 1691, and 1692. For the firſt part of his very curious tract, intitled, *Poſitiones Arithmeticæ de Seriebus Infinitis* was publiſhed at Baſil or Baſle in Switzerland (which was his native place, and in which he was at that time profeſſor of mathematics) in the year 1689; and the ſecond part of the ſaid *Poſitiones* (in the 19th Poſition of which thoſe properties of the figurate numbers from which the Binomial theorem may be deduced, are ſet down) was publiſhed at the ſame place in the year 1692. But the demonſtrations of thoſe properties of the figurate numbers, and of the Binomial theorem, which depends upon them, were never as I believe communicated to the public till the year 1713, when the author's poſthumous treatiſe *De Arte Conjectandi* made its appearance. Theſe demonſtrations are founded on clear and ſimple principles, and afford as much ſatisfaction as can well be expected on the ſubject. But the full diſplay and explanation of theſe principles, and the deduction of the ſaid properties of the figurate numbers, and ultimately of the Binomial theorem, from them, is a matter of conſiderable length. It will not therefore be amiſs to give a ſhorter proof of the truth of this important theorem, that ſhall not require a previous knowledge of the properties of the figurate numbers, but yet ſhall be equally concluſive with that which is derived from thoſe properties. Now this may be done in the manner following.

Let us ſuppoſe that the coefficients of the terms of the firſt ſix powers of the Binomial quantity $1 + x$ have been found, upon trial, to be ſuch as would be produced by the general expreſſions

$$1, \frac{m}{1}, \frac{m}{1}\cdot\frac{m-1}{2}, \frac{m}{1}\cdot\frac{m-1}{2}\cdot\frac{m-2}{3}, \text{ &c,}$$

by ſubſtituting in them firſt 1, then 2, then 3, then 4, then 5, and laſtly 6, inſtead of m. This may eaſily be tried by raiſing the ſaid firſt ſix powers of $1 + x$ by repeated multiplications by $1 + x$ in the common way, and afterwards finding the terms of the ſame powers by means of the ſaid general expreſſions above; which will be found to produce the very ſame terms as aroſe from the multiplications. After theſe trials we ſhall be ſure that thoſe general expreſſions are the true values of the coefficients of the powers of $1 + x$ at leaſt in the ſaid firſt ſix powers. And it will therefore only remain

remain to be proved that, ſince the rule is true in the ſaid firſt ſix powers, it will alſo be true in the next following, or the 7th power, and conſequently in the 8th, 9th and 10th powers, and in all higher powers whatſoever.

Now, if the coefficients of the 1ſt, 2d, 3d, 4th, and other following terms of $\overline{1+x}^{m}$ be denoted by the letters a, b, c, d, &c, reſpectively, it is evident from the nature of multiplication, that the coefficients of the 1ſt, 2d, 3d, 4th, and other following terms of the next higher power of $1+x$, to wit, $\overline{1+x}^{m+1}$ will be equal to a, $a+b$, $b+c$, $c+d$, &c, reſpectively, or to the ſums of every two contiguous coefficients of the terms of the preceding ſeries which is $=\overline{1+x}^{m}$. This will appear from the operation of multiplication, which is as follows.

$$\begin{array}{l} a + bx + cx^2 + dx^3 + ex^4 + \&c \\ 1 + x \\ \hline a + bx + cx^2 + dx^3 + ex^4 + \&c \\ \quad + ax + bx^2 + cx^3 + dx^4 + \&c. \\ \hline \end{array}$$

Therefore, if $\overline{1+x}^{m}$ is equal to the ſeries

$$a + bx + cx^2 + dx^3 + ex^4 + \&c,$$

then $\overline{1+x}^{m+1}$ will be equal to the ſeries

$$a + \overline{a+b}.x + \overline{b+c}.x^2 + \overline{c+d}.x^3 + \&c.$$

Now let n be $= m+1$. We ſhall then have to prove that, if the coefficients a, b, c, d, &c, be reſpectively equal to

$$1,\ \frac{m}{1},\ \frac{m}{1}.\frac{m-1}{2},\ \frac{m}{1}.\frac{m-1}{2}.\frac{m-2}{3},\ \&c,$$

the coefficients a, $a+b$, $b+c$, &c, will be reſpectively equal to

$$1,\ \frac{n}{1},\ \frac{n}{1}.\frac{n-1}{2},\ \frac{n}{1}.\frac{n-1}{2}.\frac{n-2}{3},\ \&c.$$

In order to prove this, there is nothing more to do than to collect together every two terms of the former of theſe two ſeries, and then ſubſtitute into theſe ſums, n inſtead of $m+1$, when there will immediately come out the terms of the latter ſeries as above, viz,

$$\overline{1+x}^{n} = 1 + \frac{n}{1}x + \frac{n}{1}.\frac{n-1}{2}x^2 + \&c. \quad \text{Q. E. D.}$$

Binomial *Theorem, Improvement of.* Mr. Bonnycaſtle, of the Royal Mil. Acad. has lately diſcovered the following ingenious improvement of this theorem, which is now publiſhed for the firſt time.

This celebrated theorem has been given under various forms, ſince the time of its firſt invention; but the following property of it is conceived to be new, and capable of an application of which the original ſeries is not ſuſceptible.

The Newtonian theorem, in one of its moſt commodious forms, is

$$\overline{1+p}^{n} = 1 + np + \frac{n.n-1}{2}p^2 + \frac{n.n-1.n-2}{2.3}p^3 + \frac{n.n-1.n-2.n-3}{2.3.4}p^4$$

&c; and the new theorem here alluded to, is

$$\overline{1+p}^{r} = 1 + sn + \frac{1}{2}s^2n^2 + \frac{1}{2.3}s^3n^3 + \frac{1}{2.3.4}s^4n^4 \ \&c;$$

where $s = p - \frac{1}{2}p^2 + \frac{1}{3}p^3 - \frac{1}{4}p^4 + \frac{1}{5}p^5$ &c.

Of which the inveſtigation is as follows:

$$\overline{1+p}^{n} = 1 + np + \frac{n.n-1}{2}p^2 + \frac{n.n-1.n-2}{2.3}p^3 + \frac{n.n-1.n-2.n-3}{2.3.4}p^4 \ \&c$$

$$= 1 + np + (n^2-1)\frac{p^2}{2} + (n^3-3n^2+2n)\frac{p^3}{2.3} + (n^4-6n^3+11n^2-6n)\frac{p^4}{2.3.4}$$

$$+ (n^5-10n^4+35n^3-50n^2+24n)\frac{p^5}{2.3.4.5}$$

$$+ (n^6-15n^5+85n^4-225n^3+274n^2-120n)\frac{p^6}{2.3.4.5.6} \ \&c.$$

Then by connecting the ſeveral powers of p with all the like powers of n, the latter ſeries will become

$$1 + (p - \frac{p^2}{2} + \frac{2p^3}{2.3} - \frac{6p^4}{2.3.4} + \frac{24p^5}{2.3.4.5} - \frac{120p^6}{2.3.4.5.6} \ \&c)n$$
$$+ (\frac{p^2}{2} - \frac{3p^3}{2.3} + \frac{11p^4}{2.3.4} - \frac{50p^5}{2.3.4.5} + \frac{274p^6}{2.3.4.5.6} \ \&c)n^2$$
$$+ (\frac{p^3}{2.3} - \frac{6p^4}{2.3.4} + \frac{35p^5}{2.3.4.5} - \frac{225p^6}{2.3.4.5.6} \ \&c)n^3$$
$$+ (\frac{p^4}{2.3.4} - \frac{10p^5}{2.3.4.5} + \frac{85p^6}{2.3.4.5.6} \ \&c)n^4$$
$$+ (\frac{p^5}{2.3.4.5} - \frac{15p^6}{2.3.4.5.6} \ \&c)n^5$$
$$+ (\frac{p^6}{2.3.4.5.6} \ \&c)n^6$$
$$\&c;$$

which by abbreviation, &c, becomes

$$1 + (p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4} + \frac{p^5}{5} - \frac{p^6}{6} \ \&c)n$$
$$+ \frac{1}{2}(p^2 - \frac{3p^3}{3} + \frac{11p^4}{3.4} - \frac{50p^5}{3.4.5} + \frac{274p^6}{3.4.5.6} \ \&c)n^2$$
$$+ \frac{1}{2.3}(p^3 - \frac{6p^4}{4} + \frac{35p^5}{4.5} - \frac{225p^6}{4.5.6} \ \&c)n^3$$
$$+ \frac{1}{2.3.4}(p^4 - \frac{10p^5}{5} + \frac{85p^6}{5.6} \ \&c)n^4$$
$$+ \frac{1}{2.3.4.5}(p^5 - \frac{15p^6}{6} \ \&c)n^5$$
$$+ \frac{1}{2.3.4.5.6}(p^6 \ \&c)n^6$$
$$\&c.$$

In which laſt ſeries, the literal parts of the coefficients of the 3d, 4th, 5th, &c terms, are the ſquare, cube, biquadrate, &c, of the coefficient of the 2d term, as will appear either from the actual involution of

$$p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4} \ \&c,$$

or by comparing its ſeveral powers with the multinomial theorem of Demoivre.

From hence it follows that,

$\overline{1+p}^{n}$

$\overline{1+p}^{n} = 1 + (p - \frac{p^2}{2} + \frac{p^3}{3} \&c)n + \frac{1}{2}(p - \frac{p^2}{2} + \frac{p^3}{3} \&c)n^2 + \frac{1}{2.3}(p - \frac{p^2}{2} + \frac{p^3}{3} \&c)n^3 + \frac{1}{2.3.4}(p - \frac{p^2}{2} + \frac{p^3}{3} \&c)n^4$ &c.

And if $p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4}$ &c be put $= s$, we shall have

$\overline{1+p}^{n} = 1 + sn + \frac{1}{2}s^2n^2 + \frac{1}{2.3}s^3n^3 + \frac{1}{2.3.4}s^4n^4$ &c,

as was to be shewn.

By a similar mode of deduction, it may also be proved that

$\overline{1-p}^{n} = 1 - fn + \frac{1}{2}f^2n^2 - \frac{1}{2.3}f^3n^3 + \frac{1}{2.3.4}f^4n^4$ &c;

where in this case $f = p + \frac{p^2}{2} + \frac{p^3}{3} + \frac{p^4}{4}$ &c.

In each of which formulæ, the index n, may be considered either as a whole number, a fraction, a surd, a given or an unknown quantity, as the circumstance may require.

For the application of these theorems, see LOGARITHMS, and EXPONENTIAL *Equations*, following.

C.

CAN

CANAL, in general, denotes a long, round, hollow instrument, through which a fluid matter may be conveyed. In which sense, it amounts to the same as what is otherwise called a pipe, tube, channel, &c. Thus the Canal of an aqueduct, is the part through which the water passes; which, in the ancient works of this kind, is lined with a coat of mastic of a peculiar composition.

CANAL more particularly denotes a kind of artificial river, often furnished with locks and sluices, and sustained by banks or mounds. They are contrived for divers purposes; some for forming a communication between one place and another; as the Canals between Bruges and Ghent, or between Brussels and Antwerp: Others for the decoration of a garden, or house of pleasure; as the Canals of Versailles, Fontainbleau, St. James's Park, &c: And others are made for draining wet and marshy lands; which last however are more properly called water-gangs, drains, ditches, &c.

It is needless to enumerate the many advantages arising from Canals and artificial navigations. Their utility is now so apparent, that most nations in Europe give the highest encouragement to undertakings of this kind wherever they are practicable. Nor did their advantages escape the observation of the Ancients. From the earliest accounts of society we read of attempts to cut through large isthmuses, to make communications by water, either between one sea and another, or between different nations, or distant parts of the same nation, where land-carriage was long and expensive.

Egypt is full of Canals, dug to receive and distribute the waters of the Nile, at the time of its inundation. They are dry the rest of the year, except the Canal of Joseph, and four or five others, which may be ranked as considerable rivers. There were also subterraneous Canals, or tunnels, dug by an ancient king of Egypt, by which those lakes, formed by the inundations of the Nile, were conveyed into the Mediterranean sea.

CAN

Herodotus relates, that the Cnidians, a people of Coria, in Asia Minor, designed to cut through the isthmus which joins that peninsula to the continent; but were superstitious enough to give up the undertaking, because it was interdicted by an oracle.

Several kings of Egypt attempted to join the Red-Sea to the Mediterranean; a project which Cleopatra was very fond of. This Canal was begun, according to Herodotus, by Necus son of Psammeticus, who desisted from the attempt on an answer from the oracle, after having lost 120 thousand men in the enterprise. It was resumed and completed by Darius son of Hystaspes, or, according to Diodorus and Strabo, by Ptolomy Philadelphus; who relate that Darius relinquished the work on a representation made to him by unskilful engineers, that the Red-Sea, being higher than the land of Egypt, would overflow and drown the whole country. It was wide enough for two galleys to pass abreast, and its length was four days sailing. Diodorus adds, that it was also called Ptolomy's river; that this prince built a city at its mouth on the Red-Sea, which he called Arsinoë, from the name of his favourite sister; and that the Canal might be either opened or shut, as occasion required. Diod. Sic. lib. 1; Strabo, Geog. lib. 17; Herod. lib. 2. Soliman the 2d, emperor of the Turks, employed 50 thousand men in this great work; which was completed under the caliphate of Omar, about the year 635; but was afterward allowed to fall into neglect and disrepair; so that it is now difficult to discover any traces of it. Hist. Acad. Scienc. ann. 1703, pa. 110.

Both the Greeks and Romans intended to make a Canal across the Isthmus of Corinth, which joins the Morea and Achaia, for a navigable passage by the Ionian sea into the Archipelago. Demetrius, Julius Cæsar, Caligula, and Nero, made several unsuccessful efforts to open this passage. But as the Ancients were entirely ignorant of the use of water-locks, their whole attention

attention was employed in making level cuts, which is probably the chief reaſon why they ſo often failed in their attempts. Charlemagne formed a deſign of joining the Rhine and the Danube, to make a communication between the Ocean and the Black-Sea, by a Canal from the river Almutz which diſcharges itſelf into the Danube, to the Reditz, which falls into the Maine, which laſt falls into the Rhine near Mayence or Mentz: for this purpoſe he employed a prodigious number of workmen; but he met with ſo many obſtacles from different quarters, that he was obliged to give up the attempt.

A new Canal for conveying the waters of the Nile from Ethiopia into the Red-Sea without paſſing into Egypt, was projected by Albuquerque, viceroy of India for the Portugueſe, to render Egypt barren and unprofitable to the Turks.—M. Gaildereau attributes the frequency of the plague in Egypt, of late days, to the decay, or ſtopping up of theſe Canals; which happened upon the Turks becoming maſters of the country.

In China, there is ſcarce a town or village without the advantage either of an arm of the ſea, a navigable river, or a Canal, by which means navigation is rendered ſo common, that there are almoſt as many people on the water as the land. The great Canal of China, is one of the wonders of art, extending from north to ſouth quite acroſs the empire, from Pekin to Canton, a diſtance of 825 miles, and was made upwards of 800 years ago. Its breadth and depth are ſufficient to carry barks of conſiderable burden, which are managed by ſails and maſts, as well as towed by hand. On this Canal it ſeems the emperor employs near ten thouſand ſhips. It paſſes through, or by, 41 large cities; there are in it 75 vaſt locks and ſluices, to keep up the water, and paſs the ſhips where the ground will not admit of ſufficient depth of channel, beſide ſeveral thouſand draw and other bridges. Indeed, F. Magaillane aſſures us, there are paſſages from one end of China to the other, the ſpace of 600 French leagues, either by Canals or rivers, except a ſingle day's journey by land, neceſſary to croſs a mountain.

The French at preſent have many fine Canals. That of Briere, otherwiſe called the Canal of Burgundy, was begun under Henry IV, and finiſhed under the direction of cardinal Richelieu in the reign of Louis XIII. This Canal makes a communication between the Loire and the Seine, and ſo to Paris. It extends 11 French great leagues from Briere to Montargis, and has 42 locks upon it.

The Canal of Orleans was begun in 1675, for eſtabliſhing a communication alſo between the Seine and the Loire. It is conſiderably ſhorter than that of Briere, and has only 20 ſluices.

The Canal of Bourbon was but lately undertaken: its deſign is to make a communication from the river Oiſe to Paris.

But the greateſt and moſt uſeful work of this kind, is the junction of the Ocean with the Mediterranean by the Canal of Languedoc, called alſo the Canal of the two ſeas. It was propoſed in the reigns of Francis I and Henry IV, and was begun and finiſhed under Louis XIV; having been planned by Francis Riquet in the year 1666, and finiſhed before his death, which happened in 1680. It begins with a large reſervoir 4000 paces in circumference, and 24 feet deep, which receives many ſprings from the mountain Noire. The Canal is about 200 miles in length, extending from Narbonne to Tholouſe, being ſupplied by a number of rivulets in the way, and furniſhed with 104 locks or ſluices, of about 8 feet riſe each. In ſome places it is carried over bridges and aqueducts of vaſt height, which give paſſage underneath to other rivers; and in ſome places it is cut through ſolid rocks for a mile together.

The new Canal of the lake Ladoga, cut from Volhowa to the Neva, by which a communication is made between the Baltic, or rather Ocean, and the Caſpian ſea, was begun by the czar Peter the 1ſt in 1719: by means of which the Engliſh and Dutch merchandize is eaſily conveyed into Perſia, without being obliged to double the Cape of Good Hope.—There was a former Canal of communication between the Ladoga lake and the river Wolga, by which timber and other goods had been brought from Perſia to Peterſburg; but the navigation of it was ſo dangerous, that a new one was undertaken.

The Spaniards have ſeveral times had in view the digging a Canal through the Iſthmus of Darien, between North and South America, from Panama to Nombre de Dios, to make a ready communication between the Atlantic and the South Sea, and thus afford a ſtraight paſſage to China and the Eaſt Indies.

In the Dutch, Auſtrian, and French Netherlands, there is a great number of Canals: that from Bruges to Oſtend carries veſſels of 200 tons. But it would be an endleſs taſk to deſcribe the numberleſs Canals in Holland, Germany, Ruſſia, &c. We may therefore only take a view of thoſe in our own country.

In England, that ancient Canal from the river Nyne, a little below Peterborough, to the river Witham, three miles below Lincoln; called by the modern inhabitants Caerdike; may be ranked among the monuments of the Roman grandeur, though it is now moſt of it filled up. Morton will have it made under the emperor Domitian. Urns and medals have been diſcovered on the banks of this Canal, which ſeem to confirm that opinion. Yet ſome authors take it to be a Daniſh work. It was 40 miles in length; and, ſo far as appears from the ruins, muſt have been very broad and deep. Notwithſtanding that early beginning, it is not long ſince Canals have been revived in this country. They are now however become very numerous, particularly in the counties of York, Lincoln, and Cheſhire. Moſt of the counties between the mouth of the Thames and the Briſtol channel are connected together either by natural or artificial navigations; thoſe upon the Thames and Iſis reaching within about 20 miles of thoſe upon the Severn.

The Canal for ſupplying London with water by means of the New River, was projected and begun by Mr. Edward Wright, author of the celebrated treatiſe on Navigation, about the year 1608; but finiſhed by Mr. (afterwards Sir Hugh) Middleton, five years after. This Canal commences near Ware, in Hertfordſhire, and takes a courſe of 60 miles before it reaches the ciſtern at Iſlington, which ſupplies the ſeveral water-pipes that convey it to the city and parts adjacent. In ſome

places

places it is 30 feet deep, and in others it is conveyed over a valley between two hills, by means of a trough ſupported on wooden arches, and riſing above 23 feet in height.

The Duke of Bridgwater's Canal, projected and executed under the direction of Mr. Brindley, was begun about the year 1759. It was firſt deſigned only for conveying coals to Mancheſter, from a mine in the duke's eſtate; but has ſince been applied to many other uſeful purpoſes of inland navigation. This Canal begins at a place called Worſley-mill, about 7 miles from Mancheſter, where a baſon is made capable of holding all the boats, and a great body of water which ſerves as a reſervoir or head to the navigation. The Canal runs through a hill by a ſubterraneous paſſage, large enough for admitting long flat-bottomed boats, which are towed by a rail on each hand, near three quarters of a mile, to the coal-works. There the paſſage divides into two channels, one of which goes off 300 yards to the right, and the other as many to the left; and both may be continued at pleaſure. The paſſage is in ſome places cut through the ſolid rock, and in others arched over with brick; and air-funnels, ſome of which are near 37 yards perpendicular, are cut, at certain diſtances, through the rock to the top of the hill. The arch at its entrance is about 6 feet wide, and about 5 feet high from the ſurface of the water; but widens within, ſo that in ſome places the boats may paſs one another, and at the pits it is 10 feet wide. When the boats are loaded and brought out of the baſon, five or ſix of them are linked together, and drawn along the Canal by a ſingle horſe, and thus reaching Mancheſter in a courſe of nine miles. It is broad enough for two barges to paſs or go abreaſt; and on one ſide there is a good road for the paſſage of the people, and the horſes or mules employed in the work. The Canal is raiſed over public roads by means of arches; and it paſſes over the navigable river Irwell near 50 feet above it; ſo that large veſſels in full ſail paſs under the Canal, while the duke's barges are at the ſame time paſſing over them. This Canal joins that which paſſes from the river Merſey towards the Trent, taking in the whole a courſe of 34 miles.

The Lancaſter Canal begins near Kendal, and terminates near Eccleſton, comprehending the diſtance of 72½ miles.

The Canal from Liverpool to Leeds is 108⅓ miles: that from Leeds to Selby, 23¼ miles; from Chicheſter to Middlewich, 26¾ miles; from the Trent to the Merſey, 88 miles; from the Trent to the Severn, 46½ miles. The Birmingham Canal joins this near Wolverhampton, and is 24¼ miles: the Droitwich Canal is 5½ miles: the Coventry Canal, commencing near Lichfield, and joining that of the Trent, is 36¼ miles: the Oxford Canal breaks off from this, and is 82 miles: the Cheſterfield Canal joins the Trent near Gainſborough, and is 44 miles.

A communication is now formed, by means of this inland navigation, between Kendal and London, by way of Oxford; between Liverpool and Hull, by the way of Leeds; and between the Briſtol channel and the Humber, by the junction formed between the Trent and the Severn. Other ſchemes have been projected, which the preſent ſpirit of improvement will probably ſoon carry into execution, of opening a communication between the German and Iriſh ſeas, ſo as to reduce a hazardous navigation of more than 800 miles by ſea, into a little more than 150 miles by land, or inland navigation; and alſo of joining the Iſis with the Severn.

In Scotland, a navigable Canal between the Forth and Clyde, which divides that country into two parts, was thought of more than a century ſince, for tranſports and ſmall ſhips of war. It was again projected in the year 1722, and a ſurvey made; but nothing more was done till 1761, when the then lord Napier, at his own expence, had a ſurvey, plan, and eſtimate made on a ſmall ſcale. In 1764, the truſtees for fiſheries, &c, in Scotland, procured another ſurvey, plan, and eſtimate of a Canal 5 feet deep, which was to coſt 79,000 pounds. In 1766, a ſubſcription was obtained by a number of the moſt reſpectable merchants in Glaſgow, for making a Canal 4 feet deep and 24 feet in breadth; but when the bill was nearly obtained in parliament, it was given up on account of the ſmallneſs of the ſcale, and a new ſubſcription ſet on foot for a Canal 7 feet deep, eſtimated at 150,000 pounds. This obtained the ſanction of parliament; and the work was begun in 1768, by Mr. Smeaton the engineer. The extreme length of the Canal from the Forth to the Clyde is 35 miles, beginning at the mouth of the Carron, and ending at Dalmure Burnfoot on the Clyde, 6 miles below Glaſgow, riſing and falling 160 feet by means of 39 locks, 20 on the eaſt ſide of the ſummit, and 19 on the weſt, as the tide does not ebb ſo low in the Clyde as in the Forth by 9 feet; and it was deepened to upwards of 8 feet. This Canal was finiſhed a few years ſince, after having experienced ſome interruptions and delays, for want of reſources, and is eſteemed the greateſt work of the kind in this iſland. Veſſels drawing 8 feet water, with 19 feet in the beam and 73 feet in length, paſs with eaſe; and the whole enterpriſe diſplays the art of man in a high degree. To ſupply the Canal with water was of itſelf a very great work. There is one reſervoir of 50 acres 24 feet deep, and another of 70 acres 22 feet deep, in which many rivers and ſprings terminate, which it is expected will afford ſufficient ſupply of water at all times.

The Practice of Canal Digging and Inland Navigations.

The particular operations neceſſary for making artificial navigations, depend upon a number of circumſtances. The ſituation of the ground; the vicinity or connection with rivers; the eaſe or difficulty with which a proper quantity of water can be obtained: theſe and many other circumſtances neceſſarily produce great variety in the ſtructure of artificial navigations, and augment or diminiſh the labour and expence of executing them. When the ground is naturally level, and unconnected with rivers, the execution is eaſy, and the navigation is not liable to be diſturbed by floods: but when the ground riſes and falls, and cannot be reduced to a level, artificial methods of raiſing and lowering veſſels muſt be employed; which likewiſe vary according to circumſtances.

Sometimes a kind of temporary ſluices are employed, to raiſe boats over falls or ſhoals in rivers, by a very ſimple operation. Two pillars of maſon-work, with grooves, are fixed, one on each bank of the river, at

ſome diſtance below the ſhoal. The boat having paſſed theſe pillars, ſtrong planks are let down acroſs the river by pulleys into the grooves; by which means the water is dammed up to a proper height for allowing the boat to paſs up the river over the ſhoal.

The Dutch and Flemings at this day ſometimes, when obſtructed by caſcades, form an inclined plane or rolling-bridge upon dry land, along which their veſſels are drawn from the river below the caſcade, into the river above it. This it is ſaid was the only method employed by the Ancients, and ſtill ſometimes uſed by the Chineſe. Theſe rolling-bridges conſiſt of a number of cylindrical rollers which turn eaſily on pivots. And a mill is commonly built near; ſo that the ſame machinery may ſerve the double purpoſe of working the mill and drawing up veſſels.

But in the preſent improved ſtate of inland navigation, theſe falls and ſhoals are commonly ſurmounted by means of what are called locks or ſluices. A lock is a baſon placed lengthwiſe in a river or Canal, lined with walls of maſonry on each ſide, and terminated by two gates placed acroſs the Canal, where there is a caſcade or natural fall of the country; and ſo conſtructed, that the baſon being filled with water by an upper ſluice to the level of the waters above, a veſſel may aſcend through the upper gate; or the water in the lock being reduced to the level of the water at the bottom of the caſcade, the veſſel may deſcend through the lower gate: for when the waters are brought to a level on either ſide, the gate on that ſide may be eaſily opened.

But as the lower gate is ſtrained in proportion to the depth of water it ſupports, when the perpendicular height of the water exceeds 12 or 13 feet, it becomes neceſſary to have more locks than one. Thus, if the fall be 16 feet, two locks are required, each of 8 feet fall; and if the fall be 25 feet, three locks are neceſſary, each having 8 feet 4 inches fall.—It is evident that the ſide-walls of locks ſhould be made very ſtrong: and where the natural foundation is bad, they ſhould be founded on piles and platforms of wood. They ſhould likewiſe ſlope outwards, in order to reſiſt the preſſure of the earth from behind.

To illuſtrate this by repreſentations: Plate 37, fig. 1, is a perſpective view of part of a Canal, with ſeveral locks &c; the veſſel L being within the lock AC.—Fig. 2 is an elevation or upright ſection along the Canal; the veſſel L about to enter.—Fig. 3, a like ſection of a lock full of water; the veſſel L being raiſed to a level with the water in the ſuperior Canal.—And fig. 4 is the plan or ground-ſection of a lock: where L is a veſſel in the inferior Canal; C, the under gate; A, the upper gate; GH, a ſubterraneous paſſage for letting water from the ſuperior Canal run into the lock; and KF, a ſubterraneous paſſage for water from the lock to the inferior Canal.

X and Y (fig. 1) are the two flood-gates, each of which conſiſts of two leaves, reſting upon one another, ſo as to form an obtuſe angle, the better to reſiſt the preſſure of the water. The firſt (X) prevents the water of the ſuperior Canal from falling into the lock; and the ſecond (Y) dams up and ſuſtains the water in the lock. Theſe flood-gates ought to be very ſtrong, and to turn freely upon their hinges. They ſhould alſo be made very tight and cloſe, that as little water as poſſible may be loſt. And, to make them open and ſhut with eaſe, each leaf is furniſhed with a long lever A*b*, A*b*; C*b*, C*b*.

By the ſubterraneous paſſage GH (fig. 2, 3, 4) which deſcends obliquely, by opening the ſluice G, the water is let down from the ſuperior Canal D into the lock, where it is ſtopped and retained by the gate C when ſhut, till the water in the lock comes to be on a level with the water in the ſuperior Canal D; as repreſented in fig. 3. When, on the other hand, the water contained by the lock is to be let out, the paſſage GH muſt be ſhut, by letting down the ſluice G; the gate A muſt alſo be ſhut, and the paſſage KF opened by raiſing the ſluice K. A free paſſage being thus given to the water, it deſcends through KF, into the inferior Canal, until the water in the lock be on a level with the water in the inferior Canal B; as repreſented in fig. 2.

Now ſuppoſe it be required to raiſe the veſſel L (fig. 2) from the inferior Canal B to the ſuperior one D. If the lock be full of water, the ſluice G muſt be ſhut, as alſo the gate A, and the ſluice K opened, ſo that the water in the lock may run out till it become to a level with the water in the inferior Canal B. When the water in the lock comes to be on a level with the water at B, the leaves of the gate C are opened by the levers C*b*, which is eaſily performed, the water on each ſide of the gate being in equilibrio; the veſſel then ſails into the lock. After this, the gate C and the ſluice K are ſhut, and the ſluice G opened, in order to fill the lock, till the water in the lock, and conſequently the veſſel, be upon a level with the water in the ſuperior Canal D; as is repreſented in fig. 3. The gate A is then opened, and the veſſel paſſes into the Canal D.

Again let it be required to make a veſſel deſcend from the Canal D into the inferior Canal B. If the lock be empty, as in fig. 2, the gate C and ſluice K muſt be ſhut, and the upper ſluice G opened, ſo that the water in the lock may riſe to a level with the water in the upper Canal D. Then, opening the gate A, the veſſel will paſs through into the lock. This done, ſhut the gate A and the ſluice G; then open the ſluice K, till the water in the lock be on a level with the water in the inferior Canal; this done, the gate C is opened, and the veſſel paſſes along into the Canal B, as was required.

CATENARY. Line 4, *for* ACB *read* BAC.—l. 6, *for* A and B *read* C and B. *After which add*, It is otherwiſe called the *Elaſtic Curve*.

CHALDRON. Line 4, *for* 2000 pounds, *read* 28 cwt. or 3136 pounds. *At the end add*, By act of parliament, a Newcaſtle Chaldron is to weigh 52½ cwt, or 3 waggons of 17½ cwt, or 6 carts of 8¾ cwt each, making 52½ cwt to the Chaldron. The ſtandard London Chaldron is to conſiſt of 36 buſhels heaped up, each buſhel to contain a Wincheſter buſhel and one quart, and to be 19½ inches diameter externally. Now it has been found by repeated trials, that 15 London Chaldrons are equal to 8 Newcaſtle Chaldrons, which, reckoning 52½ cwt to the latter, gives 28 cwt to the former, or 3136 lbs to the London Chaldron.

This I find nearly confirmed by experiment. I

weighed one peck of coals, which amounted to 21¾ lb. Then 4 times this gives 87 lb for the weight of the buſhel; and 36 times the buſhel gives 3132 lb for the Chaldron; to which if the weight of the odd quart be added, or 3 lb nearly, it gives 3135 lb for the weight of the Chaldron, which is only one pound leſs than by ſtatute.

CIRCLE *of Curvature*. To what is ſaid of this article in the Dictionary, may be added what follows.

A circular arc is the only curve line that is equally curved in every point. In all other curve lines, ſuch as the arc of an ellipſe, or a parabola, or an hyperbola, or a cycloid, the curvature is different in different points, and the degree of curvature in any point is eſtimated by the curvature of a Circle which is ſaid to have the ſame curvature as the propoſed curve line in that point; by which is underſtood the Circle which, having the tangent of the propoſed curve in the ſaid point for its tangent, approaches ſo nearly to the propoſed curve that no other Circle whatever can be drawn between it and that curve.

This Circle is alſo ſaid to *oſculate* the curve in the ſaid point, and is therefore often called the *oſculating Circle*, as well as the *Circle of equal curvature* with the curve in the ſaid point. And the radius of this Circle is called the *radius of curvature* of the propoſed curve in the ſaid point; alſo its centre is called the *centre of curvature*.

Now there are ſome curve lines ſo very highly curved in ſome particular points, that every Circle, of how ſmall a radius ſoever, having the tangent to the curve in one of thoſe points for its tangent, will paſs without the curve, or between the curve and its tangent. This, for example, is the caſe with the curve of a cycloid in the two points contiguous to its baſe, as alſo with the ciſſoid at its vertex. And in ſuch points the curvature of theſe curves is ſaid to be *infinite*, becauſe it is greater than the curvature of any Circle, how ſmall ſoever. Alſo the radius of the Circle of curvature in ſuch points is nothing; the length of that radius being always inverſely or reciprocally as the degree of curvature at any point.

The theory of theſe Circles of equal curvature with curves in particular points was firſt cultivated by Apollonius in his Conic Sections: and it has ſince been carried much farther by ſeveral great mathematicians of modern times; particularly by Mr. Huygens in his doctrine of Evolute Curves and Curves of Evolution, and by the great Sir Iſaac Newton. See CURVATURE.

CLARKE (Dr. SAMUEL), a celebrated Engliſh divine, philoſopher, and metaphyſician, was the ſon of Edward Clarke, Eſq. alderman of Norwich, and for ſeveral years one of its repreſentatives in parliament; and was born there the 11th of October 1675. He was inſtructed in claſſical learning at the free-ſchool of that town; and in 1691 removed thence to Caius college in Cambridge; where his uncommon abilities ſoon began to diſplay themſelves. Though the philoſophy of Des Cartes was at that time the eſtabliſhed philoſophy of the univerſity, yet Clarke eaſily maſtered the new ſyſtem of Newton; and in order to his firſt degree of arts, performed a public exereiſe in the ſchools upon a queſtion taken from it. He greatly contributed to the eſtabliſhment of the Newtonian philoſophy by an excellent tranſlation of Rohault's Phyſics, with notes, which he finiſhed before he was 22 years of age: a book which had been for ſome time the ſyſtem uſed in the univerſity, and founded upon Carteſian principles. This was firſt publiſhed in the year 1697, and it ſoon after went through ſeveral other editions, all with improvements.

Mr. Whiſton relates that, in that year, 1697, while he was chaplain to Dr. Moore biſhop of Norwich, he met with young Clarke, then wholly unknown to him, at a coffee-houſe in that city; where they entered into a converſation about the Carteſian philoſophy, particularly Rohault's Phyſics, which Clarke's tutor, as he tells us, had put him upon tranſlating. "The reſult of this converſation was, ſays Whiſton, that I was greatly ſurpriſed that ſo young man as Clarke then was, ſhould know ſo much of thoſe ſublime diſcoveries, which were then almoſt a ſecret to all, but to a few particular mathematicians. Nor did I remember (continues he) above one or two at the moſt, whom I had then met with, that ſeemed to know ſo much of that philoſophy as Mr. Clarke."

He afterwards turned his thoughts to divinity; and having taken holy orders, in 1698 he ſucceeded Mr. Whiſton as chaplain to Dr. Moore biſhop of Norwich, who was ever after his conſtant friend and patron. In 1699 he publiſhed two treatiſes: the one on Baptiſm, Confirmation, and Repentance; the other, Reflections on that part of a book called Amyntor, or a Defence of Milton's Life, which relates to the Writings of the Primitive Fathers, and the Canon of the New Teſtament. In 1701 he publiſhed A Paraphraſe upon the Goſpel of St. Matthew; which was followed in 1702 by the Paraphraſes upon the Goſpels of St. Mark and St. Luke, and ſoon after by a third volume upon St. John.

Mean while biſhop Moore gave him the rectory of Drayton near Norwich, with a lecture-ſhip in that city. In 1704 he was appointed to preach Boyle's lecture; and the ſubject he choſe was, The Being and Attributes of God. He ſucceeded ſo well in this, and gave ſo much ſatisfaction, that he was appointed to preach the ſame lecture the next year, when he choſe for his ſubject, The Evidences of Natural and Revealed Religion. Theſe ſermons were firſt printed in two volumes, in 1705 and 1706; and contained ſome remarks on ſuch objections as had been made by Hobbes and Spinoza, and other oppoſers of natural and revealed religion. In the 6th edition was added, A Diſcourſe concerning the Connection of the Prophecies of the Old Teſtament, and the application of them to Chriſt.

About this time, Mr. Whiſton informs us, he diſcovered that Mr. Clarke (having read much of the primitive writers) began to ſuſpect that the Athanaſian doctrine of the Trinity was not the doctrine of thoſe early ages; and it was particularly remarked of him, that he never read the Athanaſian Creed at his pariſh church.

In 1706 he publiſhed A Letter to Mr. Dodwell; anſwering all the arguments in his epiſtolary diſcourſe againſt the immortality of the ſoul. *Biſhop Hoadley* obſerves,

obſerves, that in this letter he anſwered Mr. Dodwell in ſo excellent a manner, both with regard to the philoſophical part, and to the opinions of ſome of the primitive writers, upon whom theſe doctrines were fixed, that it gave univerſal ſatisfaction. But this controverſy did not ſtop here; for the celebrated Mr. Collins, coming in as a ſecond to Dodwell, went much farther into the philoſophy of the diſpute, and indeed ſeemed to produce all that could be ſaid againſt the immateriality of the ſoul, as well as the liberty of human actions. This enlarged the ſcene of the diſpute; into which our author entered, and wrote with ſuch a ſpirit of clearneſs and demonſtration, as at once ſhewed him greatly ſuperior to his adverſaries in metaphyſical and phyſical knowledge; making every intelligent reader rejoice that ſuch an incident had happened to provoke and extort from him ſuch excellent reaſoning and perſpicuity of expreſſion.

In the midſt of theſe labours, Mr. Clarke found time to ſhew his regard to mathematical and philoſophical ſtudies, with his exact knowledge and ſkill in them. And his natural affection and capacity for theſe ſtudies were not a little improved by the friendſhip of Sir Iſaac Newton; at whoſe requeſt he tranſlated his Optics into Latin in 1706. With this verſion Sir Iſaac was ſo highly pleaſed, that he preſented him with the ſum of 500l. or 100l. to each of his five children.

The ſame year alſo, biſhop Moore procured for him the rectory of St. Bennett's, Paul's Wharf, in London; and ſoon after carried him to court, and recommended him to the favour of queen Anne. She appointed him one of her chaplains in ordinary; and alſo preſented him to the rectory of St. James's, Weſtminſter, when it became vacant in 1709. Upon this occaſion he took the degree of D. D. when the public exerciſe which he performed for it at Cambridge was highly admired.

The ſame year 1709, Dr. Clarke reviſed and corrected Whiſton's tranſlation of the Apoſtolical Conſtitutions into Engliſh, at his earneſt requeſt. In 1712 he publiſhed a moſt beautiful and pompous edition of Cæſar's Commentaries. And the ſame year, his celebrated book called, The Scripture Doctrine of the Trinity. Whiſton informs us, that ſome time before the publication of this book, there was a meſſage ſent to the author by lord Godolphin, and others of queen Anne's miniſters, importing, "That the affairs of the public were with difficulty then kept in the hands of thoſe that were for liberty; that it was therefore an unſeaſonable time for the publication of a book that would make a great noiſe and diſturbance; and that therefore they deſired him to forbear till a fitter opportunity ſhould offer itſelf:" which meſſage, ſays he, the doctor paid no regard to, but went on according to the dictates of his own conſcience with the publication of his book. The miniſters however were very right in their conjectures; for the work made noiſe and diſturbance enough, and occaſioned a great many books and pamphlets, written by himſelf and others. Nor were theſe the whole that his work occaſioned: it rendered the author obnoxious to the eccleſiaſtical power, and his book was complained of by the lower houſe of convention. The doctor drew up a preface, and afterwards gave in ſeveral explanations, which ſeemed to ſatisfy the upper houſe; at leaſt the affair was not brought to any iſſue, the members appearing deſirous to prevent diſſenſions and diviſions.

In 1715 and 1716 he had a diſpute with the celebrated Leibnitz, concerning the principles of natural philoſophy and religion; and a collection of the papers which paſſed between them, was publiſhed in 1717. This work was addreſſed to queen Caroline, then princeſs of Wales, who was pleaſed to have the controverſy paſs through her hands. It related chiefly to the ſubjects of liberty and neceſſity.

About the year 1718 he was preſented by the lord Lechmere, to the maſterſhip of Wigſton's hoſpital in Leiceſterſhire. In 1724 and 1725 he publiſhed 18 ſermons, preached on ſeveral occaſions. In 1727, on the death of Sir Iſaac Newton, he had the offer of ſucceeding him as Maſter of the Mint, a place worth from 12 to 15 hundred a year: but to this ſecular preferment he could not reconcile himſelf; and therefore abſolutely refuſed it.—In 1728 was publiſhed, a Letter from Dr. Clarke to Mr. Benjamin Hoadley, occaſioned by the Controverſy relating to the Proportion of Velocity and Force of Bodies in Motion; and printed in the Philoſophical Tranſactions, num. 401.—In the beginning of 1729 he publiſhed the firſt 12 books of Homer's Iliad: a work which biſhop Hoadley calls an accurate performance; and his notes, a treaſury of grammatical and critical knowledge. And the ſame year came out, his Expoſition of the Church Catechiſm, and 10 volumes of Sermons: books ſo well known and ſo generally approved, that they need no recommendation. But the ſame year, on Sunday the 11th of May, going to preach before the Judges at Serjeant's Inn, he was ſeized with a pain in his ſide, which made it impoſſible for him to perform his office. He was carried home and continued under his diſorder till the 17th of the ſame month, when he died, in the 54th year of his age, after long enjoying a vigorous ſtate of health, having ſcarce ever known ſickneſs.

Three years after the doctor's death, appeared the other 12 books of the Iliad, publiſhed in 4to by his ſon, Mr. Samuel Clarke, who ſays in the preface, that his father had finiſhed the annotations to the firſt three of thoſe books, and as far as the 359th verſe of the 4th; and had reviſed the text and verſion as far as verſe 510 of the ſame book.

Dr. Clarke married Catherine, the only daughter of the Rev. Mr. Lockwood, rector of Little Miſſingham in the county of Norfolk, by whom he had ſeven children, four of whom ſurvived him.

Queen Caroline took great pleaſure in the doctor's converſation and friendſhip, ſeldom miſſing a week in which ſhe did not receive ſome proof of the greatneſs of his genius, and the force of his underſtanding.

As to the character of Dr. Clarke, he is repreſented as poſſeſſing one of the beſt diſpoſitions in the world, remarkably humane and tender, free and eaſy in his converſation, cheerful and even playful in his manner. Biſhop Hare ſays of him, "He was a man who had all the good qualities that could meet together to recommend him. He was poſſeſſed of all the parts of learning that are valuable in a clergyman, in a degree that

few poſſeſs any ſingle one. He has joined to a good ſkill in the three learned languages, a great compaſs of the beſt philoſophy and mathematics, as appears by his Latin works; and his Engliſh ones are ſuch a proof of his own piety, and of his knowledge in divinity, and have done ſo much ſervice to religion, as would make any other man, that was not under a ſuſpicion of hereſy, ſecure of the friendſhip of all good churchmen, eſpecially the clergy. And to all this piety and learning was joined, a temper happy beyond expreſſion; a ſweet, eaſy, modeſt, obliging behaviour adorned all his actions; and neither paſſion, vanity, inſolence, or oſtentation appeared either in what he ſaid or wrote. This is the learning, this the temper of the man, whoſe ſtudy of the Scriptures has betrayed him into a ſuſpicion of ſome heretical opinions. Biſhop Hoadley too having remarked how great the doctor was in all branches of learning, adds, If in any one of theſe he had excelled only ſo much as he did in all, he would have been juſtly entitled to the character of a great man: but there is ſomething ſo very extraordinary, that the ſame perſon ſhould excel not only in thoſe parts of knowledge which require the ſtrongeſt judgment, but in thoſe which require the greateſt memory too. So that, in a very high degree, divinity and mathematics, experimental philoſophy and claſſical learning, metaphyſics and critical ſkill, were united in Dr. Clarke.—Much more may be ſeen, ſaid in his praiſe by biſhop Hoadley, Dr. Sykes, and Mr. Whiſton, in their Memoirs of his life.

CLEF, or CLIFF, in Muſic, a mark at the beginning of the lines of a ſong, which ſhews the tone or key in which the piece is to begin. Or, it is a letter marked on any line, which explains and gives the name to all the reſt.

Anciently, every line had a letter marked for a Clef; but now a letter on one line ſuffices; ſince by this all the reſt are known; reckoning up and down, in the order of the letters.

It is called the Clef, or key, becauſe that by it are known the names of all the other lines and ſpaces; and conſequently the quantity of every degree, or interval. But becauſe every note in the octave is called a key, though in another ſenſe, this letter marked is called peculiarly the *ſigned Clef*; becauſe, being written on any line, it not only ſigns and marks that one, but it alſo explains all the reſt. By Clef, therefore, for diſtinction ſake, is meant that letter, ſigned on a line, which explains the reſt; and by key, the principal note of a ſong, in which the melody cloſes.

There are three of theſe ſigned Clefs, *c*, *f*, *g*. The Clef of the higheſt part in a ſong, called *treble*, or *alt*, is *g*, ſet on the ſecond line counting upwards. The Clef of the baſs, or the loweſt part, is *f* on the 4th line upwards. For all the other mean parts, the Clef is *c*, ſometimes on one, ſometimes on another line. Indeed, ſome that are really mean parts, are ſometimes ſet with the *g* clef. It muſt however be obſerved, that the ordinary ſignatures of Clefs bear little reſemblance to thoſe letters. Mr. Malcolm thinks it would be well if the letters themſelves were uſed. Kepler takes great pains to ſhew, that the common ſignatures are only corruptions of the letters they repreſent. The figures of theſe now are as follow:

Character of the treble Clef.

The mean Clef.

The baſs Clef.

The Clefs are always taken fifths to one another. So the Clef *f* being loweſt, *c* is a fifth above it, and *g* a fifth above *c*.

When the place of the Clef is changed, which is not frequent in the mean Clef, it is with a deſign to make the ſyſtem comprehend as many notes of the ſong as poſſible, and ſo to have the fewer notes above or below it. So that, if there be many lines above the Clef, and few below it, this purpoſe is anſwered by placing the Clef in the firſt or ſecond line: but if there be many notes below the Clef, it is placed lower in the ſyſtem. In effect, according to the relation of the other notes to the Clef note, the particular ſyſtem is taken differently in the ſcale, the Clef line making one in all the variety.

But ſtill, in whatever line of the particular ſyſtem any Clef is found, it muſt be underſtood to belong to the ſame of the general ſyſtem, and to be the ſame individual note or ſound in the ſcale. By this conſtant relation of Clefs, we learn how to compare the ſeveral particular ſyſtems of the ſeveral parts, and to know how they communicate in the ſcale, that is, which lines are uniſon, and which not: for it is not to be ſuppoſed, that each part has certain bounds, within which another muſt never come. Some notes of the treble, for example, may be lower than ſome of the mean parts, or even of the baſs. Therefore to put together into one ſyſtem all the parts of a compoſition written ſeparately, the notes of each part muſt be placed at the ſame diſtances above and below the proper Clef, as they ſtand in the ſeparate ſyſtem: and becauſe all the notes that are conſonant, or heard together, muſt ſtand directly over each other, that the notes belonging to each part may be diſtinctly known, they may be made with ſuch differences as ſhall not confound, or alter their ſignifications with reſpect to time, but only ſhew that they belong to this or that part. Thus we ſhall ſee how the parts change and paſs through one another; and which, in every note, is higheſt, loweſt, or uniſon.

It muſt here be obſerved, that for the performance of any ſingle piece, the Clef only ſerves for explaining the intervals in the lines and ſpaces: ſo that it need not be regarded what part of any greater ſyſtem it is; but the firſt note may be taken as high or low as we pleaſe. For as the proper uſe of the ſcale is not to limit the abſolute degree of tone; ſo the proper uſe of the *ſigned* Clef is not to limit the pitch, at which the firſt note of any part is to be taken; but to determine the tune of the reſt, with reſpect to the firſt; and conſidering all the parts together, to determine the relation of their ſeveral notes by the relations of their Clefs in the ſcale: thus, their pitch of tune being determined in a certain note of one part, the other notes of that part are determined by the conſtant relations of the letters

letters of the ſcale, and the notes of the other parts by the relations of their Clefs.

In effect, for performing any ſingle part, the Clef note may be taken in an octave, that is, at any note of the ſame name; provided we do not go too high, or too low, for finding the reſt of the notes of a ſong. But in a concert of ſeveral parts, all the Clefs muſt be taken, not only in the relations, but alſo in the places of the ſyſtem abovementioned; that every part may be comprehended in it.

The natural and artificial note expreſſed by the ſame letter, as *c* and *c*♯, are both ſet on the ſame line or ſpace. When there is no character of flat or ſharp, at the beginning with the Clef, all the notes are natural: and if in any particular place the artificial note be required, it is denoted by the ſign of a flat or ſharp, ſet on the line a ſpace before that note.

If a ſharp or flat be ſet at the beginning in any line or ſpace with the Clef, all the notes on that line or ſpace are artificial ones; that is, are to be taken a ſemitone higher or lower than they would be without ſuch ſign. And the ſame affects all their octaves above and below, though they be not marked ſo. In the courſe of the ſong, if the natural note be ſometimes required, it is ſignified by the character ♮.

COMPASS. Pa. 314, col. 1, after l. 6 from the bottom, add, See alſo a new one in the Supplement to Cavallo's Treatiſe on Magnetiſm.

CONDORCET (John-Anthony-Nicholas *de* Caritat, *Marquis of*), member of the Inſtitute of Bologna, of the Academies of Turin, Berlin, Stockholm, Upſal, Philadelphia, Peterſbourg, Padua, &c, and ſecretary of the Paris Academy of Sciences, was born at Ribemont in Picardie, the 17th of September 1743. His early attachment to the ſciences, and progreſs in them, ſoon rendered him a conſpicuous character in the commonwealth of letters. He was received as a member of the Academy of Sciences at 25 years of age, namely, in March 1769, as Adjunct-Mecanician; afterwards, he became Aſſociate in 1710, Adjunct-Secretary in 1773, and ſole Secretary ſoon after, which he enjoyed till his death, or till the diſſolution of the Academy by the Convention.

Condorcet ſoon became an author, and that in the moſt ſublime branches of ſcience. He publiſhed his *Eſſais d'Analyſe* in ſeveral parts; the firſt part in 1765 (at 22 years of age); the ſecond, in 1767; and the third, in 1768. Theſe works are chiefly on the Integral Calculus, or the finding of Fluents, and make one volume in 4to.

He publiſhed the Eloges of the Academicians or members of the Academy of Sciences, from the year 1666 till 1700, in ſeveral volumes. He wrote alſo ſimilar Eloges of the Academicians who died during the time that he diſcharged the important office of Secretary to the Academy; as well as the very uſeful hiſtories of the different branches of ſcience commonly prefixed to the volumes of Memoirs, till the volume for the year 1783, when it is to be lamented that ſo uſeful a part of the plan of the Academy was diſcontinued.

His other memoirs contained in the volumes of the Academy, are the following.

1. Tract on the Integral Calculus; 1765.
2. On the problem of Three Bodies; 1767.
3. Obſervations on the Integral Calculus; 1767.
4. On the Nature of Infinite Series; on the Extent of the Solutions which they give; and on a new method of Approximation for Differential Equations of all Orders; 1769.
5. On Equations for Finite Differences; 1770.
6. On Equations for Partial Differences; 1770.
7. On Differential Equations; 1770.
8. Additions to the foregoing Tracts; 1770.
9. On the Determination of Arbitrary Functions which enter the Integrals of Equations to Partial Differences; 1771.
10. Reflexions on the Methods of Approximation hitherto known for Differential Equations; 1771.
11. Theorem concerning Quadratures; 1771.
12. Inquiry concerning the Integral Calculus; 1772.
13. On the Calculation of Probabilities, part 1 and 2; 1781.
14. Continuation of the ſame, part 3; 1782.
15. Ditto, part 4; 1783.
16. Ditto, part 5; 1784.

Condorcet had the character of being a very worthy honeſt man, and a reſpectable author, though perhaps not a firſt-rate one, and produced an excellent ſet of Eloges of the deceaſed Academicians, during the time of his ſecretaryſhip. A late French political writer has obſerved of him, that he laboured to ſucceed to the literary throne of d'Alembert, but that he cannot be ranked among illuſtrious authors; that his works have neither animation nor depth, and that his ſtyle is dull and dry; that ſome bold attacks on religion and declamations againſt deſpotiſm have chiefly given a degree of fame to his writings.

On the breaking out of the troubles in France, Condorcet took a decided part on the ſide of the people, and ſteadily maintained the cauſe he had eſpouſed amid all the ſhocks and intrigues of contending parties; till, under the tyranny of Robeſpierre, he was driven from the convention, being one of thoſe members proſcribed on the 31ſt of May 1793, and he died about April 1794. The manner of his death is thus deſcribed by the public prints of that time. He was obliged to conceal himſelf with the greateſt care for the purpoſe of avoiding the fate of Briſſot and the other deputies who where executed. He did not, however, attempt to quit Paris, but concealed himſelf in the houſe of a female, who, though ſhe knew him only by name, did not heſitate to riſk her own life for the purpoſe of preſerving that of Condorcet. In her houſe he remained till the month of April 1794, when it was rumoured that a domiciliary viſit was to be made, which obliged him to leave Paris. Although he had neither paſſport nor civic card, he eſcaped through the Barrier, and arrived at the Plain of Mont rouge, where he expected to find an aſylum in the country-houſe of an intimate friend. Unfortunately this friend had ſet out for Paris, where he was to remain for three days.—During all this period, Condorcet wandered about the fields and in the woods,

not

not daring to enter an inn on account of not having a civic card. Half dead with hunger, fatigue, and fear, and ſcarcely able to walk on account of a wound in his foot, he paſſed the night under a tree.

At length his friend returned, and received him with great cordiality; but as it was deemed imprudent that he ſhould enter the houſe in the day-time, he returned to the woods till night. In this ſhort interval between morning and night his caution forſook him, and he reſolved to go to an inn for the purpoſe of procuring food. He went to an inn at Clamars, and ordered an omlette. His torn clothes, his dirty cap, his meagre and pale countenance, and the greedineſs with which he devoured the omlette, fixed the attention of the perſons in the inn, among whom was a member of the Revolutionary Committee of Clamars. This man conceiving him to be Condorcet, who had effected his eſcape from the Bicetre, aſked him whence he came, whither he was going, and whether he had a paſſport? The confuſed manner in which he replied to theſe queſtions, induced the member to order him to be conveyed before the Committee, who, after an examination, ſent him to the diſtrict of Boury la Reine. He was there interrogated again, and the unſatisfactory anſwers which he gave, determined the directors of the diſtrict to ſend him to priſon on the ſucceeding day.—During the night he was confined in a kind of dungeon. On the next morning, when his keeper entered with ſome bread and water for him, he found him ſtretched on the ground without any ſigns of life.

On inſpecting the body, the immediate cauſe of his death could not be diſcovered, but it was conjectured that he had poiſoned himſelf. Condorcet indeed always carried a doſe of poiſon in his pocket, and he ſaid to the friend who was to have received him into his houſe, that he had been often tempted to make uſe of it, but that the idea of a wife and daughter, whom he loved tenderly, reſtrained him. During the time that he was concealed at Paris, he wrote a hiſtory of the Progreſs of the Human Mind, in two volumes.

CUBICS. The method of reſolving all the caſes of Cubic equations by the tables of ſines, tangents and ſecants, are thus given by Dr. Maſkelyne, p. 57, Taylor's Logarithms.

"The following method is adapted to a Cubic equation, wanting the ſecond term; therefore, if the equation has the ſecond term, it muſt be firſt taken away in the uſual manner. There are four forms of Cubic equations wanting the ſecond term, whoſe roots, according to known rules equivalent to Cardan's, are as follow:

1ſt. $x^3 + px - q = 0$ ..... $x = \sqrt[3]{\frac{q}{2} + \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}} - \sqrt[3]{-\frac{q}{2} + \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}}$

2d. $x^3 + px + p = 0$ ..... $x = \sqrt[3]{-\frac{q}{2} + \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}} - \sqrt[3]{\frac{q}{2} + \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}}$

3d. $x^3 - px - q = 0$ ..... $x = \sqrt[3]{\frac{q}{2} + \sqrt{\frac{q^2}{4} - \frac{p^3}{27}}} + \sqrt[3]{\frac{q}{2} - \sqrt{\frac{q^2}{4} - \frac{p^3}{27}}}$

4th. $x^3 - px + q = 0$ ..... $x = -\sqrt[3]{\frac{q}{2} - \sqrt{\frac{q^2}{4} - \frac{p^3}{27}}} - \sqrt[3]{\frac{q}{2} + \sqrt{\frac{q^2}{4} - \frac{p^3}{27}}}$

The roots of the firſt and ſecond forms are negatives of each other; and thoſe of the third and fourth are alſo negatives of each other. The firſt and ſecond forms have only one root each. The third and fourth forms have alſo only one root each, when the quadratic ſurd $\sqrt{\frac{q^2}{4} - \frac{p^3}{27}}$ is poſſible; but have three roots each when that ſurd is impoſſible.

The roots of all the four forms may, in all caſes, be eaſily computed as follows:

Forms 1ſt and 2d. Put $\frac{q}{2} \times \sqrt{\frac{3}{p}}^{\frac{3}{2}} = \text{tang. } z$; and $\sqrt[3]{\text{tan. } 45^\circ - \frac{1}{2}z} = \text{tan. } u$. Then $x = \pm\sqrt{\frac{4p}{3}} \times$ cot. $2u$; where the upper ſign belongs to the firſt form, and the lower ſign to the ſecond form.

Forms 3d and 4th. Put $\frac{2}{q} \times \sqrt{\frac{p}{3}}^{\frac{3}{2}}$ if leſs than unity, elſe its reciprocal $\frac{q}{2} \times \sqrt{\frac{3}{4}}^{\frac{3}{2}} = \text{cof. } z$. Then,

Caſe 1ſt. $\frac{2}{q} \times \sqrt{\frac{p}{3}}^{\frac{3}{2}} <$ unity. Put $\sqrt[3]{\text{tan. } 45^\circ - \frac{1}{2}z} = \text{tan. } u$. Then $x = \pm\sqrt{\frac{4p}{3}} \times$ cofec. $2u$; where the upper ſign belongs to the third form, and the lower ſign to the fourth form.

Caſe 2d. $\frac{2}{q} \times \sqrt{\frac{p}{3}}^{\frac{3}{2}} >$ unity. Then x has three values in each form, viz, $x = \pm\sqrt{\frac{4p}{3}} \times \text{cof. } \frac{z}{3} = \mp\sqrt{\frac{4p}{3}} \times \text{cof. } 60^\circ - \frac{z}{3} = \mp\sqrt{\frac{4p}{3}} \times \text{cof. } 60^\circ + \frac{z}{3}$; where the upper ſigns belong to the third form, and the lower ſigns to the fourth form.

By

By Logarithms.

Forms 1ſt and 2d. Log. $\frac{q}{2} + 10 - \frac{3}{2} \times \log. \frac{p}{3} =$ log. tan. z, and $\frac{\log. \text{tan. } 45^\circ - \frac{1}{2}z + 20}{3} =$ log. tan. u.

Then log. $x = \frac{1}{2}$ log. $\frac{4p}{3}$ + log. cot. $2u - 10$; and x will be affirmative in the firſt form, and negative in the ſecond form.

Forms 3d and 4th. $\frac{3}{2} \times$ log. $\frac{p}{3} + 10 -$ log. $\frac{q}{2}$ being leſs than 10 (which is caſe firſt) or log. $\frac{q}{2} + 10 - \frac{3}{2} \times$ log. $\frac{p}{3}$ being leſs than 10 (which is caſe 2d) = log. cof. z.

Caſe 1ſt. $\frac{\text{Log. tan. } 45^\circ - \frac{1}{2}z + 20}{3} =$ log. tan. u.

Then log. $x = \frac{1}{2}$ log. $\frac{4p}{3}$ + 10 − log. ſin. $2u$; and x will be affirmative in the third form, and negative in the 4th form.

Caſe 2d. Here x has three values.

1ſt. Log. $\pm x = \frac{1}{2}$ log. $\frac{4p}{3}$ + log. cof. $\frac{z}{3} - 10$.

2d. Log. $\mp x = \frac{1}{2}$ log. $\frac{4p}{3}$ + log. cof. $60^\circ - \frac{z}{3}$,

3d. Log. $\mp x = \frac{1}{2}$ log. $\frac{4p}{3}$ + log. cof. $60^\circ + \frac{z}{3} - 10$;

where the upper ſigns belong to the third form, and the lower ſigns to the fourth form; that is, the firſt value of x in the third form is poſitive, and its ſecond and third values negative; and the firſt value of x in the fourth form is negative, and its ſecond and third values affirmative."

DIPPING *Needle*. Pa. 383, col. 2, after line 38 *add*, See a new Dipping-needle by Dr. Lorimer, in the Philoſ. Tranſ. 1775, alſo in the Supplement to Cavallo's Treatiſe on Magnetiſm.

DOME. In plate 33 is repreſented the plan and elevation of a Dome conſtructed without centring, by Mr. S. Bunce; viz, Fig. 1 the plan, and Fig. 2 the elevation. The firſt courſe conſiſts of the ſtones marked 1, 1, 1, &c, of different ſizes, the large ones exactly twice the height of the ſmall ones, placed alternately, and forming intervals to receive the ſtones marked 2, 2, 2. The other courſes are continued in the ſame manner, according to the order of the figures to the top.

It is evident, from the converging or wedgelike form of the intervals, that the ſtones they receive can only be inſerted from the outſide, and cannot fall through: therefore the whole Dome may be built without centring or temporary ſupport. To break the upright joints, the ſtones may be cut of the form marked in Fig. 3; and thoſe marked 16, 17, &c, near the key-ſtones, may be enlarged as at Fig. 4.

E.

EUTOCIUS, a reſpectable Greek mathematician, lived at Aſcalon in Paleſtine about the year of Chriſt 550. He was one of the moſt conſiderable mathematicians that flouriſhed about the decline of the ſciences among the Greeks, and had for his preceptor Iſidorus the principal architect of the church of St. Sophia at Conſtantinople. He is chiefly known however by his commentaries on the works of the two ancient authors, Archimedes and Apollonius. Thoſe two commentaries are both excellent compoſitions, to which we owe many uſeful circumſtances in the hiſtory of the mathematics.

His commentaries on Apollonius are publiſhed in Halley's edition of the works of that author; and thoſe on Archimedes, firſt in the Baſle edition, in Greek and Latin, in 1543, and ſince in ſome others, as the late Oxford edition. Of theſe commentaries, thoſe rank the higheſt, which illuſtrate Archimedes's work on the Sphere and Cylinder; in one of which we have a recital of the various methods practiſed by the ancients in the ſolution of the Delian problem, or that of doubling the cube. The others are of leſs value; though it cannot but be regretted that Eutocius did not purſue his plan of commenting on all the works of Archimedes, with the ſame attention and diligence which he employed in his remarks on the ſphere and cylinder.

GROIN, with Builders, is the angle made by the interſection of two arches. It is of two kinds, regular and irregular; viz, Regular when both the arches have the ſame diameter, but an Irregular Groin when one arch is a ſemicircle and the other a ſemiellipſis. Groins are chiefly uſed in forming arched roofs, where one hollow arched vault interſects with another; as in the roofs of moſt churches, and ſome cellars in large houſes.

I.

IMPOSSIBLE *Binomial*. See BINOMIAL.

IRREDUCIBLE *Caſe*, in Algebra. Mr. Bonnycaſtle has communicated the following additional obſervations on this caſe, and, an improved ſolution by a table of ſines. The

IRREDUCIBLE *Caſe, in Algebra*, is a cubic equation of the form $x^3 - ax = \pm b$, having $\frac{1}{27}a^3$ greater than $\frac{1}{4}b^2$, or $4a^3$ greater than $27b^2$; in which caſe, it is well known, that the ſolution cannot be generally obtained, either by Cardan's rule, or any other which has yet been deviſed.

One of the moſt convenient methods of determining the roots of equations of this kind, is by means of a Table of Natural Sines, &c, for which purpoſe the following formulæ will be found extremely commodious, the arc, in each caſe, being always leſs than a quadrant, and therefore attended with no ambiguity.

If the equation be $x^3 - ax = b$; let A be put = arc whose cos. is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$ to rad. 1, then the three roots, or values of x, will be as follows:

$$x = 2\sqrt{\frac{a}{3}} \times \text{cosine } \frac{A}{3}$$

$$x = -2\sqrt{\frac{a}{3}} \times \text{sine } \frac{90^\circ + A}{3}$$

$$x = -2\sqrt{\frac{a}{3}} + \text{sine } \frac{90^\circ - A}{3}$$

And, if the equation be $x^3 - ax = -b$; let A be put = arc whose sine is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$ to rad. 1; then the three roots, or values of x, will be as follows.

$$x = 2\sqrt{\frac{a}{3}} \times \text{sine } \frac{A}{3}$$

$$x = 2\sqrt{\frac{a}{3}} \times \text{cos. } \frac{90^\circ + A}{3}$$

$$x = -2\sqrt{\frac{a}{3}} \times \text{cos. } \frac{90^\circ + A}{3}$$

Ex. 1. Let $x^3 - 3x = 1$, to find the 3 roots of the equation.

Here $\frac{3b}{2a}\sqrt{\frac{3}{a}} = \frac{3}{6}\sqrt{\frac{3}{3}} = \frac{1}{2} = .5 = \text{cos. } 60^\circ = A$.

Hence
$$\begin{cases} x = 2\text{cos.}\frac{60^\circ}{3} = 2\text{cos. } 20^\circ = 1.8793852 \\ x = -2\text{sine}\frac{150^\circ}{3} = -2\text{sine } 50^\circ = -1.5320888 \\ x = -2\text{sine}\frac{30^\circ}{3} = -2\text{sine } 10^\circ = -.3472964 \end{cases}$$

Ex. 2d. Let $x^3 - 3x = -1$, to find the 3 roots of the equation.

Here $\frac{3b}{2a}\sqrt{\frac{3}{a}} = \frac{3}{6}\sqrt{\frac{3}{3}} = \frac{1}{2} = .5 = \text{sine } 30^\circ = A$,

Hence
$$\begin{cases} x = 2\text{sine}\frac{30^\circ}{3} = 2\text{ sine } 10^\circ = .3472964 \\ x = 2\text{ cos.}\frac{120^\circ}{3} = 2\text{cos. } 40^\circ = 1.5320888 \\ x = -2\text{ cos. }\frac{60^\circ}{3} = -2\text{ cos. } 20^\circ = -1.8793852 \end{cases}$$

The investigation of this method is as follows:

It is shewn, by the writers on Trigonometry, that if c be the cosine of any arc to rad. 1, $4c^3 - 3c$ will be the cosine of 3 times that arc; and consequently c is the cosine of $\frac{1}{3}$ of the arc whose cosine is $4c^3 - 3c$, or any other equal quantity.

In order, therefore, to reduce the equation $x^3 - ax = b$ to this form, let $x = \frac{y}{z}$; then

$\frac{y^3}{z^3} - a \times \frac{y}{z} = b$, or $y^3 - az^2y = bz^3$, or $4y^3 - 4az^2y = 4bz^3$; whence if $4az^2$ be put = 3, we shall have $z = \sqrt{\frac{3}{4a}} = \frac{1}{2}\sqrt{\frac{3}{a}}$, and consequently $4y^3 - 3y = \frac{3b}{2a}\sqrt{\frac{3}{a}}$.

From which last equation, it appears that y = cos. $\frac{1}{3}$ arc whose cos. is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$; and therefore $x = \frac{y}{z} = \frac{y}{\frac{1}{2}\sqrt{\frac{3}{a}}}$

$= 2\sqrt{\frac{a}{3}} \times y = 2\sqrt{\frac{a}{3}} \times$ (cos. $\frac{1}{3}$ arc whose cos. is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$),

or, if A be put = arc whose cos. is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$, x is $= 2\sqrt{\frac{a}{3}} \times \text{cos. } \frac{A}{3}$.

But the arc of which $\frac{3b}{2a}\sqrt{\frac{3}{a}}$ is the cosine, is either A, $A + 360^\circ$ or $A + 720^\circ$; whence $x = 2\sqrt{\frac{a}{3}} \times \text{cos. } \frac{A}{3}$ or $2\sqrt{\frac{a}{3}} \times \text{cos. } \frac{A + 360^\circ}{3}$, or $2\sqrt{\frac{a}{3}} \times \text{cos. } \frac{A + 720^\circ}{3}$; the two latter of which being converted into sines, will give the same formulæ as in the rule.

In like manner, if s be the sine of any arc to rad. 1, $3s - 4s^3$ is well known to be the sine of 3 times that arc; and consequently s is the sine of $\frac{1}{3}$ of the arc whose sine is $3s - 4s^3$. Whence, to reduce the equation $x^3 - ax = -b$, to this form, let $x = \frac{y}{z}$, as before; then $\frac{y^3}{z^3} - a \times \frac{y}{z} = -b$, or $y^3 - az^2y = -bz^3$, or $az^2y - y^3 = bz^3$, or $4az^2y - 4y^3 = 4bz^3$; where, if $4az^2$ be put = 3, we shall have $z = \frac{1}{2}\sqrt{\frac{3}{a}}$, and consequently $3y - 4y^3 = \frac{3b}{2a}\sqrt{\frac{3}{a}}$.

From which last equation it appears that y = sine $\frac{1}{3}$ arc whose sine is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$, and therefore $x = \frac{y}{z} = 2\sqrt{\frac{a}{3}} \times$ (sine $\frac{1}{3}$ arc whose sine is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$), which is the same as the rule, the other two roots being found as in the former case.

LOCK, for Canals, in Inland Navigations. See CANAL.

LOGARITHMS. Mr. Bonnycastle has communicated the following new method of making these useful numbers:

LOGARITHMS. The series now chiefly used in the computation of Logarithms were originally derived from the hyperbola, by means of which, and the logistic curve, the nature and properties of these numbers are clearly and elegantly explained.

The doctrine, however, being purely arithmetical, this mode of demonstrating it, by the intervention of certain curves, was considered, by Dr. Halley, as not conformable to the nature of the subject.

He

M. Betancourt deduces ſeveral uſeful and ingenious conſequences and applications from this courſe of experiments. He ſhews, for inſtance, that the effect of Steam engines muſt, in general, be greater in winter than in ſummer; owing to the different degrees of temperature in the water of injection. And from the very ſuperior ſtrength of the vapour of ſpirit of wine, over that of water, he argues that, by trying other fluids, ſome may be found, not very expenſive, whoſe vapour may be ſo much ſtronger than that of water, with the ſame degree of heat, that it may be ſubſtituted inſtead of water in the boilers of Steam-engines, to the great ſaving in the very heavy expence of fuel: nay, he even declares, that ſpirit of wine itſelf might thus be employed in a machine of a particular conſtruction, which, with the ſame quantity of fuel, and without any increaſe of expence in other things, ſhall produce an effect greatly ſuperior to what is obtained from the ſteam of water. He makes ſeveral other obſervations on the working and improvement of Steam-engines.

Another uſe of theſe experiments, deduced by M. Betancourt, is, to meaſure the height of mountains, by means of a thermometer, immerſed in boiling water, which he thinks may be done with a preciſion equal, if not ſuperior, to that of the barometer. As ſoon as I had obtained exact reſults of my experiments, ſays he, and was convinced that the degree of heat received by water depends abſolutely on the preſſure upon its ſurface, I endeavoured to compare my obſervations with ſuch as have been made on mountains of different heights, to know what is the degree of heat which water can receive when the barometer ſtands at a determinate height; but from ſo few obſervations having been made of this kind, and the different ways employed in graduating inſtruments, it is difficult to draw any certain conſequences from them.

The firſt obſervation which M. Betancourt compared with his experiments, is one mentioned in the Memoirs of the Academy of Sciences, anno 1740, page 92. It is there ſaid, that M. Monnier having made water boil upon the mountain of Canigou, where the barometer ſtood at 20·18 inches, the thermometer immerſed in this water ſtood at a point anſwering to 71 degrees of Reaumur: whereas in M. Betancourt's table of experiments, at an equal preſſure upon the ſurface of the water, the thermometer ſtood at 73·7 degrees. This difference he thinks is owing partly to the want of preciſion in the obſervation, and partly to the different method of graduating the thermometer, and the neglect of purging the barometer tube of air.

M. Betancourt next compared his experiments with ſome obſervations made by M. De Luc on the tops of ſeveral mountains; in which, after reducing the ſcales of this gentleman to the ſame meaſures as his own, he finds a very near degree of coincidence indeed. The following table contains a ſpecimen of theſe compariſons, the inſtances being taken at random from De Luc's treatiſe on the Modifications of the Atmoſphere.

Degrees of Heat in Boiling Water upon the Tops of Mountains, obſerved by De Luc.				Heat of the Water in M. Betancourt's Experim.
Places of Obſervation.	Heat of the air.	Height of the Bar.	Heat of the Wa. by Th.	
Beaucaire -	14¼	28·248	80·37	80·29
Geneva - -	12½	27·056	79·33	79·33
Grange Town	16¼	24·510	77·11	77·42
Lans le Bourg		24·145	77·18	77·14
Grange le F.	15	24·089	76·76	77·09
Grenairon	10¼	20·427	73·25	73·89
Glaciere de B.	6½	19·677	72·56	73·24

Where it is remarkable, that the difference between the two is of no conſequence in ſuch matters.

Many other advantages might be deduced from the exact knowledge of the effect which the preſſure of the atmoſphere has upon the heat which water can receive: one of which, M. Betancourt obſerves, is of too great importance in phyſics not to be mentioned. As ſoon as the thermometer became known to philoſophers, almoſt every one endeavoured to find out two fixed points to direct them in dividing the ſcale of the inſtrument; having found that thoſe of the freezing and boiling of water were nearly conſtant in different places, they gave theſe the preference over all others: but having diſcovered that water is capable of receiving a greater or leſs quantity of heat, according to the preſſure of the atmoſphere upon its ſurface, they felt the neceſſity of fixing a certain conſtant value to that preſſure, which it was almoſt generally agreed ſhould be equal to a column of 28 French inches of mercury. This agreement however did not remove all the difficulties. For inſtance, if it were required to conſtruct at Madrid a thermometer that might be comparable with another made at Paris, the thing would be found impoſſible by the means hitherto known, becauſe the barometer never riſes ſo high as 27 inches at Madrid; and it was not certainly known how much the ſcale of the thermometer ought to be increaſed to have the point of boiling water in a place where the barometer is at 28 inches. But by making uſe of the foregoing obſervations, the thing appears very eaſy, and it is to be hoped that by the general knowledge of them, thermometers may be brought to great perfection, the accurate uſe of which is of the greateſt importance in phyſics.

Beſides, without being confined to the height of the barometer in the open air, in a given place, we may regulate a thermometer according to any one aſſigned heat of water, by means of ſuch an apparatus as M. Betancourt's. For, in order to graduate a thermometer, having a barometer ready divided; it is evident that by knowing, from the foregoing table of experiments, the degree of heat anſwering to any one expanſive force, we can thence aſſign the degree of the thermometer correſponding to a certain height of the barometer. A determination admitting of great preciſion, eſpecially in the higher temperatures, where the motion of the barometer is ſo conſiderable in reſpect to that of the thermometer.
